There are, generally speaking, two types of selective means used in radio receiving sets, one a circuit containing one or more adjustable resonant elements and the other a circuit hvaing a fixed selective element with adjustable means for converting the received radio waves into waves of frequencies which will pass through the selective element. With the first type of selectivity, which includes the selectivity obtained with regeneration, the distortion of the reproduced sounds is obviously not fixed but will vary with the sharpness of tuning used. With the second type of set, the selectivity is fixed in the design and involves, therefore, a predetermined compromise between distortion of reproduced sounds and degree of selectivity. Fig. 8 illustrates quantitatively what this compromise entails and also the range of distortion which may be obtained with a set of the variable selectivity type. Curve *A* shows the characteristic for one stage of audio frequency amplification in a particular receiving set, which is seen to cause appreciable distortion only at the low frequencies. As the distortion caused by radio tuning affects only the higher audio frequencies, curve *A* corresponds to a set with no radio selectivity. Curves

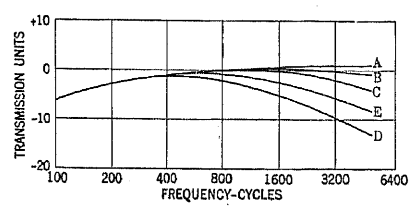

Fig. 8—Variation of Audio Frequency Response Characteristics of Radio Receiving Sets with Different Degrees of Selectivity

Selectivity expressed in terms of attenuation for radio frequency 10,000 cycles from frequency for which set is tuned.

Curve *A*—Attenuation 0 transmission units
Curve *B*— " 10 " "
Curve *C*— " 20 " "
Curve *D*— " 40 " "
Curve *E*—Radio set with fixed selectivity.

B, *C* and *D* indicate the effect of increasing degrees of radio selectivity. These three degrees of selectivity are such that if there is an interfering signal having the same intensity in the ether as the signal being received, but having its carrier frequency 10,000 cycles higher or lower, it will produce an audio signal at the output of the set 10, 20 and 40 transmission units respectively lower than the level of the signal being received. In other words a receiving set having the characteristic *B* which is very desirable from the quality standpoint will be much less selective against interference than one having the higher distortion characteristic *D*. As an example of a practical compromise, curve *E* shows the characteristic of a set of the fixed selectivity type which was designed for general all around use in receiving both local and long distance broadcasting. In this set a frequency 10,000 cycles higher or lower than the frequency to which the set is tuned suffers a loss of 34 transmission units.

The fixed selectivity type of set has some advantage in that its operation is definite and is less likely to give poor quality due to improper operation. The operation of this type of set can be materially improved by employing for the fixed selective element a band pass

12. Telephone Transformers, W. L. Casper. Presented A. I. E. E., Feb. 8, 1924.

filter. Such a filter has the advantage that the characteristic of the transmitted range can be made practically flat for any desired band width and to present a large attenuation for frequencies outside the band. For example, with a well designed filter of this type, the characteristic of the transmitted audio frequency band can be made practically flat up to 5000 cycles and the discrimination against other signals can be made even greater than that given above for curve *D*. This type of selectivity employing a band pass filter was used in the receiving sets of the Catalina Island radio telephone system.[13]

Conversion from Radio to Audio Frequency. In converting the electrical energy obtained from the antenna from radio to audio frequency, there is in general no difficulty from the standpoint of distortion provided the "detector" for making this conversion is worked below saturation.

Conversion from Electrical Power to Sound. The conversion from electrical power to sound may be accomplished either by the head type telephone receiver or by a loud-speaking telephone, the latter being obviously more desirable for this purpose.

In Fig. 9 is shown the frequency response characteristic of a good type of commercial head receiver when held to ear in the usual manner. It will be noted that this introduces appreciable distortion. A material reduction in this distortion can be obtained with the type of damped receiver used in the high quality telephone system described in the first part of the paper. The characteristic of such a damped receiver is shown also in Fig. 9.

In Fig. 10, Curve *A* gives the frequency response curve for one of the best types of commercial loud speaker. This also introduces considerable distortion, being particularly weak at the lower end of the frequency range. This deficiency while not so serious for speech, is easily noticeable for music. In this figure are given also two curves showing the response characteristic of laboratory models of loud speakers. These are of interest since the means for converting from electrical power to sound are the most serious source of distortion in a system for transmitting and reproducing sounds, and the reproduction given by these models (demonstrated at the time of presenting this paper) is markedly superior to that obtained with the commercially available apparatus, and indicates the future possibilities of broadcasting.

CONCLUSION

From this consideration of systems for the electrical transmission and reproduction of sound, it has been shown that it is practicable to get almost perfect electrical transmission over a broad band of frequencies from the terminals of the pick-up transmitter to the radio transmitter and from there out into the air. With the condenser transmitter and proper associated amplifiers the conversion from sound striking the diaphragm to electrical energy can also be made without appreciable distortion. With a properly designed and operated broadcasting station, therefore, high quality material can be delivered to the receiving stations.

At present the commercial radio receiving sets and the means for converting from electrical energy to sound now generally available can not fully utilize this high quality material. These receiving and reproducing means can, however, be materially improved. The problem now is to make such improvements available in such a form that their cost will not make their use prohibitive. As yet the commercial production of apparatus incorporating such improvements is in the future.

In view of the distortion which exists at the present receiving stations, the question may arise as to the justification for going as far as has been indicated in the other part of the system. The fact is that with the reproducing means now available, material deviations from the frequency characteristics which have been given for the other parts of the system are detectable and the effect of non-linear distortion readily noticed. In a broadcasting system where one element is used for converting from sound to electrical energy and for distributing this energy to a large number of elements for reconverting it into sound, the expense of getting good results in this one element is not prohibitive and, taking into account the whole system, relatively small.

In broadcasting, the novelty of the system was undoubtedly a large factor in its rapid growth and development. Those who make use of the system are, however, becoming more critical of the service which it renders and the quality of reproduction will be of increasing importance in the future.

The Function and Design of Horns
for Loud Speakers

BY C. R. HANNA and J. SLEPIAN
Associate, A. I. E. E. Associate, A. I. E. E.
Both of the Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—*A discussion of the function of the horn, together with theoretical consideration as to the design of the horn to perform this function in the best way, are given. In the body of the paper, a proof is given to show that the exponential increase in section gives the best results. For this reason, a large part of the appendix is given to the analytical solution of sound propagation in exponential horns. From the results of this work and the well known equations relating first order effects in the telephone receiver, formulas are developed which make possible the design of horns.*

CONTENTS

I. Introduction

With the growth of radio broadcasting and the development of public address systems, the electric loud speaker has come to be an apparatus of general interest. A very important part of a loud speaker is its horn, which when properly designed can greatly increase the acoustic power delivered, and go a long way towards minimizing the distortions arising from the inherent inertia and stiffness of the moving parts of the receiver. The purpose of this paper is to discuss the function of the horn, and how it should be proportioned to best perform this function.

For perfect reproduction from a loud speaker two requirements must be met: (1) a current of a given frequency must produce sound of that frequency and that frequency only; and (2) the power radiated in the form of sound must be proportional to the square of the current independent of frequency. This assumes that the available current is an exact reproduction of the pressure of sound applied to the microphone.

Several things are responsible for the introduction of extraneous frequencies. (1) If the diaphragm is insufficiently damped, the transient in the building up of vibrations will always contain the frequencies corresponding to the free vibrations of the system. This is readily eliminated by damping. (2) Double frequency may be introduced if the alternating variations of flux are not small compared to the permanent flux. This is made negligible by employing strong permanent fields. Modern balanced magnetic constructions of receiver elements were devised principally to provide for a large permanent flux without increasing the mass of the vibrating system excessively. (3) If the diaphragm deflections are large, extraneous frequencies will be introduced because of the non-linear characteristics as to restoring force and magnetic pull. Proper design of the horn will allow ample sound radiation with small diaphragm displacement and thus overcome this difficulty. So the first requirement for perfect reproduction may be closely approached.

The second requirement for perfect reproduction, that of a uniform response characteristic over the acoustic frequency range, can not be met with present day receiver elements. Variations in acoustic power of the order of ten to one between 200 and 4000 cycles are not noticed by the ear, however, and the departure from a uniform response can be kept within this range by proper design of the horn.

Contrary to the prevalent conception, the horn does not merely gather up the sound energy from the receiver and concentrate it in certain directions. Its relation to the diaphragm is much more intimate. It causes an actual increase in the load on the diaphragm, making it advance against a greater air pressure, and withdraw from a greater opposing rarefaction. Anyone can assure himself that the average sound energy in a room is greatly reduced on removing the horn from a good loud speaker. And frequently when the horn is removed the amplitude of vibration of the diaphragm becomes so great that it strikes against the pole pieces. A receiver element without a horn is analogous to a motor without a connected load; or better yet, a receiver element without a horn is like a closed oscillation circuit from which little radiation takes place (radiation resistance zero); while with a horn it is like an open oscillation circuit with an antenna (radiation resistance considerable). The horn is the antenna of the loud speaker.

In order to load, a horn need not resonate. Resonances of course increase the loading at certain frequencies, but cannot be made to provide uniform loading over a wide range of frequencies. That a horn can load without resonating is shown by the increase in sound radiation at the high frequencies where air column resonances are of small intensity. Resonances in the horn due both to material vibration and air column vibration being undesirable because of the distortion they produce, and being entirely unnecessary, should be reduced to a minimum.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

Proceeding now to the detailed consideration of the function and design of horns for loud speakers, we may set down three requisites:

1. A given applied force acting on the diaphragm must cause the air at the throat of the horn to have a nearly uniform velocity over the acoustic frequency range. Proper design of the air chamber above the diaphragm and the initial area of the horn will bring this about.

2. The area of the mouth of the horn must be such that only a small part of the sound is reflected back at that point, because reflections cause air column resonances.

3. The law of increase and the rapidity of increase of section must be such that:

(a) The most complete propagation of sound energy shall take place, and

(b) For a given air velocity at the throat, the power shall be nearly constant as the frequency is varied.

II. Throat Area and Diaphragm Chamber Volume

As we have indicated above, the horn is a radiator of the power which it causes the diaphragm to deliver. We may, therefore, well begin by considering the simplest sound radiating system, namely, a uniform straight tube infinitely long in one direction. Any air disturbance at the end of such a tube is propagated unchanged along the tube. In Fig. 1 suppose the piston is moved to the right. The air immediately ahead is given a velocity. Because of the elasticity of the air it is also compressed in the region next to the piston. Suppose the piston is stopped. There is now a region of pressure and in that region the air has a velocity to the right. The volumetric rate of flow of air into the region just ahead is greater than the volumetric rate of flow out, and so the pressure there rises. As long as the pressure behind is greater than the pressure ahead, the air ahead will be accelerated. When the two pressures become equal there will be no further acceleration. As the air ahead reaches a higher pressure the air behind will be retarded, and will finally reach a condition of zero velocity and normal pressure. Pressure and velocity are thus propagated along the tube. That propagation takes place in only one direction is shown by the fact that the velocity of the air is always in one direction, and that pressure can rise only when air is flowing into a region faster than it is flowing out. If the piston is moved to the left the propagation of disturbance will be in the same direction, but the pressure and velocity of the air will be reversed.

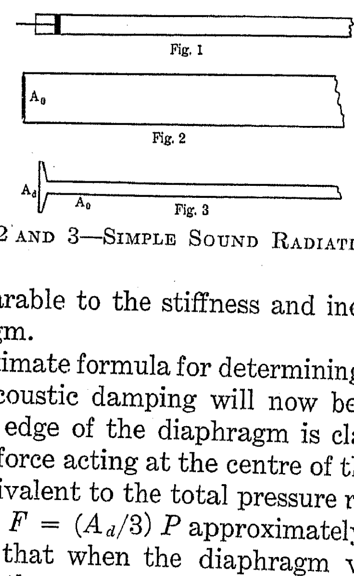
From this discussion it is seen that in a traveling sound wave, pressure and velocity are associated together in time and space phase. Neither can exist without the other. If P is the increase in pressure above atmospheric at any point, and the average air velocity at the same point and at the same time is v, $P = (\rho\, a)\, v$, where ρ is the density of air, a is the velocity of sound in air, c. g. s. units being used.

Suppose in place of the piston there is a diaphragm as in Fig. 2, and for simplicity assume that every part of it vibrates through the same distance. If when it vibrates the air is given a velocity v at a certain instant, the total reaction force over the face of the diaphragm will be that due to the developed pressure, so that

$$F = P\, A_0 = (\rho\, a)\, v\, A_0.$$

If the initial construction of the loud speaker were made in this way it would not be possible to make this force comparable with the stiffness and inertia forces of the diaphragm at the low and high frequencies, respectively. Hence the motion of the diaphragm would be determined almost entirely by its own mass and stiffness, and its motion at its resonant frequency would far exceed that at other frequencies. Hence, also, the power radiated at the resonant frequency would greatly exceed that at other frequencies.

Suppose the arrangement is changed to that of Fig. 3. Here a small velocity of the diaphragm gives the air in the tube a large velocity and much higher pressures are therefore developed. Thus this arrangement, by the principle of the hydraulic press, increases the reaction force on the diaghragm so that it may be made comparable to the stiffness and inertia forces of the diaphragm.



Figs. 1, 2 and 3—Simple Sound Radiating Systems

An approximate formula for determining the quantity known as acoustic damping will now be derived. If in Fig. 3 the edge of the diaphragm is clamped and F is the single force acting at the centre of the diaphragm which is equivalent to the total pressure reacting on it,

$$F = (A_d/3)\, P \text{ approximately.}$$

Assuming that when the diaphragm vibrates with velocity, $\dot{u}$, the volumetric rate of displacement of air is, $A_d/3\, \dot{u}$, the velocity of air in the tube, assuming all the displaced air gets into the tube will be,

$$v = A_d/3 \quad \dot{u}/A_0.$$

From the relation between P and v,

$$F = \frac{\rho\, a}{9}\, (A_d^2/A_0)\, \dot{u}$$

Acoustic damping will be defined as equivalent reaction force per unit diaphragm velocity

$$\alpha_a = F/\dot{u} = \frac{\rho\, a}{9}\, A_d^2/A_0$$

In appendix II α_a is determined more accurately, but for the present this formula will be used to illustrate the point.

That a large value of α_a is desirable may be shown as follows. If β_0 and m are the diaphragm stiffness and mass respectively, and α_0 the internal damping,

$$\dot{u} = \frac{\text{force}}{(\alpha_0 + \alpha_a) + j\,(\omega\, m - \beta_0/\omega)} \quad \text{where,}$$

$\dfrac{\omega}{2\,\pi}$ is the frequency of the sinusoidal force driving the diaphragm. This is analogous to the equation for current in an electrical circuit,

$$\dot{i} = \frac{\text{e. m. f.}}{(R_0 + R_a) + j\left(\omega\, L - \dfrac{1}{\omega\, C}\right)}, \text{ where,}$$

R_0 is the internal resistance of the generator and R_a the load resistance, L and C being series inductance and capacitance. In the electrical case the power dissipated in the load is

$$W = \dot{i}^2\, R_a.$$

Similarly in the acoustic case

$$W = \dot{u}^2\, \alpha_a.$$

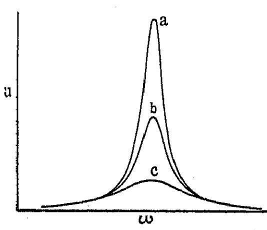


FIG. 4

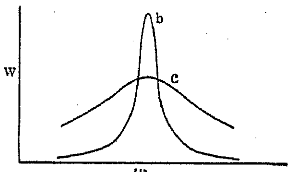

FIG. 5—DIAPHRAGM RESONANCE

If α_a is zero $\dot{u}$ plotted against $\dot{\omega}$ will be as shown in Fig. 4A. The radiated power will be zero. If α_a is increased $\dot{u}$ will be as in Fig. 4B—lower at resonance but about the same at the extreme frequencies. In this case W will be as in curve 5B. Now let α_a be increased still further. The velocity $\dot{u}$ becomes as in 4C, and the radiated power as in 5C. A more uniform radiation of power is secured over the frequency range, and yet the average over the range is about the same.

From the simple formula for acoustic damping it is seen that to increase it we must decrease A_0. Two effects give a lower limit to A_0, however. First, frictional losses in small tubes become great. Second, if the throat is made very small the air instead of being forced out into the tube will be compressed in the chamber above the diaphragm. To prevent this the chamber volume must be decreased, and there is a physical limitation here.

Neglecting frictional losses it is shown in appendix II, that if the radiated power at two extreme frequencies $\dfrac{\omega_1}{2\,\pi}$ and $\dfrac{\omega_2}{2\,\pi}$ is to be $1/n$ times that at resonance $\dfrac{\omega_r}{2\,\pi}$, the area of the throat of the horn and the volume of the chamber above the diaphragm are determined by,

$$A_0 = \frac{\rho\, a}{9}\,\sqrt{n-1}\,\frac{A_d^2\,\omega_1}{\beta_0}$$

$$V_0 = A_0 \frac{\omega_r^4 - \omega_1^2\,\omega_2^2}{\dfrac{\rho\, a}{p_0}\,\omega_1\,\omega_2^2\left(-\dfrac{\omega_r^2}{\sqrt{n-1}} + \sqrt{\dfrac{n}{n-1}\,\omega_r^4 - \omega_1^2\,\omega_2^2}\right)}$$

The following sample calculation will show relative values. Assume

$A_d = 15.5$ cm.²
$\beta_0 = 20 \times 10^6$ dynes/cm.
$\omega_1 = 2\,\pi \times 200$
$\omega_r = 2\,\pi \times 1000$
$\omega_2 = 2\,\pi \times 4000$
$n = 10$

Substituting in the formulas,

$A_0 = 0.2075$ cm.²

If circular in section, the diameter,

$d_0 = 0.514$ cm. $= 0.202$ in.
$V_0 = 0.258$ cm.³

These values of A_0 and V_0 are much smaller than have been used heretofore.

The fact that greater acoustic damping is provided by horns having small throat areas means that the same sound radiation takes place with smaller diaphragm velocities, and hence smaller diaphragm deflections. This will prevent the introduction of extraneous frequencies due to non-linear characteristics of large deflections.

III. FINAL OPENING OR MOUTH OF HORN

The infinite straight tube which we have just been considering loads the diaphragm, and conducts away the resulting acoustic power. It does not, however, communicate this power to surrounding space, and thereby fails to fulfill completely the function of a horn. Evidently the tube must be made to open up into the atmosphere. We are thus led to consider what happens at the open end of a finite tube.

Consider a half wave length of sound, in which there is positive pressure and forward velocity traveling along the tube. While progressing within the tube it is uniformly confined and occupies a constant volume. Hence the pressure and velocity in it remain constant. As it leaves the open end of the tube, however, it expands into an approximately hemispherical shape, Fig. 6A. There is thus an increase in the volume occupied by the wave as it leaves the tube. Evidently a fall in pressure must result. But if the pressure just outside the tube remains lower than that within the tube, the velocity of the air just within the tube will be

increased; this causes the pressure just behind to decrease, and the velocity to increase, and so we have produced a wave traveling back in the tube, which near the open end reduces the pressure and increases the velocity in the oncoming wave. This is the familiar phenomenon of reflection.

The reflected wave not only represents power which does not get out into the air but, depending on the phase in which it reaches the diaphragm, it may produce resonance or dissonance. Obviously the less intense the reflection is, the less marked will be the resonance or dissonance.

It is now easy to see what influence the size of the final opening of the tube has upon the intensity of the reflection. It is evident from Fig. 6A that the larger the section of the tube is, the less will be the relative increase in volume occupied by a half wave length just within and just without the tube, and therefore the less intense will be the reflection. For wave lengths which are less than the diameter of the tube, Fig. 6B, the increase in volume on passing out of the tube is slight, and therefore the reflection is negligible; but for wave lengths which are greater than the tube diameter, Fig. 6A, the increase in volume becomes considerable, and the reflection becomes appreciable.

Thus a horn, to transmit a 500-cycle wave with wave length 68.8 cm. to the atmosphere without reflection would need to have a final opening of diameter about 70 cm.

For many purposes this is an inconveniently large diameter, and it is therefore interesting to determine

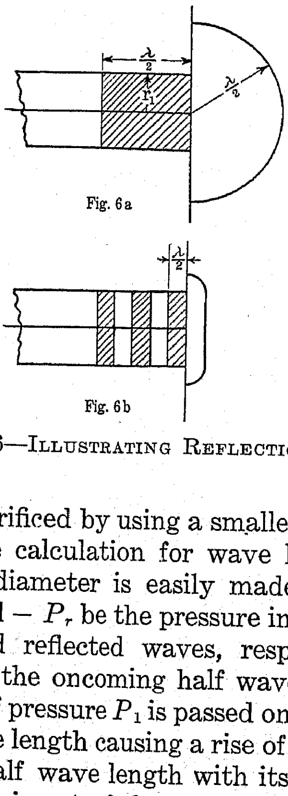

FIG. 6—ILLUSTRATING REFLECTION

how much is sacrificed by using a smaller final opening. An approximate calculation for wave lengths greater than the tube diameter is easily made.

Let P_1, P_2 and $-P_r$ be the pressure in the oncoming, transmitted and reflected waves, respectively. The excess of air in the oncoming half wave length which causes the rise of pressure P_1 is passed on into the transmitted half wave length causing a rise of pressure there. The reflected half wave length with its negative pressure also draws air out of the tube and into the transmitted hemispherical half wave length. This mass of air, which is taken from the half wave length within the tube and transferred to the half wave length outside the tube, causes a reduction in pressure within equal to $P_1 + P_r$, and an increase of pressure outside equal to P_2. Since these two pressure changes are inversely proportional to the volumes involved, we have

$$\frac{P_1 + P_r}{P_2} = \frac{2/3\ \pi\ (\lambda/2)^3}{\pi\ r_1^2\ \lambda/2} = 1/6\ \lambda^2/r_1^2\text{, where}$$

λ is the wave length, and
r_1 is the radius of tube.

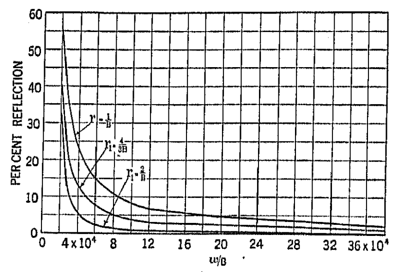

FIG. 6C—VARIATION OF REFLECTION

Furthermore, $P_2 = P_1 - P_r$, so that finally,

$$P_r = \frac{\lambda^2 - 6\,r_1^2}{\lambda^2 + 6\,r_1^2}\,P_1$$

If $\lambda = 68.8$ cm. corresponding to 500 cycles and $r_1 = \lambda/4 = 17.2$ cm.

$$P_r = P_1 \left(\frac{1 - 6/16}{1 + 6/16} \right) = 0.45\,P_1$$

In Appendix IV an approximate determination of reflections is given for the exponential horn in which the area at any distance x from the small end is given by

$$A = A_o\,e^{Bx}$$

where B is a constant which determines the rate of increase. The curves of (Fig. 6C) show how the reflection varies for different values of ω, B, and final radius r_1 of the horn. These curves also indicate that the larger the final radius and the higher the frequency, the less the reflection.

IV. SHAPE OF HORN

We have now shown that to load the diaphragm effectively the initial opening or throat of the horn must be small, and to communicate the resulting acoustic power effectively to the atmosphere, the final opening or mouth of the horn must be large. We must now consider how these two extremities are to be joined; what the length of the horn should be, and according to what law the section should increase.

Consider a uniform straight tube which at a certain point opens up abruptly into a second uniform straight tube of larger section. A sound wave in the first tube propagates in the simple manner described under section II. At the point of sudden change of section more complicated conditions appear, but beyond this point, in the second tube, simple propagation again

takes place. As is well known, the ultimate result of the discontinuity is a reflection, which reduces the energy which passes on to the second tube. Furthermore, the magnitude of this reflection is proportional to the *relative* increase in section at the point of discontinuity, that is to $\frac{A_2 - A_1}{A_1}$, A_1 and A_2 being the sectional areas of the tubes respectively. We may then say that the departure from simple propagation is proportional to the relative increase in section.

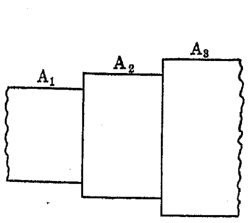

FIG. 7—DISCONTINUING IN STRAIGHT TUBE

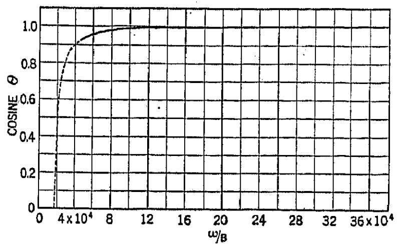

FIG. 8—VARIATION OF LOADING IN EXPONENTIAL HORNS

Returning now to the horn, with continuously increasing section, it seems fairly reasonable to suppose that at each point, the departure from simple propagation will depend on the *relative* increase in section per unit length, that is to $1/A \, \frac{d\,A}{d\,x}$. The initial and final section areas having been determined, the total relative increase in area is prescribed. All this being granted, it seems entirely reasonable to suppose that the best horn will be one in which this relative increase in area is uniformly distributed over its whole length, rather than one in which the relative increase in area is large at some points and small at others. Thus we conclude that for the best horn, $1/A \, \frac{d\,A}{d\,x}$ is constant along its length. To have this property, the sectional area must increase exponentially with the length, that is

$$A = A_0 \, e^{Bx}$$

We may give a more quantitative turn to this argument as follows. Consider two discontinuities in a straight tube as shown in Fig. 7, the areas of the three sections being A_1, A_2 and A_3. A wave having air velocity v_1 in passing from A_1 into A_2 is partially reflected. Let v_{1r} be the velocity in the reflected wave and v_2 be the velocity in the transmitted wave. Similarly in passing from A_2 into A_3 let v_{2r} be the velocity in the reflected wave and v_3 the velocity in the transmitted wave. Let P with the corresponding subscripts represent the pressures associated with each of these velocities.

$$A_2 \, v_2 = A_1 \, v_1 - A_1 \, v_{1r}$$
$$A_3 \, v_3 = A_2 \, v_2 - A_2 \, v_{2r}$$
$$P_2 = P_1 + P_{1r}$$
$$P_3 = P_2 + P_{2r}$$

Because of the constant ratio of pressure to velocity in straight tubes, the last two equations become

$$v_2 = v_1 + v_{1r}$$
$$v_3 = v_2 + v_{2r}$$

From these four equations we may eliminate v_{1r}, v_2 and v_{2r} and obtain

$$v_3 = \frac{4 \, A_1 \, A_2}{(A_1 + A_2)\,(A_2 + A_3)} \, v_1$$

If v_1, A_1 and A_3 are fixed, v_3 will be maximum, if

$$A_2 = \sqrt{A_1 \times A_3}$$

This again leads to the exponential horn.

In Appendix III, with certain approximations, the characteristics of the exponential horn are determined analytically. Pressure and velocity have the same absolute ratio as in the straight tube; but are out of phase by an angle whose cosine is a function of ω/B. Curve Fig. 8 shows the plot of this cosine. It approaches unity (or the straight tube radiation characteristic) if ω is large enough or B small enough. In section I it was shown that a sufficiently uniform power radiation characteristic could be obtained with the straight tube if its section were made small compared to the area of the diaphragm. With the exponential horn having the same throat area, neglecting reflections at the open end, the power will differ from that of the straight tube by the cosine of the angle between pressure and velocity. Since this cosine begins to fall off rapidly below

$$\omega/B = 2.5 \times 10^4,$$

if the radiation is to be uniform down to 200 cycles, corresponding to $\omega = 1257$, B must be less than $\frac{1257}{2.5 \times 10^4}$ or approximately 0.05. This value of B gives a horn which opens up very slowly. Since the initial area must be small and the final area reasonably large, this small value of B will result in a long horn.

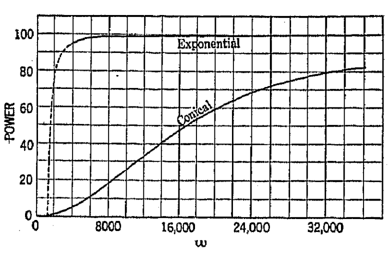

FIG. 9—COMPARISON OF LOADING OF EXPONENTIAL AND CONICAL HORNS

The superior radiating power of the exponential horn is well brought out by comparing it with a conical horn of the same initial and final areas and the same length. Assuming circular sections, let the

initial section radius, $y_0 = 0.254$ cm.
final " " $y_1 = 14.3$ cm.
length $l = 115$ cm.

For the exponential horn, this gives $B = 0.07$. The conical horn will have an angle whose sine is 0.122.

From the equations given in Appendix III, the power propagated at various frequencies for a given velocity in the throat may be calculated. The results are shown in Fig. 9, expressed in per cent of the power for high frequencies which is the same for the two horns. This is a positive indication of the advantage of the exponential horn over the conical.

V. Experimental Work

In the experiments to be described, the several horns shown in the photograph (Fig. 10) were arranged so that a receiver element could be quickly transferred from one to another for comparison. Horn No. 1 is a pyramid 4½ feet long, with initial and final areas 0.0315 and 324 square inches respectively. Horn No. 2 is an exponential horn of the same terminal areas and about the same length. The percentage increase in area per inch is about 20, corresponding to $B = 0.07$ for centimeter units of length. The lower part of this horn may be removed or replaced by the straight extension of diameter 1¼ in. and the same length shown to the right. Horn No. 3 is an exponential horn having the same initial and final areas as horn

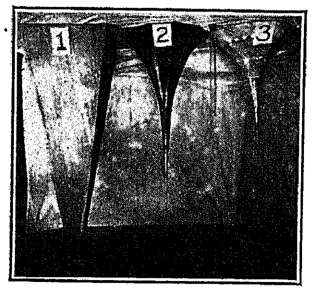

Fig. 10—Horns for Experimental Comparison

No. 2, but the percentage increase per inch is about 35, corresponding to $B = 0.12$.

Experiment I. To compare the loading of conical and exponential horns. Horns 1 and 2 as shown were compared. A receiver having a resonance at 2200 cycles was connected to an audio frequency oscillator. At frequencies below 1500 cycles or above 3000 cycles, it is assumed that the addition of a horn will not materially alter the velocity of the diaphragm. Under such circumstances, the horn having the greatest value of acoustic damping will radiate the most sound.

At each frequency the receiver was placed first on one horn and then on the other. From 250 to 500 cycles the response of the conical horn was weak, while the exponential was very strong. As the frequency was raised the response of the conical increased. Above 3000 cycles the difference was much less marked, being only slightly in favor of the exponential. This test substantiates the curves of Fig. 9.

Experiment II. To compare exponential horns having different rates of increase, horns 2 and 3 as shown were compared. Using the same receiver, and gradually lowering the frequency from 1000 cycles, the two horns radiated nearly equally until about 350 cycles frequency was reached. At this point the response from horn No. 3 fell off abruptly and remained low down to 250 cycles, the lowest frequency of the oscillator used. The quantity ω/B for the small horn at 350 cycles is 18,300. This value of ω/B corresponds closely to the point on curve of Fig. 8 where the loading falls off.

Experiment III. To determine the effect of changing the initial opening, keeping the rate of increase the same, horn No. 2 was used with and without the lower part. A receiver having its diaphragm resonance at 500 cycles was employed. Below and above resonance the response was much greater using the extension. At resonance the rattle and blasting produced without the extension was entirely eliminated with the extension. These results indicate greater loading with the extension.

Experiment IV. To show that increase in loading in Experiment III was due to reduction of area and not to increased length, the upper part of horn No. 2 was used with and without the straight section shown to the right; and then first with the straight extension and then with the exponential extension. Very little difference was noticed with and without the straight section. About the same response was observed below and above resonance and the same blasting at resonance.

Comparing the horn first with the straight extension and then with the exponential extension gave results similar to those of Experiment III, indicating that the addition of the straight part did not increase the loading.

VI. Conclusions

The following are major points in the function and design of horns for loud speakers.

1. The purpose of the horn is to load the diaphragm, and to radiate the power which it causes the diaphragm to deliver. Great loading is required in order to smooth out diaphragm resonances; and to allow ample sound radiation with small diaphragm velocities, thereby reducing extraneous frequencies introduced when diaphragm displacements are beyond the range of linear characteristics.

2. The exponential horn in all probability provides greater loading than any other horn having the same length and terminal dimensions. Experiment I confirms this in the case of the conical horn.

3. The maximum loading of an exponential horn on a given receiver is determined entirely by its initial area, the loading increasing with decrease in area until friction begins to play an important part. This assumes that the chamber volume above the diaphragm is small so that most of the air is forced out into the horn instead of being compressed in the chamber. Experiments III and IV show that decreasing the throat area increases the loading. Experiment II shows that

above a certain frequency, two horns having different rates of increase but the same initial area will provide the same loading.

4. The uniformity of loading of an exponential horn is determined by its rapidity of increase in section—the less the rate of increase, the more uniform the loading. Uniform loading may be expected down to the frequency where $\omega/B = 2.5 \times 10^4$ approximately. Experiment II showed that when ω/B was reduced to 1.8×10^4 the loading fell off considerably.

5. The larger the final opening, the less pronounced will be the horn resonances. The intensity of resonances decreases with increase of frequency. It has been found that, in exponential horns, the resonances are hardly noticeable above the frequency when the horn begins to load if the final section is over 14 in. in diameter.

In loud speakers with horns designed according to the data contained in this paper, the reproduction of music is not just pleasing but close to the original, and the reproduction of voice is not only intelligible but natural.

Appendix I

Mechanical Damping and Motional Impedance

The simple equations for the telephone receiver are:

$$L\frac{d\,i}{d\,t} + R\,i + 10^{-7}\,M\frac{d\,u}{d\,t} = e = E\,e^{j\omega t} \qquad (1)$$

$$m\frac{d^2\,u}{d\,t^2} + \alpha\frac{d\,u}{d\,t} + \beta\,u = M\,i, \qquad (2)$$

when

e = impressed e. m. f., volts
i = current through windings, amperes
L = damped inductance, henries
R = damped resistance, ohms
M = equivalent force per unit current, dynes/amperes
$10^{-7}\,M$ = generated back e. m. f./unit velocity of diaphragm, volts/(cm./sec.)
u = deflection at centre of diaphragm, cm.
m = equivalent mass of vibrating system
α = total damping factor, dynes/(cm./sec.)
β = total stiffness factor, dynes/cm.

M may or may not be complex. Eddy currents and hysteresis which produce a phase difference between flux and current cause M to have an imaginary part.

The steady state solutions of the above equations for an alternating impressed voltage of frequency $\dfrac{\omega}{2\,\pi}$ are,

$$Z = e/i = R + j\,\omega\,L + \frac{10^{-7}\,M^2}{\alpha + j\,(m\,\omega - \beta/\omega)}\text{ ohms.} \qquad (3)$$

It is seen that the impedance is made up of the damped impedance $(R + j\,\omega\,L)$ plus another term which is known as the motional impedance:

$$Z_m = \frac{10^{-7}\,M^2}{\alpha + j\,(m\,\omega - \beta/\omega)} = \frac{10^{-7}\,M^2\,\alpha}{\alpha^2 + (m\,\omega - \beta/\omega)^2} - j\frac{10^{-7}\,M^2\,(m\,\omega - \beta/\omega)}{\alpha^2 + (m\,\omega - \beta/\omega)^2} \qquad (4)$$

This is the equation for the well-known motional impedance circle having diameter

$$\frac{M^2 \times 10^{-7}}{\alpha}$$

and depressed from the horizontal by an angle $-\,2\,\gamma$ where γ is the angle of M, if M is complex. (See Fig. 11.) The above separation of real and imaginary parts is with respect to an axis of slope $-\,2\,\gamma$.

The solution for the deflection is

$$u = \frac{M\,i}{\beta - m\,\omega^2 + j\,\omega\,\alpha} \qquad (5)$$

We shall be more concerned with the velocity of the diaphragm, however, the value of which is given by

$$\dot{u} = j\,\omega\,u = \frac{M\,i}{\alpha + j\,(m\,\omega - \beta/\omega)} = \frac{M\,i}{\sqrt{\alpha^2 + (m\,\omega - \beta/\omega)^2}} \qquad (6)$$

The power put into the diaphragm is given by the average value of $\dot{u}^2\alpha$.

$$W = I^2/2\,\frac{M^2\,\alpha}{\alpha^2 + (m\,\omega - \beta/\omega)^2}\text{ ergs/sec.} \qquad (7)$$

where I is the maximum value of the sine wave of current i. Expressing W in watts or joules per sec.,

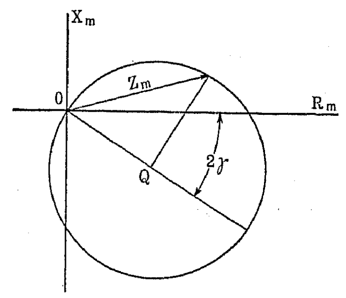

Fig. 11—Motional Impedance Diagram

$$W = I^2/2\,\frac{10^{-7}\,M^2\,\alpha}{\alpha^2 + (m\,\omega - \beta/\omega)^2}. \qquad (8)$$

It is seen from equations (8) and (4) that the factor by which the average square of current must be multiplied to obtain the diaphragm power at a given frequency is the projection $O\,Q$ of the corresponding motional impedance vector on the principal diameter of the impedance circle.

The several constants of the receiver may be determined as described in papers by A. E. Kennelly, R. L. Wegel,[1] and others. Suppose impedance circles are taken on a given receiver element with and without a horn. The damping in the two cases may be represented by $(\alpha_0 + \alpha_a)$ and α_0, respectively. After the power input to the diaphragm with the horn attached has been determined at different frequencies as stated above, the input to the horn is approximately

$$\frac{\alpha_a}{\alpha_0 + \alpha_a} \text{ times the values determined.}$$

The acoustic damping α_a, is large as compared with α_0 in the best loud speakers, and so this ratio approximates unity. For this reason in what follows the acoustic damping will be considered as the total damping.

Appendix II

THROAT AREA AND DIAPHRAGM CHAMBER VOLUME

In the text of this paper the propagation of waves along an infinite straight tube is considered. In Appendix III it is shown that the characteristics of the exponential horn approach those of the straight tube as a radiator of sound over most of the acoustic range of frequency. Therefore, in considering what takes place at the beginning of the horn, the simpler relations between air pressure and velocity which correspond to a straight tube will be assumed.

The following is an approximate determination of the correct chamber volume and initial opening for given loud speaker, when power variation of n:1 between resonance and the upper and lower limits of frequency is allowable. In Fig. 12 let

A_0 = area of throat, cm.^{2}
V_0 = chamber volume, cm.^{3}
p_0 = atmospheric pressure, dynes/cm^2 [$=1.01\times10^6$].
p = pressure developed, dynes/cm.^{2} in chamber and throat
$P_0 = p - p_0$ = change of pressure, dynes/cm.^{2}
$= (\rho\, a)\, v = 41.2\, v$
v = velocity of air in throat
u = deflection of diaphragm
$\dot{u}$ = velocity of diaphragm, cm./sec.
A_d = area of diaphragm.

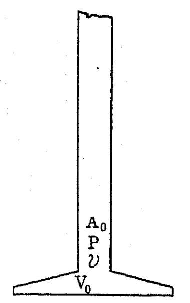

FIG. 12—THROAT AREA AND DIAPHRAGM CHAMBER VOLUME

It will be assumed that when the diaphragm is displaced the change in volume is given by $A_d\, u/3$.

$$p/p_0 = \frac{V_0}{V_0 - A_d\, u/3 + A_0 \int v\, d\, t} \qquad (9)$$

1. The Electromagnetic Theory of the Telephone Receiver, A. E. Kennelly and H. Nukiyama, PROCEEDINGS A. I. E. E., April 1919.

Theory of Magneto-Mechanical Systems, R. L. Wegel, JOURNAL A. I. E. E., October 1921.

$$\frac{p - p_0}{p_0} = \frac{P_0}{p_0} = \frac{A_d\, u/3 - A_0 \int v\, d\, t}{V_0} \qquad (10)$$

$$\frac{d\, P_0}{d\, t} = p_0/V_0 \times A_d/3 \frac{d\, u}{d\, t} - \frac{A_0\, p_0}{V_0}\, v \qquad (11)$$

$$41.2\, V_0 \frac{d\, v}{d\, t} + A_0\, p_0\, v = \frac{p_0\, A_d}{3} \frac{d\, u}{d\, t}$$

$$= \frac{p_0\, A_d}{3}\, \dot{u} = \frac{p_0\, A_d}{3}\, \dot{U}\, e^{j\omega t} \qquad (12)$$

The steady state solution of this equation is:

$$v = \frac{p_0\, A_d/3\, \dot{u}}{A_0\, p_0 + j\, \omega\, .\, 41.2\, V_0} \qquad (13)$$

$$v = \frac{1/3\, A_d\, \dot{u}}{A_0 + j\, \omega \times 4.08 \times 10^{-5}\, V_0}$$

$$= \frac{1/3\, A_d\, .\, j\, \omega\, u}{A_0 + j\, \omega\, .\, 4.08 \times 10^{-5}\, V_0} \qquad (14)$$

Rationalizing denominator,

$$v = \frac{1/3\, A_d\, A_0}{A_0^2 + (4.08 \times 10^{-5}\, \omega\, V_0)^2}\, \dot{u}$$

$$+ \frac{1/3\, A_d\, \omega^2 \times 4.08 \times 10^{-5}\, V_0}{A_0^2 + (4.08 \times 10^{-5}\, \omega\, V_0)^2}\, u \qquad (15)$$

It will be assumed that,

$$F = \frac{P_0\, A_d}{3} \left(= \frac{41.2\, v\, A_d}{3} \right) \qquad (16)$$

$$F = 41.2/9 \frac{A_d^2\, A_0 \times \dot{u}}{A_0^2 + (4.08 \times 10^{-5}\, \omega\, V_0)^2} + 41.2/9$$

$$\times \frac{A_d^2 \times 4.08 \times 10^{-5}\, \omega^2\, V_0}{A_0^2 + (4.08 \times 10^{-5}\, \omega\, V_0)^2}\, u \qquad (17)$$

It is seen that the force acting at the center of the diaphragm must overcome a force in phase with the diaphragm velocity, and one in phase with the displacement. The unit forces are: (1) the acoustic damping,

$$\alpha_a = 41.2/9 \frac{A_d^2\, A_0}{A_0^2 + (4.08 \times 10^{-5}\, \omega\, V_0)^2} \qquad (18)$$

and (2) the increase in stiffness due to the compression of part of the air in the chamber.

$$\beta_a = 41.2/9 \frac{A_d^2 \times 4.08 \times 10^{-5}\, \omega^2\, V_0}{A_0^2 + (4.08 \times 10^{-5} \times \omega\, V_0)^2} \qquad (19)$$

Let α_m = damping when ω is small,

$$\alpha_m = 41.2/9\, A_d^2/A_0 \qquad (20)$$

$$\alpha_a = \alpha_m \frac{A_0^2}{A_0^2 + (4.08 \times 10^{-5}\, \omega\, V_0)^2} \qquad (21)$$

$$\beta_a = \alpha_a \frac{4.08 \times 10^{-5}\, \omega^2\, V_0}{A_0} \tag{22}$$

The general equation for power radiated is:

$$W = \frac{M^2\, I^2}{2} \quad \frac{\omega^2\, \alpha_a \times 10^{-7}}{(\beta - m\, \omega^2)^2 + \alpha_a^2\, \omega^2} \tag{23}$$

β is made up of β_0 the stiffness due to the diaphragm and β_a the increase in stiffness due to the compression of air in the chamber.

Therefore
$$\beta = \beta_0 + \beta_a \tag{24}$$

$$W = \frac{10^{-7}\, M^2\, I^2}{2} \frac{\omega^2\, \alpha_a}{(\beta_0 + \beta_a - m\, \omega^2)^2 + \alpha_a^2\, \omega^2} \tag{25}$$

$$= \frac{10^{-7}\, M^2\, I^2}{2} \frac{\omega^2\, \alpha_a}{(\beta_0 - m\, \omega^2)^2 + 2\, \beta_a\, (\beta_0 - m\, \omega^2) + \beta_a^2 + \alpha_a^2\, \omega^2} \tag{26}$$

$$= \frac{10^{-7}\, M^2\, I^2}{2} \times \frac{\omega^2\, \alpha_a}{\left[(\beta_0 - m\, \omega^2)^2 + 2\, \alpha_a \dfrac{4.08 \times 10^{-5}\, \omega^2\, V_0}{A_0} (\beta_0 - m\, \omega^2) + \alpha_a^2 \left\{ \left(\dfrac{4.08 \times 10^{-5}\, \omega^2\, V_0}{A_0} \right)^2 + \omega^2 \right\} \right]} \tag{27}$$

$$= \frac{10^{-7}\, M^2\, I^2}{2} \times \frac{1}{\left[\dfrac{(\beta_0 - m\, \omega^2)^2}{\omega^2\, \alpha_a} + \dfrac{8.16 \times 10^{-5}\, V_0}{A_0} (\beta_0 - m\, \omega^2) + \alpha_a \dfrac{(4.08 \times 10^{-5}\, \omega\, V_0)^2 + A_0^2}{A_0^2} \right]} \tag{28}$$

$$= \frac{10^{-7}\, M^2\, I^2}{2} \times \frac{1}{\left[\dfrac{(\beta_0 - m\, \omega^2)^2\, [A_0^2 + (4.08 \times 10^{-5}\, \omega\, V_0)^2]}{\omega^2\, \alpha_m\, A_0^2} + \dfrac{8.16 \times 10^{-5}\, V_0}{A_0} (\beta_0 - m\, \omega^2) + \alpha_m \right]} \tag{29}$$

At very low frequencies, the middle term in the denominator is negligible as compared with the first term, and we may write for ω_1 the lower limit.

$$W_1 = \frac{10^{-7}\, M^2\, I^2}{2} \quad \frac{1}{\dfrac{\beta_0^2}{\omega_1^2\, \alpha_m} + \alpha_m} \tag{30}$$

At resonance,

$$W_r = \frac{10^{-7}\, M^2\, I^2}{2} \times 1/\alpha_m \tag{31}$$

If the power at resonance is n times that at ω_1, we have

$$\frac{\beta_0^2}{\omega_1^2\, \alpha_m} = (n - 1)\, \alpha_m \tag{32}$$

$$\alpha_m = \frac{1}{\sqrt{n - 1}} \times \beta_0 / \omega_1 \tag{33}$$

This determines the proper amount of damping at low frequencies, and since we have α_m expressed as a function of the initial throat area we may determine A_0:

$$\alpha_m = 41.2/9\, A_d^2 / A_0 = \frac{1}{\sqrt{n - 1}} \times \beta_0 / \omega_1 \tag{34}$$

$$A_0 = 41.2/9\, \sqrt{n - 1}\, \frac{A_d^2\, \omega_1}{\beta_0} \tag{35}$$

At ω_2 the upper limit of frequency we may write for the power radiated,

$$W_2 = \frac{10^{-7}\, M^2\, I^2}{2} \times \frac{1}{\left[\dfrac{m^2\, \omega_2^2\, [A_0^2 + (4.08 \times 10^{-5}\, \omega_2\, V_0)^2]}{\alpha_m\, A_0^2} - \dfrac{8.16 \times 10^{-5}\, V_0 \times m\, \omega_2^2}{A_0} + \alpha_m \right]} \tag{36}$$

To fulfill the condition that the power at resonance shall be n times that at ω_2:

$$\frac{m^2\, \omega_2^2\, [A_0^2 + (4.08 \times 10^{-5}\, \omega_2\, V_0)^2]}{\alpha_m\, A_0^2} - \frac{8.16\, V_0\, m\, \omega_2^2 \times 10^{-5}}{A_0} = (n - 1)\, \alpha_m\, . = \frac{\beta_0^2}{\omega_1^2\, \alpha_m} \tag{37}$$

$$m^2\, \omega_2^2\, \omega_1^2\, [A_0^2 + (4.08 \times 10^{-5}\, \omega_2\, V_0)^2] - 8.16 \times 10^{-5}\, V_0\, m\, \omega_2^2\, \omega_1^2\, \alpha_m\, A_0 = \beta_0^2\, A_0^2 \tag{38}$$

$$(\beta_0 / m^2 - \omega_1^2\, \omega_2^2)\, A_0^2 + \frac{8.16 \times 10^{-5}\, V_0\, \omega_2^2\, \omega_1^2 \dfrac{1}{\sqrt{n - 1}} \beta_0 / \omega_1}{m} A_0 - (4.08 \times 10^{-5}\, \omega_2^2\, V_0)^2\, \omega_1^2 = 0 \tag{38}$$

Substituting $\beta_0 / m = \omega_r^2$

$$(\omega_r^4 - \omega_1^2\, \omega_2^2) A_0^2 + \left(\frac{8.16 \times 10^{-5}}{\sqrt{n - 1}} V_0\, \omega_2^2\, \omega_1\, \omega_r^2 \right) A_0 - (4.08 \times 10^{-5}\, \omega_2^2\, V_0)^2\, \omega_1^2 = 0 \tag{39}$$

from which

$$V_0 = A_0 \frac{\omega_r^4 - \omega_1^2\, \omega_2^2}{4.08 \times 10^{-5}\, \omega_1\, \omega_2^2 \left(- \dfrac{\omega_r^2}{\sqrt{n - 1}} + \sqrt{\dfrac{n}{n - 1}\, \omega_r^4 - \omega_1^2\, \omega_2^2} \right)} \tag{40}$$

Repeating the two formulas:

$$A_0 = 41.2/9\,\sqrt{n-1}\,\frac{A_d^2\,\omega_1}{\beta_0} \tag{41}$$

$$V_0 = A_0\,\frac{\omega_r^4 - \omega_1^2\,\omega_2^2}{4.08 \times 10^{-5}\,\omega_1\,\omega_2^2\left(-\dfrac{\omega_r^2}{\sqrt{n-1}} + \sqrt{\dfrac{n}{n-1}\,\omega_r^4 - \omega_1^2\,\omega_2^2}\right)} \tag{42}$$

These completely determine the conditions at the throat of the horn.

Appendix III

Propagation in Exponential and Conical Horns

The theory of propagation of waves along a horn is simplified by considering it one dimensional. At any point whose abscissa is x, Fig. 13, let A be the area of a section where at any instant the velocity and pressure of the air are uniform all over the section.

If at any instant the air in the element shown is being accelerated, and ρ is the density,

$$\rho\,A\,(\Delta\,x)\,\frac{\partial\,v}{\partial\,t} = -\,A\,(\Delta\,P) \tag{43}$$

If at a given instant the volumetric rate of flow of air at $x + \Delta\,x$ is greater by $\Delta\,(A\,v)$, the volumetric rate of flow at x, the change of pressure in a time $\Delta\,t$ is given by,

$$\Delta\,P = -\,k\,\frac{\Delta\,(A\,v)\,\Delta\,t}{A\,(\Delta\,x)} \tag{44}$$

Taking limits, the following two differential equations of propagation are obtained,

$$\rho\,\frac{\partial\,v}{\partial\,t} = -\,\frac{\partial\,P}{\partial\,x} \tag{45}$$

$$\frac{\partial\,P}{\partial\,t} = -\,k/A\,\frac{\partial}{\partial\,x}\,(A\,v) \tag{46}$$

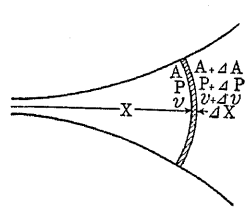

Fig. 13

Let φ be a function of x and t such that

$$v = -\,\frac{\partial\,\varphi}{\partial\,x} \tag{47}$$

$$P = \rho\,\frac{\partial\,\varphi}{\partial\,t} \tag{48}$$

These satisfy equation (45).

Substituting in (46),

$$\rho\,\frac{\partial^2\,\varphi}{\partial\,t^2} = k/A\,\frac{\partial}{\partial\,x}\left(A\,\frac{\partial\,\varphi}{\partial\,x}\right) \tag{49}$$

$$\rho\,\frac{\partial^2\,\varphi}{\partial\,t^2} = k\,\frac{\partial^2\,\varphi}{\partial\,x^2} + k/A\,\frac{d\,A}{d\,x}\,\frac{\partial\,\varphi}{\partial\,x} \tag{50}$$

$$\rho\,\frac{\partial^2\,\varphi}{\partial\,t^2} = k\,\frac{\partial^2\,\varphi}{\partial\,x^2} + k\,\frac{d\log A}{d\,x}\,\frac{\partial\,\varphi}{\partial\,x} \tag{51}$$

In the case of an exponential horn, Fig. 14,

$$A = A_0\,e^{Bx} \tag{52}$$

$$\frac{d\log A}{d\,x} = B \tag{53}$$

$$\rho\,\frac{\partial^2\,\varphi}{\partial\,t^2} = k\left(\frac{\partial^2\,\varphi}{\partial\,x^2} + B\,\frac{\partial\,\varphi}{\partial\,x}\right) \tag{54}$$

$$\text{Let } \varphi = z\,(x)\,w\,(t) \tag{55}$$

$$\rho\,z\,w'' = w\,k\,(z'' + B\,z') \tag{56}$$

$$\frac{\rho\,w''}{w} = \frac{k(z''+Bz')}{z} = \text{constant} = C \tag{57}$$

This is because w contains t alone and z contains x alone.

$$\text{Therefore} \quad \rho\,w'' - C\,w = O \tag{58}$$

The solution of this is:

$$w\,(t) = c_1\,e^{\sqrt{C/\rho}\,t} + c_2\,e^{-\sqrt{C/\rho}\,t} \tag{59}$$

$$k\,z'' + k\,B\,z' - z\,C = O \tag{60}$$

The solution is,

$$z\,(x) = c_3 e^{-B/2\,x + \sqrt{B^2/4 + C/k}\,x} + c_4\,e^{-B/2\,x - \sqrt{B^2/4 + C/k}\,x} \tag{61}$$

Using only the first solution of (59) and for forwardly propagated waves the second solution of (61).

$$\varphi = z\,(x)\,w\,(t) = H\,e^{-B/2\,x} e^{\sqrt{C/\rho}\,t - \sqrt{B^2/4 + C/k}\,x} \tag{62}$$

where H is a constant.

$$P = \rho\,\frac{\partial\,\varphi}{\partial\,t} = H\,\sqrt{C\,\rho}\,e^{-B/2\,x} e^{\sqrt{C/\rho}\,t - \sqrt{B^2/4 + C/k}\,x} \tag{63}$$

$$v = -\,\frac{\partial\,\varphi}{\partial\,x} = H\,(B/2 + \sqrt{B^2/4 + C/k})\,e^{-B/2\,x}\;e^{\sqrt{C/\rho}\,t - \sqrt{B^2/4 \times C/k}\,x} \tag{64}$$

When $x = O$, suppose,

$$P = P_0\,e^{j\omega t} \tag{65}$$

$$\sqrt{C/\rho} = j\,\omega \qquad C = -\,\rho\,\omega^2 \tag{66}$$

$$H\,\sqrt{C\,\rho} = P_0 \qquad H = \frac{P_0}{\sqrt{-\,\rho^2\,\omega^2}} = -\,j\,\frac{P_0}{\rho\,\omega} \tag{67}$$

Substituting,

$$P = P_0\,e^{-B/2\,x}\,e^{j\omega\left(t - \sqrt{\rho/k - \frac{B}{4\omega}}\,x\right)} \tag{68}$$

$$v = P_0\left(\sqrt{\frac{1}{k\,\rho} - \frac{B^2}{4\,\omega^2\,\rho^2}} - j\,\frac{B}{2\,\omega\,\rho}\right)\;e^{-B/2\,x}\,e^{-j\omega\left(t - \sqrt{\rho/k - \frac{B^2}{4\omega^2}}\,x\right)} \tag{69}$$

The value of k will now be found. From equation (44),

$$\frac{\partial\,P}{\partial\,t} = k\,\frac{-\,\Delta\,(A\,v\,\rho)}{A\,\rho\,(\Delta\,x)}$$

$$= k\,\frac{\text{time rate of change of mass}}{\text{mass}} \tag{70}$$

$$= k\,\frac{\partial\log\rho}{\partial\,t}$$

$$d\,P = k\,d\log\rho \tag{71}$$

For adiabatic changes

$$\rho = Q\,(P + p_0)^{1/1.4} \tag{72}$$

$$\log \rho = \log Q + 1/1.4 \log (P + p_0) \tag{73}$$

$$d \log \rho = 1/1.4 \, \frac{d\,P}{P + p_0} = 1/1.4 \, \frac{d\,P}{p_0} \tag{74}$$

$$k = 1.4\, p_0 \tag{75}$$

If a is the normal velocity of sound for plane and spherical waves

$$\rho/k = \frac{\rho}{1.4\, p_0} = 1/a^2 \tag{76}$$

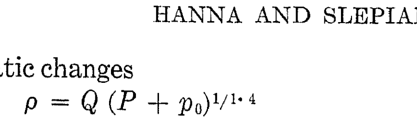

FIG. 14

and

$$\frac{1}{k\,\rho} = \frac{1}{1.4\,p_0\,\rho} = \frac{1}{a^2\,\rho^2} \tag{77}$$

The equations for P and v become

$$P = P_0\, e^{-B/2\ x}\, e^{j\omega\,(t - x/a')} \tag{78}$$

$$v = P_0 \left(\sqrt{\frac{1}{a^2\,\rho^2} - \frac{B^2}{4\,\omega^2\,\rho^2}} - j\,\frac{B}{2\,\omega\,\rho} \right) e^{-B/2\ x}\, e^{j\omega(t - x/a')} \tag{79}$$

where the velocity of sound in the exponential horn is

$$a' = \frac{1}{\sqrt{1/a^2 - \dfrac{B^2}{4\,\omega^2}}} \tag{80}$$

From equations (**78**) and (**79**) it is seen that the absolute relation between pressure and velocity in the exponential horn is the same as in a straight tube.

$$P = (\rho\,a)\,v, \tag{81}$$

but the velocity lags behind the pressure by an angle

$$\theta = \cos^{-1} \frac{\sqrt{\dfrac{1}{a^2\,\rho^2} - \dfrac{B^2}{4\,\omega^2\,\rho^2}}}{\sqrt{\left(\dfrac{1}{a^2\,\rho^2} - \dfrac{B^2}{4\,\omega^2\,\rho^2}\right) + \dfrac{B^2}{4\,\omega^2\,\rho^2}}}$$

$$= \cos^{-1} \sqrt{1 - \frac{a^2\,B^2}{4\,\omega^2}} \tag{82}$$

The value of $\cos\theta$ is therefore a measure of the effectiveness of an exponential horn as compared with a straight tube, as far as radiation along it is concerned. It is a function of ω/B as shown in Fig. 8.

Equation (**80**) indicates that the velocity of propagation of waves in an exponential horn is greater than the velocity of sound in free space, and becomes infinite at a frequency corresponding to $\omega/B = a/2$. This obviously cannot be true on physical grounds, so that we must conclude that the equations derived are only approximations, and very poor approximations for frequencies in the neighborhood of $\omega/B = a/2$. Inasmuch as equation (**80**) follows rigorously from the differential equations (**45**) and (**46**), these must also only approximately represent the actual physical phenomena.

Analysis shows that the considerable departure of equation (**36**) from the physical truth at low frequencies is due to the simplifying assumption that the problem is one dimensional, *i. e.*, that "wave-front" surfaces exist such that on any one of them both the pressure and air velocity are constant and uniform, and that the air velocity is normal to these surfaces. This assumption does not hold strictly for any but conical horns.

We may, however, make use of equation (**80**) which gives, a', the velocity of propagation in the horn calculated on the assumption of "wave-front" flow, as a criterion for determining over what range of frequencies this assumption is approximately valid. For those frequencies for which a' differs only slightly from a, the various formulas derived will be good approximations. In the curves of Figs. 8 and 9 those portions for which a' exceeds a by more than 10 per cent are shown dotted.

For backwardly propagated waves, if the pressure at any point is $P_r\, e^{j\omega t}$ the velocity

$$v_r = P_r \left(- \sqrt{\frac{1}{a^2\,\rho^2} - \frac{B^2}{4\,\omega^2\,\rho^2}} - j\,\frac{B}{2\,\omega\,\rho} \right) e^{j\omega t} \tag{83}$$

This is readily seen if the second part of equation (**61**) is used in the derivation instead of the first.

In the case of the conical horn, Fig. 15, or for spherical waves.

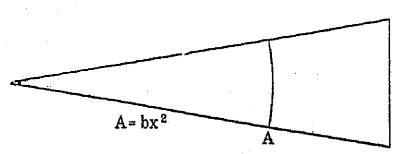

FIG. 15—PROPAGATION IN HORNS.

$$A = b\,r^2 \tag{84}$$

$$\frac{d \log A}{d\,r} = 2/r \tag{85}$$

Equation (**51**) becomes on replacing x by r,

$$\rho\,\frac{\partial^2 \varphi}{\partial t^2} = k\left(\frac{\partial^2 \varphi}{\partial r^2} + 2/r \,.\, \frac{\partial \varphi}{\partial r}\right) \tag{86}$$

$$\text{Let } \varphi = \psi/r \tag{87}$$

$$\frac{\partial \varphi}{\partial r} = -\,\psi/r^2 + 1/r\,\frac{\partial \psi}{\partial r} \tag{88}$$

$$\frac{\partial^2 \varphi}{\partial r^2} = +\,\frac{2\,\psi}{r^3} - 2/r^2\,\frac{\partial \psi}{\partial r} + 1/r\,\frac{\partial^2 \psi}{\partial r^2} \tag{89}$$

$$\rho\,1/r\,\frac{\partial^2 \psi}{\partial t^2} = k\left(1/r\,\frac{\partial^2 \psi}{\partial r^2}\right) \tag{90}$$

$$\frac{\partial^2 \psi}{\partial t^2} = k/\rho \frac{\partial^2 \psi}{\partial r^2} = a^2 \frac{\partial^2 \psi}{\partial r^2} \qquad (91)$$

The general solution is,

$$\psi = f\,(t - r/a) + g\,(t + r/a) \qquad (92)$$

Therefore $\varphi = \dfrac{f\,(t - r/a)}{r} + \dfrac{g\,(t + r/a)}{r}$ (93)

Keeping only $(t - r/a)$ terms which represent forward propagation:

$$\varphi = \frac{f\,(t - r/a)}{r} \qquad (94)$$

$$v = -\frac{\partial \varphi}{\partial r} = 1/r^2 f\,(t - r/a) - 1/r\, f'\,(t - r/a) \qquad (95)$$

$$P = \rho \frac{\partial \varphi}{\partial t} = \rho/r\, f'\,(t - r/a) \qquad (96)$$

Let $f\,(t - r/a) = M\, e^{j\omega(t - r/a)}$ (97)

$$P = M \frac{j\,\omega\,\rho}{r} \cdot e^{j\omega(t - r/a)} \qquad (98)$$

$$v = M\left(1/r^2 + \frac{j\,\omega}{a\,r}\right) e^{j\omega(t - r/a)} \qquad (99)$$

When $r = r_1$, let,

$$P = P_2\, e^{j\omega t} \qquad (100)$$

$$M \frac{j\,\omega\,\rho}{r_1} e^{j\omega(t - r_1/a)} = P_2\, e^{j\omega t} \qquad (101)$$

$$M = -P_2 \frac{j\, r_1}{\omega\,\rho} e^{j\omega r_1/a} \qquad (102)$$

$$P = P_2\, r_1/r\, e^{j\omega\left(t - \frac{r - r_1}{a}\right)} \qquad (103)$$

$$v = P_2^{r_1/r}\left(\frac{1}{a\,\rho} - j \frac{1}{\rho\,\omega\,r}\right) e^{j\omega\left(t - \frac{r - r_1}{a}\right)} \qquad (104)$$

These are the solutions for spherical wave propagation in the forward direction. They may also be used in determining the characteristics of conical horns.

Appendix IV

Calculations of Reflections

The following is proposed as an approximate method of calculating the reflections which take place at the open end of an exponential horn.

At the open end let P_1 = oncoming pressure, P_2 = the transmitted pressure, and P_r the reflected pressure. The corresponding velocities as found in equations (**35**), (**37**) and (**83**) are:

$$v_1 = P_1\left(\sqrt{\frac{1}{a^2\,\rho^2} - \frac{B^2}{4\,\omega^2\,\rho^2}} - j\,\frac{B}{2\,\omega\,\rho}\right) \qquad (105)$$

$$v_2 = P_2\left(\frac{1}{a\,\rho} - j\,\frac{1}{\rho\,\omega\,r_1}\right) \qquad (106)$$

$$v_r = P_r\left(-\sqrt{\frac{1}{a^2\,\rho^2} - \frac{B^2}{4\,\omega^2\,\rho^2}} - j\,\frac{B}{2\,\omega\,\rho}\right) \qquad (107)$$

If r_1 is the radius of the final opening of the horn, it is assumed that the transmitted wave is spherical and of radius r_1.

The following relations hold,

$$P_1 + P_r = P_2 \qquad (108)$$

$$v_1 + v_r = v_2 \qquad (109)$$

$$\frac{v_1 + v_r}{P_1 + P_r} = v_2/P_2 = \frac{1}{a\,\rho} - j\,\frac{1}{\rho\,\omega\,r_1} \qquad (110)$$

$$\frac{\left[\begin{array}{l} P_1\left(\sqrt{\dfrac{1}{a^2\,\rho^2} - \dfrac{B^2}{4\,\omega^2\,\rho^2}} - j\,\dfrac{B}{2\,\omega\,\rho}\right) \\ + P_r\left(-\sqrt{\dfrac{1}{a^2\,\rho^2} - \dfrac{B^2}{4\,\omega^2\,\rho^2}} - j\,\dfrac{B}{2\,\omega\,\rho}\right)\end{array}\right]}{P_1 + P_r} = \frac{1}{a\,\rho} - j\,\frac{1}{\rho\,\omega\,r_1} \qquad (111)$$

$$P_r = P_1 \frac{\left[\begin{array}{l} \sqrt{\dfrac{1}{a^2\,\rho^2} - \dfrac{B^2}{4\,\omega^2\,\rho^2}} - \dfrac{1}{a\,\rho} \\ \quad + j\left(\dfrac{1}{\rho\,\omega\,r_1} - \dfrac{B}{2\,\omega\,\rho}\right)\end{array}\right]}{\left[\begin{array}{l} \sqrt{\dfrac{1}{a^2\,\rho^2} - \dfrac{B^2}{4\,\omega^2\,\rho^2}} + \dfrac{1}{a\,\rho} \\ \quad - j\left(\dfrac{1}{\rho\,\omega\,r_1} - \dfrac{B}{2\,\omega\,\rho}\right)\end{array}\right]} \qquad (112)$$

$$P_r = P_1 \frac{\sqrt{1/a^2 - \dfrac{B^2}{4\,\omega^2}} - 1/a + j\left(\dfrac{1}{\omega\, r_1} - \dfrac{B}{2\,\omega}\right)}{\sqrt{1/a^2 - \dfrac{B^2}{4\,\omega^2}} + 1/a - j\left(\dfrac{1}{\omega\, r_1} - \dfrac{B}{2\,\omega}\right)} \qquad (113)$$

Since we wish to find the values of per cent P_r for different values of r_1 as well as for different values of ω and B, it is convenient to let,

$$r_1 = N/B \qquad (114)$$

$$\frac{P_1}{P_r} = \frac{\sqrt{1/a^2 - \dfrac{B^2}{4\,\omega^2}} - 1/a + j\,B/\omega\left(\dfrac{2 - N}{2N}\right)}{\sqrt{1/a^2 - \dfrac{B^2}{4\,\omega^2}} + 1/a - j\,B/\omega\left(\dfrac{2 - N}{2N}\right)} \qquad (115)$$

Taking a = 34,400 cm./sec. at 20 deg. cent., 760 mm. Hg., P_r/P_1 may be plotted as a function of ω/B for each assigned value of N. Curves of Fig. 6c show this for $N = 1$, $N = 4/3$ and $N = 2$, corresponding to $r_1 = 1/B$, $r_1 = 4/3\,B$ and $r_1 = 2/B$. It is seen that reflections decrease with increase in ω and decrease of B; also that the larger r_1 is, the less the reflection.

Mathematically the above function is minimum if $r_1 = 2/B$, which may be taken as a probable indication that further reduction in reflection will not be great if $r_1 > 2/B$. This value corresponds to a 45 deg. slope between the walls of the horn and the axis.

Discussion

H. Fletcher: The mathematical presentation of the design of horns is one of the best that has appeared in recent years. The equations evolved point out not only some of the criteria for good design, but show the serious limitation of the horn for producing natural reproduction. As pointed out by the authors, the applications of the equations are limited because of the assumptions involved in deducing them.

I desire to emphasize some of the results predicted by these equations and also some of the limitations in the application of them. First, I should like to discuss briefly the criteria the authors set up for good quality transmission. As they mentioned they are essentially the same as given in the paper by Mr. Martin and myself. However, I would interpret somewhat differently the things put down as responsible for the introduction of extraneous frequencies.

The so-called transients set up in the diaphragm are only present when corresponding transients are in the driving force. In the steady state they are absent; so it seems to me better to consider that the diaphragm produces a frequency distorting effect which is the same for all kinds of driving forces. This is particularly true when dealing with speech where there is an almost continuous variation in the form of the waves coming from the diaphragm.

One of the requirements given in the paper for an ideal loud speaker is that the energy radiated at each frequency be proportional to the square of the current. In practically every loud speaker the electrical impedance at the terminals varies over a wide range as the frequency varies, and consequently, maintaining a constant current does not maintain a constant energy input. So it seems to me that it would be better if this requirement were modified to read that the relation between the electrical energy absorbed to the acoustic energy radiated shall be constant for all frequencies.

Also, one of the principal points brought out in the paper is that by loading the diaphragm by making the opening into the horn small, the frequencies introduced by the non-linear characteristics of the diaphragm will be greatly reduced due to the reduced amplitude at which the diaphragm is working. I should like to call attention to the fact that this reduction in amplitude is accompanied by a corresponding increase in the pressure variation in the air chamber which may in some cases produce just as serious overloading as that due to the large diaphragm amplitude. Very frequently in ordinary conversation, the pressure amplitude is greater than 50 dynes. To reach large gatherings this amplitude must be increased at least 100 times, so that the pressure amplitude at the large end of the horn may frequently be greater than 5000 dynes. For the horns discussed in this paper then, the pressure amplitude in the small air chamber would frequently exceed 500,000 dynes or one-half atmospheric pressures. For such large amplitudes, harmonics which are from 50 to 100 per cent of the fundamental, will be created. This difficulty is overcome in the type of loud speaker used in our demonstration by using a large diaphragm and doing away with the enclosed air chamber. The magnetic system is loaded by the large mass of air in front of the diaphragm and consequently no excessively large amplitudes of either pressure or diaphragm motion exist anywhere in the system.

Equations **41** and **42** of the Appendix are important from a design standpoint. It is interesting to note that these equations predict that you cannot build a loud speaker having a horn connected to a diaphragm in the way indicated which will have a uniform response.

For the numerical case discussed on page 3 of the paper, if I interpret the equations correctly, the power radiated at 40 cycles would be only 1/250th of that at resonance. Even for this case, the volume of the air chamber is so small that air friction is beginning to play an important part, and as mentioned, the non-linear distortion of the air chamber is beginning to be very appreciable, due to the excessive values of the air pressure. For the dimensions of the diaphragm and the air chamber given, the distance between the diaphragm and the stationary plate is less than one-fifth of a millimeter. You see, that is a very small gap in order to reach the condition that I just mentioned, that the power radiated be only 1/250th of that radiated at resonance.

This limitation imposed upon the loud speaker, as indicated by these equations, is due largely to the assumption that the diaphragm and the moving magnetic system can be represented by a single degree of freedom and it is coupled to the horn by a single air chamber. If the moving magnet and the air chambers coupling the diaphragm to the horn are composed of several members, this limitation is largely removed. It is always possible to design the driving mechanism and its coupling to any horn of known physical characteristics so that as nearly a uniform radiation at all frequencies as is desired will result. Also, having given a driving mechanism of known characteristics, it is possible theoretically to design the horn and connecting chambers so that approximately uniform radiation will result. However, when one tries to meet these requirements in a practical design, it is found that no materials available have the proper physical characteristics and it is therefore necessary to make compromises.

The discussion regarding exponential horns is very interesting and confirms in a very beautiful way some of the earlier work along this line.

I might call attention to the fact that horns having cross-sections which vary exponentially are not new. The horns used in the public address system and which have been used during this convention are so designed and have been used throughout the country during the past two or three years.

Prof. V. Karapetoff: This problem of horns is a "house-on-fire" problem, in the sense that loud speakers are now being manufactured by the thousand, and while they are being manufactured and sold, we are trying to find out their fundamental theory.

At different times this Institute harbored various orphan branches of natural sciences. While we are harboring acoustics and acoustical papers, I want to be sure that we are carrying on this branch of science in the right way. To me, the right way is that of physics, and it is in this respect that I regret that the authors of this otherwise excellent paper do not even refer to the previous work of physicists on horns.

It was the privilege of this Institute, from the year 1918 to 1922, to have among its fellows one of the greatest physicists of this country—Dr. Arthur Gordon Webster—and one of his great contributions to physics was a theory of horns.

It was my privilege in 1918 to spend a day with Dr. Webster. He showed me two horns, both shaped like the flare of a trombone—one made out of brass; the other made out of plaster of paris. He said: "I'll bet you couldn't tell the sound of one from the other." I was offended, but accepted the challenge—and he won. At that time he said: "I worked out a complete mathematical theory of horns and I checked it with my phone and phonometer"—two wonderful instruments that he had developed—"and it checks very well." Later I saw his papers in the 1919 and 1920 *Proceedings* of the National Academy of Sciences—two classical papers—and I sincerely hope that the authors will at least add a reference to these papers in a footnote, for the benefit of further investigators.

While it is true that a horn has the function of an antenna, are we sure that the horn shape is the best possible shape for an acoustic antenna? Consider an expensive violin or the cello. Either of these is a complicated physical body, with at least four hundred years of development by great masters behind it. The response of these instruments is perfect within a wide range of frequencies. I hope that someone interested in acoustic antennas will try to couple a diaphragm with a violin body and see what results may be obtained.

S. Boyajian: The authors have clearly brought out the

difference in the characteristics of conical and exponential horns, namely that the conical horn intensifies the higher frequencies more than the lower frequencies, while the exponential horn affects them all equally. I would like to ask the opinion of the authors about a possible application of the conical horn to phonographic work. A phonographic record is not true to original; what it lacks is not volume but intelligibility which indicates that the higher harmonics have been recorded much weaker than lower harmonics. Would it not be a good thing, therefore, to use a conical horn so as to intensify the higher harmonics more than the lower harmonics, approaching thereby the original ratio of amplitudes of various harmonics? In the leading types of phonographs with internal horns, the horns consist of a few conical sections. All of the sections do not have the same angle, and the complete horn, therefore, is an intermediate product between the conical and the exponential type, probably nearer the former than the latter. It appears, therefore, that the phonograph manufacturers have (either knowingly or unknowingly) selected a construction which is more desirable for phonograph reproduction than the theoretical exponential horn.

A. Nyman: The paper by Dr. Slepian and Mr. Hanna is a very good and novel treatment of the subject. It gives a mathematical analysis of the subject and proves by experiment that this analysis is correct.

I believe that this same treatment of loud speakers could be extended farther. Two of the essentials of the loud speakers were mentioned: One, that the loudness at different frequencies should be constant; and the other one, I believe, the intelligibility. With regard to intelligibility, there is a quality in loud speakers that has been very little appreciated so far. I call that quality persistence. It consists of the existence of sound emerging from the horn after the applied electrical vibration has ceased in the loud speaker.

Some time ago I was able to conduct some very simple experiments by mechanically listening to a loud speaker after cutting off the applied current, and I found that at certain frequencies, there was an apparent presence of sound.

I believe that a large amount of distortion in the loud speakers is due to this one cause. Quite recently a loud speaker was brought to my attention where this was remedied to a large extent and apparently clarified the sound quite considerably. I believe that similar treatment, as that which has been exercised so far by Dr. Slepian and Mr. Hanna, could be applied to this one quality.

Another quality is directive action of the horn. Everybody is aware that there is such a directive action, and I believe that by proper design of the horn, it could be spread out so that every direction from the horn would receive the same amount of sound.

E. W. Kellogg (by letter): As a means of conversion of electrical into sound energy the loud speaker is extremely inefficient, and one of the chief reasons is the low transfer of energy from the diaphragm to the air. The paper under discussion describes an effort to obtain an approximate impedance fit between the air column and the diaphragm. It would be interesting to know whether it has been possible in practise to obtain very much higher sensitivity in this way than has been obtained with the usual horn proportions.

Another question of practical interest is whether it has been found possible to coil up the horn without impairing its action.

In section II a certain volume is called for in the cavity in front of the diaphragm. The effect of a cavity any larger than necessary at this point would be to reduce the output of some of the highest frequencies. Since it is not evident that such a thing is desirable, this requirement is a little puzzling. Does it not come about from having specified that the output at both ω_2 and ω_1 shall be $\frac{1}{n}$ times that at resonance The resonant frequency 1000 is slightly above the geometrical mean of the upper and lower limits 4000 and 200. Therefore without the cavity, the output at 4000 cycles comes out a little greater than at 200 cycles, and to equalize the two an air cushion is introduced. Would it not be simpler and more satisfactory to impose the condition that at *neither* of the extreme frequencies shall the output be less than $\frac{1}{n}$ times that at resonance? I am asking this question in the interest of simplifying the calculations rather than for its bearing on actual design, for the volume of the cavity as given in the illustrative example is about as small as it would be practical to make it. I would expect that any cavity volume less than that in a quarter wave length of the tube would have very slight effect.

At the end of the paper is a statement that reflections decrease with decrease of B. This is misleading. The curves of Fig. 16 show that for a given value of r_1 and ω, the larger the value of B, the less the reflection. For example, take $r_1 = 20$ centimeters, $B = 0.05$ and $\omega = 5000$, giving $r_1 B = 1$ and $\frac{\omega}{B} = 10 \times 10^4$. The reflection as shown by the top curves is 8 per cent. Now if B is given the value 0.1, $r_1 B$ becomes 2, and $\frac{\omega}{B}$ becomes 5×10^4, for which the reflection as shown on the lowest curve is about 3 per cent.

A word of interpretation of Fig. 16 may be of interest. Each curve represents a certain shape of horn, without saying anything as to its absolute size. For example $r_1 = \frac{2}{B}$, or $r_1 B = 2$, represents a horn ending with a flare angle of 45 deg. to the axis. If we take two such horns, one just twice the size of the other, the larger horn will react to sound waves of a certain length exactly as the smaller one does to sound waves of half the length. The horizontal scale might equally well have been made to read "diameter of bell divided by wave length."

An interesting analogy to an exponential horn is an electrical transmission line in which starting from one end, the inductance decreases exponentially with distance, and the shunt capacity increases so that their product remains constant. The propagation equations for such a line take the identical form shown in Appendix III of the paper. Above a certain frequency waves are propagated along such a line very much as they are over a uniform line, except that the velocity is higher than for a uniform line with the same value of the product $L\,C$. Such a tapered line provides a possible substitute for a transformer for fitting two unequal impedances together. The telephone companies have employed this principle in the form of tapered loading to prevent excessive reflection losses at junctions of loaded and unloaded lines. A horn performs the same function of providing a better impedance fit between the relatively stiff, heavy diaphragm and the very light, or low-impedance air in free space. The equations for the electrical line show an infinite velocity at a certain critical frequency and at all frequencies below this.

The writers express some doubt as to the validity of the equations in Appendix III for frequencies for which the velocity of propagation becomes infinite. I think the difficulty lies, not in the approximations mentioned, but in our understanding of the term "infinite velocity" and in the assumption of zero reflection. In transmission calculations we say that the velocity of propagation is equal to $2\pi f$ divided by the quantity that expresses the change of phase per unit length of line. Now it is quite possible to have the current in phase at all points along a line, for example in a low-loss line less than a quarter-wave-length long, and open-circuited at the far end. A quarter-wave-

length organ pipe also has zero phase difference from point to point. This is true only of steady-state conditions and does not mean that energy is transmitted at infinite velocity. You notice that in the examples I have mentioned, no power is being transmitted to the far end. As soon as power is taken from the end of the line a phase shift appears. This is true also of the horn. The equations given are for a zero-loss line infinitely long, and they show that such a line has a zero-power-factor impedance, or transfers no power, for frequencies below the critical value. Abover the critical frequency, absorption of power at the bell end of the horn is what is required to prevent reflections, and the equations for simple outward propagation represent a possible condition. Below the critical frequency, an infinite line can be simulated only by a zero-power-factor terminating impedance, which is not the condition under which a horn works. Therefore the complete solution, using both values of propagation constant, must be retained for frequencies below the critical value. It will then appear that when power is radiated from the bell, there is a progressive shift of phase along the horn.

L. P. Rundle (by letter): In nearly all of the better grades of radio loud-speaker horns there is at least one right-angle bend; in others there are two and in still others a circle and a half, *i. e.*, six right-angle bends. In this paper no mention is made of bends, what effect they have on the acoustics of the horn or how they should be designed. I should like to know the mathematical treatment and design for bends and curves in the horn. Again no mention is made of the effect of different materials for horns, or the proper thickness in relation to the other distribution of the material, and this is an important item.

No mathematical and physical treatment is given which has to do with the tone color and quality and what, for instance, will make some sound-radiating devices give a sound that is full, rich, and mellow. This is very noticeable in phonographs, as well as loud speakers for radio work, For instance, it is easily noticeable in comparing a Victor and a Brunswick phonograph, in which both have five right angle bends from diaphragm to the end of the horn but which play the same record with a considerable difference in tone quality. I have noticed the same difference in different makes of loud speakers, and to a less extent in the loud speakers of the same make connected to the same receiver set. Now what makes this difference in tone quality?

Another thing that is quite noticeable in some of the loud speakers is that the sound appears to come from the far end of a long hall, which may be due to a sound-image effect and which is a great detriment to any sound-radiating device. How can this be taken care of in the design of horns?

The papers says nothing about the principle of reflected tone or sound, which is one of the principal points in the advertisements of one maker of a very pleasing loud talker. I would like to know if the authors have any data on the design of this type of loud speaker and how it compares with the exponential design of horns.

The equation giving V_o (the volume of the air behind the diaphram) does not tell anything in regard to the shape of that air volume. It may be very thin at the outer edge of the diaphragm. This brings up another point that was not treated in the paper, namely, the limiting size of the throat of the horn and the closeness of the diaphragm backing when friction would cause severe losses. I should like to know if the authors have any data on these points, and if they have made any tests to determine the coefficient of air friction for various materials such as mica, iron, aluminum, fibre, wood, etc. If so, what are these coefficients? It would be interesting to know if the authors have made any experiments on a horn such as coating the inside with various materials such as oils, waxes, graphite, etc., to see what effect it had on the sound-radiating qualities of the horn.

In regard to the shape of the air volume behind the diaphragm of a phonograph, I have found that the shape of that volume is quite important in that it has considerable to do with the sound intensity and somewhat with the quality, this latter evidently being due to the reflections of sound from diaphragm to backing and vice versa, as well as the echoes from rim to rim of the sound box. It seems quite possible that in a sound box of poor design these things will cause stray noises and blasts that blur the quality of tone at certain frequencies.

In the example worked out, N is taken as 10. I should like to know what determines the best value of N to use in the design of a given horn.

I should like to know how the power radiated at resonance, $W\,r = 2\pi \times 1000$, is determined in designing a new horn.

The paper makes no mention of the shape of the diaphragm or the material. Some loud speakers have a corrugated diaphragm, some a concave or arched construction with corresponding curves at the back of the diaphragm and others a mica diaphragm. I should like to know from the authors if they have made any experiments on diaphragms and what effect the size, thickness, shape and material has on the size and shape of V_o and the force required to set the diaphragm in vibration. A mathematical treatment of the physics of vibrating materials of which diaphragms are made would be a proper subject to go with this horn, since the design of the horn is intimately linked with the characteristics of the diaphragm which it loads.

John Minton (by letter): The work which Dr. Slepian and Mr. Hanna have presented is a valuable contribution to existing literature on the subject of horns. Their results apply almost entirely to horns of infinite length, in which case we do not need to consider reflection from the end of the horn. In this case the radiated sound energy can be calculated readily, provided certain simplifying assumptions are made.

Independently of the work of the authors Dr. Goldsmith and I have been engaged in a rather extensive experimental and theoretical study of horns of finite lengths and in a forthcoming paper we shall present a review of certain phases of our work.

In connection with the paper which has just been given, I desire to discuss certain phases of it, particularly those treated in Appendix III. Inasmuch as the publications on this subject are rather meagre, it is desirable, it seems to me, to call attention to certain of these which are of fundamental importance to this subject. This is particularly true because the authors apparently have not made use of such publications and they have, therefore, duplicated much that has been published for some time.

Lord Rayleigh, "Theory of Sound", Volume II, page 158, gave the equations for the pressure, velocity and energy radiation in a straight tube of unlimited length. His three equations for these quantities are respectively:

$$\rho \frac{d\,\phi}{d\,t} = - \frac{\partial a A}{2\,\sigma} \cos k\,(a\,t - x) \qquad (1)$$

$$\sigma \frac{d\,\phi}{d\,x} = \frac{1}{2}\,A \cos k\,(a\,t - x) \qquad (2)$$

$$P = \frac{\rho\,a\,A^2}{2\,\sigma} \qquad (3)$$

where ρ = air density, $k = 2\,\pi$ divided by the wave length (λ), a = velocity of sound, σ = cross sectional area of tube, ϕ = velocity potential and A determines the strength of the source of sound. The source of sound is considered placed at one end of the tube which is closed at the end adjacent to the source. The first two equations show that the pressure and velocity are in phase. The third equation shows that the sound radiation along the tube is inversely proportional to the area of the tube and constant with, or independent of the frequency.

Lord Rayleigh's equations, "Theory of Sound", Volume II, page 113, for the straight conical horns in which the source of sound is located at the vertex are as follows:

$$\rho \quad \frac{d\,\phi}{d\,t} = -\frac{\rho\,k\,a\,A}{\omega\,r}\sin k\,(a\,t - r) \tag{4}$$

$$\omega\,r^2\,\frac{d\,\phi}{d\,r} = A\,[\cos k\,(a\,t - r) - k\,r\sin k\,(a\,t - r)] \tag{5}$$

$$P = \frac{\rho\,k^2\,a\,A^2}{2\,\omega} \tag{6}$$

The additional factors involved are defined as follows: r = the radial distance and ω = the solid angle of the cone. The first two equations show that the velocity leads the pressure by an angle whose cosine is $\frac{k\,r}{\sqrt{1 + k^2\,r^2}}$. That is:

$$\cos\,\theta = \frac{k\,r}{\sqrt{1 + k^2\,r^2}} \tag{7}$$

When the frequency is very high or when r becomes large the expression for $\cos\,\theta$ becomes essentially unity and the propagation is the same as in the straight tube where the current and pressure are in phase. This does not mean that the radiation in the two cases is equal, but merely that the wave propagation is the same as that in plane waves. We may observe, also, that at low frequencies, where $k^2\,r^2$ can be neglected compared with unity, the pressure and current become more separated in phase which reaches quadrature at zero frequency. Later we shall see that the exponential horn does not perform at these low frequencies as well as the straight conical horn.

The radiation along an infinitely long conical horn is given by equation (6). It is proportional to the square of the frequency and inversely proportional to the solid angle, ω. On comparing equations (3) and (6), the ratio of radiation along a tube to that along a straight cone for equal sound sources is thus equal to $\frac{\omega}{k^2\,\sigma}$. That is:

$$\frac{\text{Radiation along infinite tube}}{\text{Radiation along infinite cone}} = \frac{\omega}{k^2\,\sigma} \tag{8}$$

(See Rayleigh, "Theory of Sound," page 159, eq. 7.)

This ratio is equal to unity for a given tube and cone at some particular frequency, when the radiation in the two cases will be equal. For frequencies below this "critical" frequency the radiation along the tube will be the greater; while for frequencies above it, the radiation along the cone will be greater. To illustrate this, suppose $\omega = 0.01$ radian and $\sigma = 1$ sq. cm. Then when $k^2 = 0.01$, or the frequency is about 550 cycles, the straight pipe and cone give equal radiation. The cone is superior above 550 cycles and inferior below this frequency.

We have developed equations for the performance of exponential horns independently of Dr. Slepian and Mr. Hanna, using as the basis for this work the general equations given by Professor A. G. Webster in the *Proceedings* of the National Academy of Sciences, pages 275-282, 1919. Webster derived the same equation for pressure as given by Messrs. Hanna and Slepian in equation (51). Professor Webster also derived a similar equation for the current or velocity. Inasmuch as the authors have made no reference to Webster's publications, I presume they made no use of them. I think that Professor Karapetoff's remarks are appropriate and I am in accord with them.

Webster's equations apply to horns of any profile. He applied them to the following special cases:

(1) Straight pipe (σ = constant)
(2) Straight cone ($\sigma = \sigma_0\,X^2$)
(3) Exponential horn ($\sigma = \sigma_0\,\epsilon^{mx}$)
(4) For the case where $\sigma = \sigma_0\,X^n$ (hyperbolic when $n = -2$)
(5) For the case where $\sigma = \sigma_0\,\epsilon^{mx^2}$

Cases (1) and (2) were treated by him in some detail. The general equations for the pressure and velocity for the exponential horn were given. Case (4) was dealt with and the general equations given. In case (5), however, the method of analysis only was indicated.

If we separate Webster's exponential equations into the direct and reflected waves and put in the time factor, we obtain for the direct wave in the case of a horn of infinite length

$$\rho \quad \frac{d\,\phi}{d\,t} = -\frac{e^{-\frac{mx}{2}}\,\rho\,A\,g\,a}{2\,\sigma_0\,k}\left[\cos\,(k\,a\,t - g\,x) - \frac{m}{2\,g}\sin\,(k\,a\,t - g\,x)\right] \tag{9}$$

$$2\,\sigma_0\,\epsilon^{\frac{mx}{2}}\,\frac{d\,\phi}{d\,x} = A\cos\,(k\,a\,t - g\,x) \tag{10}$$

$$P = \frac{\rho\,A^2\,e^{\frac{-mx}{2}}\,a\sqrt{k^2 - \frac{m^2}{4}}}{2\,\sigma_0\,k} \tag{11}$$

where $g = \frac{1}{2}\sqrt{4\,k^2 - m^2}$ and $\sigma = \sigma_0\,e^{mx}$.

The first two equations for the pressure and current correspond to equations (78) and (79) of Slepian and Hanna. The current equation (10) was written in the form given so that a comparison could readily be made between the cone and exponential horn for the same current or air velocity. The exponential horn is considered closed at the small end.

A comparison of equations (9) and (10) shows a leading phase angle between the pressure and current such that:

$$\cos\,\theta = \sqrt{1 - \frac{m^2}{4\,k^2}} = \sqrt{1 - \frac{m^2\,a^2}{4\,n^2}} \tag{12}$$

This result is identical to that given by Dr. Slepian and Mr. Hanna in their equation (82) n being equivalent to their ω. Our theoretical deductions, therefore, are in agreement for horns of infinite length.

I desire, however, to emphasize some of the deductions that may be drawn from these results. When $\sqrt{1 - \frac{m^2}{4\,k^2}}$ is zero the pressure and current are 90 deg. out of phase and no radiation results. This occurs when $m^2 = 4\,k^2$, or at a frequency, whose wave length is, $\lambda = \frac{4\,\pi}{m}$. If we take $m = 0.07$, then $\lambda = 180$ cm., which corresponds to a frequency of about 185 cycles. m can be made smaller than 0.07 and in this case the frequency at which this occurs would be correspondingly lower. However, too small an m necessitates either too long a horn or too small a final opening in the case of horns of finite lengths.

In the case of the conical horn, however, we saw that it had a finite phase angle all the way down in frequency. At these lower frequencies, then, the conical horn should be superior on the basis of this simple theory.

If we refer to equation (11), the sound radiation at the initial end of the exponential horn is

$$P_{x=0} = \frac{\rho\,A^2\,a\sqrt{k^2 - \frac{m^2}{4}}}{2\,\sigma_0\,k} \tag{13}$$

At frequencies sufficiently high to make $m^2/4$ negligible compared with k^2, equation (13) becomes

$$\underset{\text{(High Freq.)}}{P_{x=0}} = \frac{\rho\,A^2\,a}{2\,\sigma_0} \tag{14}$$

This result is identical with the straight pipe as shown by equation (3), provided the initial opening, σ_0, is the same as the

cross sectional area of the pipe. That is, if $\sigma_0 = \sigma$ (of equation 3) the pipe and the exponential horn are identical in phase relations of current and pressure, as well as in the magnitude of the radiation from the source of sound into them.

To make a comparison under these conditions between the exponential and conical horns, suppose $\sigma_0 = 1$ sq. cm. and $\omega = 0.01$ radian. Under these conditions the exponential horn is inferior to the conical horn at all frequencies above 550 cycles as can be calculated from the relation:

$$\frac{P_c}{P_E} = \frac{k^2 \sigma_0}{\omega} \tag{15}$$

If, therefore, m is 0.07, $\sigma_0 = 1$ and $\omega = 0.01$ and the source of sound used gives the same velocity when used on both horns, the conical would be superior below 185 cycles and above 550 cycles, while the exponential is superior between these two frequencies. Incidently, curves which we have taken of sound pressure and frequency on horns of finite lengths indicate that this result holds approximately even when the source is placed at a finite distance from the vertex of the cone.

It is important, therefore, to observe that in the three cases considered the cross sectional area of the pipe, the solid angle of the cone and the initial area of the exponential horn all enter the power equations in the same manner and have nothing whatever to do with the phase between the pressure and velocity. This is important to observe in any comparative tests that may be made. For this reason it seems to me, if for no other, the demonstration with the various horns made by the authors are not conclusive and are apt to be misleading for by changing slightly the conditions the comparative results are altered greatly.

These results, of course, do not detract from the excellent results which the authors have presented—they merely emphasize certain features and indicate what we owe to Professor Webster for his splendid work in the field of acoustics.

Since these conclusions are of practical value, it is of importance to test them experimentally. Two horns of heavy galvanized iron were made—one being exponential and the other conical. Their lengths were 122 cm., had an initial opening of 1.6 cm. and a final opening of 31 cm. for the conical horn and 38 cm. for the exponential one. As far as radiation is concerned the larger final opening of the exponential horn gives to it a slight advantage. m corresponds to 0.052 and therefore the "cut-off" frequency, so to speak, was about 135 cycles.

Curves of sound pressure at various frequencies taken for these two horns indicate clearly the correctness of our conclusions. There was no question about the result that at those frequencies below 200 cycles the conical horn was much superior in accordance with our theory. These results suggest that the author's conclusions in section IV are probably only partly correct. These experimental results also suggest that if a receiver unit is placed at the small end of a conical horn, the latter perhaps radiates as though the unit were placed at the vertex and not as though it were placed at a finite initial opening. That is, it seems to me, that equations **100** to **104** given by the authors perhaps do not hold experimentally and are perhaps of theoretical value only since the basis of their derivation may be found to be incorrect experimentally.

As stated in the beginning of my discussion, the above results are of theoretical interest only because they deal with horns of infinite length in which no end reflection occurs and hence no resonant phenomena come into play. As already stated, Dr. Goldsmith and I will present in a forthcoming publication[1] experimental and theoretical results on horns of finite lengths, covering certain phases of our work in which the questions of acoustic impedances, resonance, effect of horn on external pressures, energy radiation, end reflection, etc., will be considered in some detail.

1. "Performance and Theory of Loud Speaker Horns," Proceedings Institute Radio Engineers, August 1924.

Merely to illustrate the type of results obtained, I give below two equations. One shows the effect of the conical horn on the external pressure, p_e, and the other shows the effect of the exponential horn. The ear, of course, is a pressure device and for this reason we are more interested in pressures than in other factors. The first equation was derived by Professor G. W. Stewart and published in the *Physical Review*, pages 313-326, 1920. The second equation, derived by us, is similar to Professor Stewart's, except it applies to the exponential horn. p_1 is the pressure at the small end of the horn.

$$p_1 = \frac{p_e}{\dfrac{\sin k r}{k r} + \dfrac{\sigma_2 \sin k (r - \epsilon)}{r \sin k \epsilon} \left(\dfrac{k}{2 \pi} i - \dfrac{1}{c_0} \right)} \tag{15}$$

(Stewart) conical horn.

$$p_1 = \frac{\sqrt{\dfrac{\sigma_2}{\sigma_1}}\, p_8}{\cos g L + \dfrac{m}{2 g} \sin g L + \dfrac{\sigma_2 k Z_0}{g \beta} \sin g L} \tag{16}$$

(Minton-Goldsmith) exponential horn.

Symbols which have not already been defined are as follows: r = radial length of the cone, L = axial length of the exponential horn, c_0 = acoustic conductance of the large end of the horn, $i = \sqrt{-1}$, ϵ is defined by $\tan k t = k r$ and σ_2 is the cross sectional area of the large end of the horn. Z_0 is the acoustic impedance of the large end treated as a fictitious cylinder of definite length and an opening equal to the diameter of the large end. The equation for Z_0 is $p\, a^2 k^2 \left(\dfrac{k i}{2 \pi} - \dfrac{1}{c_0} \right)$ (see our paper referred to, Appendix II, eq. **19**, p. 473) and is similar to the same factor in equation (**15**) above. $\beta = \rho_a k^2$, whose factors have been defined $g = \sqrt{k^2 - \dfrac{m^2}{4}}$.

By means of these two equations we are able to study pressure changes caused by both the finite exponential and conical horns. The effect of resonance, therefore, on external pressures is easily observed. Since experimental data on pressure are available we are able to check the theory. Similar equations have been obtained for the other factors enumerated above, but need not be given here. We believe, therefore, that an extension of Professor Webster's and Professor Stewart's work has led to results which are of prime importance in the study of horns of finite lengths and of various sizes and shapes.

J. Slepian (by letter): The simple experiments which Mr. Hanna has performed are not the only experimental verification of the theoretical results in the paper. Mr. Hanna has measured the increase in loading or acoustic damping produced by a horn, by impedance measurements of the receiver with an a-c. bridge, and has obtained very good checks with the theory. I have also some experimenting curves obtained by Prof. Dayton Miller of Cleveland, which bring out some points very clearly.

Prof. Miller used a specially constructed diaphragm and mirror, which could be attached to any of the various horns which was tested. On sounding a series of organ pipes before the horn, Prof. Miller observed the motion of the diaphragm by means of the mirror, and thus obtained a curve of diaphragm motion against frequency, such as those which I am about to show.

At first sight it would seem that these curves would not give the information desired as to the performance of horns on loud speakers, for what is wanted here is the sound which is produced at various frequencies for a given force on the diaphragm. However, a very interesing and general relation exists which enables us to change over from this data on the properties of a horn as a

pickup of sound, or means for converting acoustic power into diaphragm vibrations, to data on a horn as a radiator, or means for converting diaphragm vibrations into sound.

This being a gathering of electrical men, I shall give the electrical form for this relation; first, this is known as the reciprocal relation for electrical networks. Let A and B, Fig. 1A, be two pairs of terminals joined by a network built up out of simple impedances in any manner. Then if one ampere is made to flow into the terminals A, the same voltage will be produced at B as would be produced at A if one ampere is caused to flow at B. It is very interesting to check this relation for a few simple cases.

The acoustic analog of this relation is then as follows: In a given space containing bounding walls of any description, a source of sound of given intensity at a point A, Fig. 1B, will produce the same pressure on a diaphragm at a second point B, as would be produced on a diaphragm at A if the source of sound were moved to B. A more precise statement of this proposition may be found in Rayleigh's Theory of Sound, Vol. II, p. 131.

It follows then that on sounding organ pipes of different frequencies, but with the same intensitybefore a horn, the curve of pressures developed on an attached diaphragm will be the same as the curve of acoustic loading which the horn would impose on the diaphragm if used as a loud speaker. For an ex-

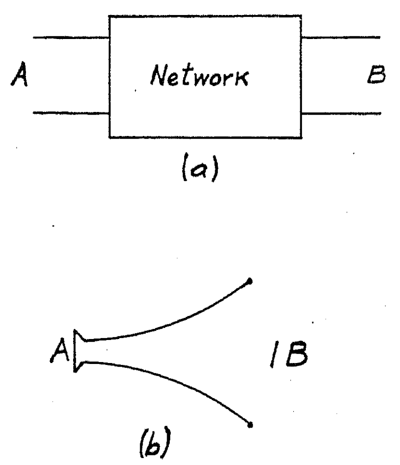

FIG. 1

ponential horn, we should then expect to reproduce the curve, Fig. 8, of Hanna and Slepian's paper.

However, Prof. Miller did not measure the pressure developed at the diaphragm, but the motion resulting from this pressure. We should therefore consider what motion would be produced in the diaphragm by a constant force of varying frequency. The motion of the diaphragm will be determined by its mass, stiffness and damping. The influence of the horn, when it is effective, will be to increase the damping. An important point brought out in Hanna and Slepian's paper is that the loading of a horn for the frequencies for which it is effective, is the same as that which would be produced by an infinite straight tube having the same section as the throat of the horn.

Mr. Hanna has calculated what the motion of the diaphragm would be under a constant force when loaded by an infinite straight tube of the same section as the throat of the horn. His results are shown by the smooth curves in Figs. 2 and 3.

Before discussing these curves, I would like to call attention for comparison to Fig. 10 of Martin and Fletcher's paper. Curve A of that figure is said to be the output curve of one of the best commercial types of loud speakers. The response begins to fall off at about 800 cycles and is one tenth of its maximum at 600 cycles. Now the falling off in response of this type of loud speaker at low frequencies is entirely due to the failure of its horn to sufficiently load the diaphragm, for the electromagnetic force for a given current is just as great or greater at low frequencies as for high. That is, when the acoustic loading of the horn is too small, such large amplitudes of vibration of the diaphragm are necessay to produce appreciable sound that most of the magnetic force is used in overcoming the stiffness of the diaphragm, and little is left for doing work on the air. We should expect then that if a better horn were used, one which would load down to lower frequencies, a much better response curve would be obtained.

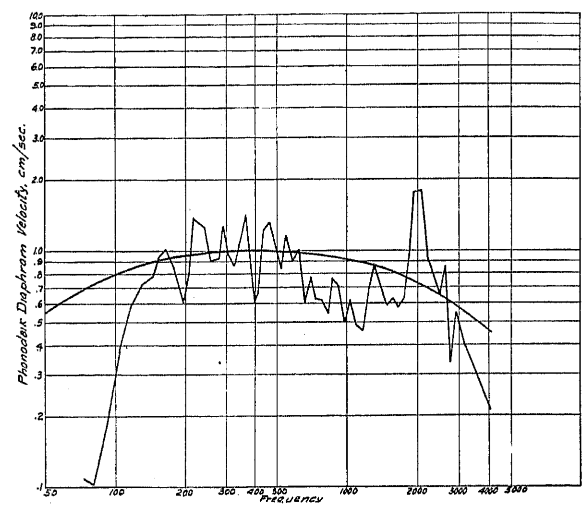

FIG. 2

The curves obtained by Prof. Miller bear this out. Fig. 2 is for a horn whose throat area was 0.81 cm^2. and whose section increased at the rate of 4.5 per cent per cm. of length. We see that it gives the full loading corresponding to an infinite straight tube of the same section down to about 150 cycles, and we must go down to about 100 cycles before its loading effect is reduced to one tenth. This is not only very much better than the curve for

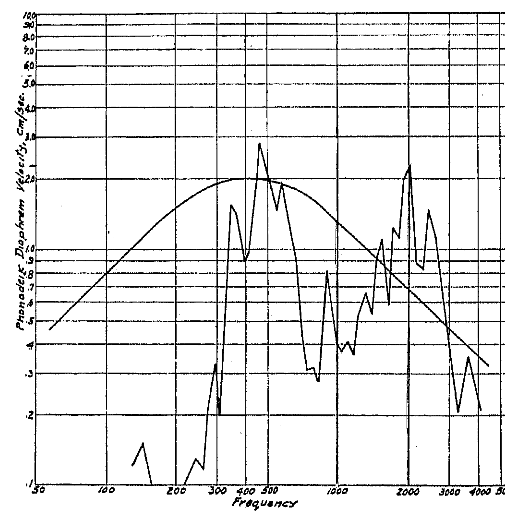

FIG. 3

the commercial type of loud speaker shown by Messrs. Martin and Fletcher, but even compares well with their laboratory models.

Fig. 3 is for an exponential horn having three times the throat area, and two times the rate of increase of section as the horn of Fig. 2. According to the theory, the loading of this horn with larger throat should be only one third that of the other horn, and so the resonances of the diaphragm should be more marked. This is seen to actually be the case. Besides the fundamental

diaphragm resonance, which is the only one which Mr. Hanna considered in calculating his smooth curve, there is also a higher order resonance at about 2000 cycles. Since the rate of increase of section of this horn was about twice that of the preceding horn, the experimental curve should depart from the smooth curve at about twice the frequency for the first horn, and again this is seen to be the case.

The question has been raised as to whether the use of a horn is essential to a loud speaker, or whether sufficiently good results may not be obtained by acting on the air with a sufficiently large diaphragm. The principal objection to a horn is that if it is to be good, it must be quite long. However, the length which a horn must have is determined very largely by the amount of acoustic loading which it must impose upon the diaphragm. A uniform response will be obtained if this acoustic damping force on the diaphragm is about as large or larger than the force required to accelerate the diaphragm because of its mass, or the force required to displace the diaphragm due to its stiffness. Now, with materials capable of being used at present, it is not possible to get acoustic loading large compared to the inertia reaction of the diaphragm if the diaphragm acts directly upon the air.

Thus, suppose a large diaphragm is used, made of material whose density is 2, and whose thickness is 0.01 cm. The mass per cm^2. is then 0.020 grams. Suppose this diaphragm is vibrated at 3000 cycles, generating sound waves. The reaction of the air which gives a damping force on the diaphragm, has for one component the force necessary to accelerate about one quarter wave-length of air, for this amount of air may be said to move with the diaphragm. Now at 3000 cycles, one quarter of a wave-length is only about two and one-half centimeters long, and the mass of a column of this length and one square centimeter in section is only 0.003 grams, which is only 15 per cent of the mass of a square centimeter of the diaphragm. Of the total force on the diaphragm, only 15 per cent is doing useful work on the air, and the rest is consumed in merely moving the mass of the diaphragm to and fro. It is true that this wattless component of force may be counterbalanced by a wattless component of force arising from the stiffness of the diaphragm, but for a finite diaphragm, having no mechanical loss, this compensation can be effective only at certain particular resonant frequencies. Between each successive pair of resonant frequencies, there will be an anti-resonant frequency at which the ratio of force actually acting on the air to total force on the diaphragm will be very much less than the 15 per cent above.

If, for the sake of discussion, we consider an infinite diaphragm, then the resonances disappear, but most of the force on diaphragm is spent in producing waves in the diaphragm itself, which radiate away from the region of application of the force. These waves will be only slightly attenuated by the air. Hence, returning to the finite diaphragm, if there is to be no reflection of these waves at the periphery of the diaphragm and resulting resonances, these waves must be caused to be more strongly attenuated by internal losses in the diaphragm itself, or reflection prevented by losses at the periphery.

In any case, we may conclude, that with a diaphragm of the mass considered, at least seven times as much force must be expended on the diaphragm as actually takes hold of the air, and in practical cases, allowing for losses and anti-resonances, it will be 20 to 100 times as much.

Any electrical engineer will recognize that what is needed is some kind of a coupling or transformer which will compensate for the great disparity in masses of the air and diaphragm. The corresponding electrical problem would be to effectively load a source of alternating voltage having a high internal reactance when only a resistance of relatively small value is available. The obvious solution of this electrical problem is to interpose a transformer which will cause a large current to flow through the resistor with only a small current through the source of voltage. The effective resistance of the load referred to the primary side of the transformer is to the actual resistance in the secondary as the square of the ratio of turns, so that the resistance is thus stepped up to a value where it is comparable with the internal reactance of the source of voltage.

Now the chamber and throat of a loud speaker constitute just the kind of transformer desired. A small velocity of the diaphragm causes the air in the throat to have a large velocity. In the horns described by Messrs. Hanna and Slepian, the ratio of these velocities is 25 or more. The effective mass of the air is thus stepped up several hundred fold to where it is comparable with the mass of even the ordinary iron diaphragm. When loaded by such a horn, 50 per cent or more of the total force on the diaphragm is actually spent on the acoustic load over most of the acoustic range. The mechanical power factor is thus high, and mechanical resonances greatly reduced.

Without a horn, then, for diaphragm materials so far available, the mechanical power factor is very low except at certain resonant frequencies. A very large mechanical input is necessary for a given volume of sound. To reduce the troublesome distorting effect of mechanical resonances, mechanical losses or electrical losses, electrical filter circuits will be necessary. These, however, will not reduce the mechanical input necessary, but rather increase it. A relatively large electrical power plant is then necessary.

Will a large hornless diaphragm save space, then? Possibly, since the large amount of extra electrical apparatus necessary may be made very compact, and may perhaps be put in a somewhat smaller volume than required for a horn. But the saving will be small, and in my opinion, will not be worth while because of the extra complication and expense. Future improvements in the use of light weight diaphragm materials may reduce the amount of electrical apparatus necessary, but a diaphragm of such material would also permit a shorter horn to load it properly. The normal course of development, it seems to me, as we learn how to use lighter diaphragms, would be to use loud speakers with large diaphragms and shorter horns, but the possibility of arriving at a diaphragm so light that it is best used directly on the air without a horn, is quite remote.

Certain Factors Affecting Telegraph Speed

BY H. NYQUIST

American Telephone & Telegraph Co., New York, N. Y.

Review of the Subject.—*In considering methods for increasing the speed of telegraph circuits, the engineer is confronted by the problem of transmitting over a circuit the maximum amount of intelligence using a given frequency range, without causing undue interference, either in the circuit being considered or from that circuit to other circuits.*

In this paper the following two fundamentally important factors in connection with this problem are given principal attention:

1. Signal shaping, i. e., giving signals the best wave shape before impressing them on the transmitting medium so as to be able to send signal elements at maximum speed without undue interference into other circuits.

2. Choice of codes so as to transmit the maximum amount of intelligence with a given number of signal elements.

These factors are discussed with the idea of indicating the best methods, as well as to give an idea of what may be expected from these methods.

In connection with the choice of codes, consideration is given to the effect of codes differing in the number of "current values" employed. By this is meant the number of different current values which are employed in a system in forming the different characters. To illustrate, an ordinary land line telegraph circuit makes use of two current values, that is, zero current and the current which flows when the battery is connected to the circuit, or it may use a current value in one direction when battery is connected to the circuit with one polarity and a second current value in the opposite direction of similar magnitude when the battery is connected to the circuit with the opposite polarity. Submarine cables, on the other hand, ordinarily employ three different current values, that is, a definite value in one direction, a similar value in the opposite direction, and zero current. If a quadruplex circuit is analyzed, it will be seen that there are four different current values employed. There is, of course, no theoretical limit to the number of current values which may be thus employed.

The paper also contains a discussion of certain telegraph systems which have been advocated[1], and an endeavor is made to clear up various misconceptions relative to the possibilities of these systems.

Signal Shaping

SEVERAL different wave shapes will be assumed and comparison will be made between them as to:

1. Excellence of signals delivered at the distant end of the circuit, and
2. Interfering properties of the signals.

Consideration will first be given to the case where direct-current impulses are transmitted over a distortionless line, using a limited range of frequencies. Transmission over radio and carrier circuits will next be considered. It will be shown that these cases are closely related to the preceding one because of the fact that the transmitting medium in the case of either radio or carrier circuits closely approximates a distortionless line. Telegraphy over ordinary land lines employing direct currents will next be considered. This will be followed by a consideration of the more complicated case of transmission over long submarine cables.

It will be shown that the waves produced by sending rectangular signal elements through suitable electrical networks which round them off before they are impressed on the transmitting medium are probably best in most cases. Comparison will be made between waves shaped by sending rectangular signal elements through suitable networks and waves made up of half cycles of a sine wave, bringing out the inferiority of the latter.

Direct-Current Telegraph Transmission Over a Distortionless Line

Before proceeding with this discussion, two terms, which will be used in this paper, and which are considered to be of fundamental importance, will be defined—"signal element" and "line speed." It is usually possible, especially when sending is done mechanically, to divide the time into short intervals of approximately *equal* duration, such that each is characterized by a definite, not necessarily constant, voltage impressed at the sending end. The part of the signal which occupies one such unit of time will be called a "signal element." For example, the letter *a* in ordinary land telegraphy will be said to be made up of five signal elements, the first constituting a dot, the second a space and the next three a dash. The "line speed," as used in this paper, equals the number of signal elements per second divided by two. In ordinary land telegraphy the line speed is equal to the dot frequency when a series of dots separated by unit spaces is transmitted.

The discussion will first be limited to the case of direct-current telegraphy over a distortionless line. This case is the simplest and in addition the results will aid in understanding the more complex cases. It may aid in obtaining an understanding of this case to assume that the distortionless line is made up simply of series and shunt resistances.

A distortionless line, such as the one which has been assumed, will transmit all frequencies with equal efficiency from zero upward. In considering applying direct-current telegraph to this line, it will be assumed

that the telegraph circuit will have assigned to it only a limited range of frequencies from zero upward, the remaining frequency range being assigned to some other uses, such as ordinary telephone and carrier telephone and telegraph. It will also be assumed that the direct-current telegraph circuit is worked at as high a speed as the frequency range assigned to it will permit.

A number of different wave forms which might be employed to make up the telegraph signal elements will next be examined, consideration being given first to the waves which will be received at the distant end when the different wave forms are impressed at the transmitting end and second to the interference which will be produced in the higher range of frequencies which has been assigned to other uses.

Three forms of voltage waves which will be considered are shown in Fig. 1. A in that figure shows the simplest form of voltage wave, namely, the rectangular form which is produced by applying a battery for a given interval of time and then substituting a short circuit for it. C in the figure is the wave produced by transmitting the rectangular voltage wave A through an electrical network which is the one indicated by the

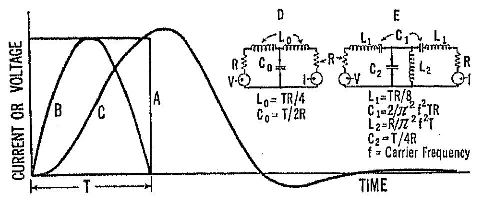

Fig. 1

A - Rectangular Voltage Wave
B - Half Cycle of Sinusoidal Voltage Wave
C - Rectangular Voltage Wave Modified by Being Passed through Network Shown at D or E.

letter D in the figure. (Other forms of networks might also be selected which would produce similar results.) B in the figure is a wave which has the shape of a half cycle of a sine wave. In what follows this wave will be referred to as the "half-cycle sine wave."

In considering the waves which will be received when the above waves are applied at the transmitting end, use will be made of the following general principles, which have been stated by Malcolm[2], for the case of a submarine cable circuit and discussed for the general case in Appendix A.

When a telegraph circuit is worked at a line speed as high as will be permitted by the available frequency range, the shape of the received signal will be practically independent of the shape of the transmitted signal, and further, the magnitude of the received signal will be approximately directly proportional to the area included within the impressed voltage wave.

The area included within the impressed voltage wave being of principal importance so far as the wave received at the distant end is concerned, the areas under the three voltage waves shown in Fig. 1 will next be examined. The areas under waves A and C will be found to be substantially equal while the area under the wave B is only about 0.6 as great. Consequently, it should be expected that waves A and C will be about equally good from the standpoint of the received signals, while wave B will be poorer, producing received signals only about 0.6 as great in magnitude. If the maximum voltage (or power) impressed at the sending end is limited to some given value, the rectangular wave is seen to be the optimum, since this wave has the maximum area. While the area shown under curve C is approximately equal to that under the rectangular wave, the effect produced when a number of signal elements of the same polarity and magnitude are sent in succession is such that the maximum voltage transmitted will exceed slightly the corresponding voltage for the case of the unmodified rectangular wave due to overlapping of adjacent signal elements.

The above comparison of the three waves of Fig. 1 from the standpoint of received signals holds not only for signal elements, but also for complex waves comprising a number of elements. Since for the speeds under consideration the received currents for different shapes of signals applied at the sending end are substantially of the same form, differing, at most, in magnitude, it follows from the principle of superposition that any complex signal, whether built up of elements of one shape or another at the sending end, will produce substantially the same wave form at the receiving end, the differences in the shapes of the elements at the sending end producing differences principally in magnitude of the received waves.

Consideration will next be given to the relative interference which the different wave forms of Fig. 1 will produce in the frequency range assigned to other circuits. Since interference into other circuits results from having the telegraph signal elements contain frequencies which spread into the ranges assigned to other circuits, it is evident that the wave will be the best from the standpoint of interferences which contains the least amount of these outside frequencies. By making use of a method which is discussed in Appendix C, the frequency components of the three waves illustrated in Fig. 1 have been computed and are shown in Fig. 2. The frequency marked $1/2\,T$ in the drawing equals the line speed. T in this connection has the same value as in Fig. 1. The letters in this figure refer to the corresponding waves in Fig. 1, A being the components of an isolated rectangular wave, B the corresponding components for the half-cycle sine wave, and C those for the rectangular wave after it has been transmitted through the network D in Fig. 1. It is seen from Fig. 2 that the rectangular wave form A contains the greatest amount of currents of higher frequencies and is, therefore, the poorest from the standpoint of interference. The half-cycle sine wave contains less of these

2. H. W. Malcolm. "Theory of the Submarine Telegraph and Telephone Cable." The Electrician Printing & Publishing Co., London, March 1917.

higher frequencies although, as will be seen, the high-frequency components are far from negligible. The wave C is the best from the standpoint of interference, since it contains the least amount of these higher frequencies.

From the preceding it is concluded that for the case under consideration, the wave form C in Fig. 1 produced by sending a rectangular shaped signal element through a suitable network is the most suitable. This wave form is almost the optimum from the standpoint of the received signals while from the standpoint of interference into other circuits it leaves little to be desired.

Carrier and Radio

The results for the distortionless line are particularly applicable to the cases of radio and carrier telegraphy because in these cases we have a transmitting medium which is substantially distortionless. We may again make use of Fig. 1 to illustrate three possible voltages, it being understood that these curves represent

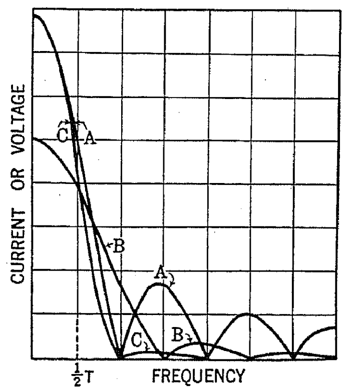

Fig. 2

A - Frequency Components of a Single Dot, Rectangular Wave
B - Frequency Components of a Single Half Cycle of a Sine Wave
C - Frequency Components of a Single Dot, Rectangular Wave Passed through Network Shown in Fig. 1

the envelope or outline of the transmitted currents which are in reality of a frequency considerably higher than the signaling frequency. If now we limit consideration to the case where the carrier frequency is located in the middle of the transmitted frequency band, then this case becomes very similar to the direct-current case and what has been said about the received wave shape being independent of the transmitted one and its magnitude being directly proportional to the area under the transmitted voltage curve still holds. One important difference is that, whereas in the direct-current case the network shown at D, Fig. 1, is used in the alternating-current case having the carrier located in the middle of the free transmitted range, the network shown at E, Fig. 1, is used. A further difference is that in the case of radio where very high frequencies are involved, it may not be practicable to construct the required networks. In that case, however, it is practicable to produce the corresponding direct-current wave and utilize it to modulate the radio wave.

What was said about interference from the circuit in question into other circuits in the direct-current case above also holds for the case of radio and carrier with the difference that, whereas Fig. 2 shows a band of frequencies extending from zero up, the corresponding curve in the case of radio and carrier consists of two such bands. The complete curve for radio and carrier is substantially symmetrical with respect to the ordinate corresponding to the carrier frequency, and the right-hand portion is similar to the curve shown in Fig. 2. It will be obvious that the rectangular wave and the half-cycle sine wave are both objectionable, as voltage waves to be applied to the transmitting medium, because they contain frequency components which may easily extend into the range allotted to neighboring carrier bands. For this reason it is customary in carrier telegraph practise to make use of a transmitting filter to cut off these interfering frequencies. The voltage impressed on this filter is substantially rectangular in outline but after passing the filter it has a shape which is approximately similar to curve C in Fig. 1, and which, therefore, produces less interference than a half-cycle sine wave.

Land Lines

The case of land lines is somewhat different from the case discussed previously because it is not economically desirable to utilize the full frequency range available. In other words, the great expenditure for terminal apparatus that may be proper in the case of submarine cables and long distance radio circuits is not warranted. In land circuits the highest frequencies transmitted are considerably greater than the required line speed. When this is the case, it is usually possible and desirable to make use of the available range to increase the steepness of the received wave. A steep wave front results in prompt operation of the receiving relay and this in turn results in minimum distortion. If a half-cycle sine wave were to be employed instead of the usual rectangular wave or if a network were to be employed which were to round off the wave to the extent indicated in Fig. 1, the received wave would necessarily lose a great part of its steepness and as a consequence the response of the receiving relay would be less positive and the signals would be distorted. It will of course be understood that by means of suitably proportioned networks the wave can be rounded just enough to meet the interference requirement, still retaining sufficient steepness to insure prompt operation of the receiving relay. Therefore, rounding by means of networks is preferable.

If it should be desirable and practicable to utilize the frequency range to its fullest, what has been said above about a distortionless line holds without any substantial modification and it would, in that case also, be more advantageous to use a wave rounded by means of suitable networks than to impress on the line a wave of the half-cycle sine form.

Submarine Cables

In the case of submarine-cable telegraphy, there is a limitation on voltage which has not been emphasized in the simple direct-current case discussed above. The voltage which may be impressed on the cable is limited to a definite value. Moreover, for certain reasons, the cable has an impedance associated with it at the sending end which may make the voltage on the cable differ from the voltage applied to the sending-end apparatus. Inasmuch as the limitation in this case is voltage limitation at the cable, the ideal wave is one which applies a rectangular wave to the cable rather than to the apparatus, because it insures that the area under the curve should be the maximum consistent with the imposed limitations. It would be possible to make the transmitting-end impedance approximately proportional to the cable impedance throughout most of the important range. This would insure that the wave applied to the cable would have approximately the same shape as the wave applied to the apparatus. It would probably be desirable for practical reasons to make this impedance infinite for direct current.

In connection with the submarine cable a special kind of interference is particularly important, namely, that due to imperfect duplex balance. For a given degree of unbalance, the interference due to this source may be reduced by putting networks either in the path of the outgoing current or in the path of the incoming current. These facts, together with the frequency distributions deduced above for each of the several impressed waves as exhibited in Fig. 2, make it apparent that the beneficial reaction on the effect of duplex unbalance, which can be obtained by the use of a half-cycle sine wave instead of a rectangular wave, can be obtained more effectively by the use of a simple network, either in the path of the outgoing or in the path of the incoming currents. Either of these locations is equally effective in reducing interferences from duplex unbalance, but the location of the network in the path of the outgoing current has the advantage that it decreases the interference into other circuits, whereas the location in the path of the incoming current has the effect of reducing the interference from other circuits.

Before leaving the matter of submarine telegraphy, it may be well to point out that it is common in practise to shorten the period during which the battery is applied so as to make it less than the total period allotted to the signal element in question. For instance, if it is desired to transmit an *e* the battery may be applied for, say, 75 per cent of the time allotted to that *e* and during the remaining 25 per cent the circuit is grounded. The resulting voltage is shown in Fig. 3F. From the foregoing, it is concluded that this method is less advantageous than the application of the voltage for the whole period, because while the shape of the received signal is substantially the same in the two cases, the magnitude, being proportional to the area under the voltage curve, will be less. A cursory examination of the literature does not disclose that anything has been published on the experimental side either to confirm or to oppose this result.

Choice of Codes

A formula will first be derived by means of which the speed of transmitting intelligence, using codes employing different numbers of current values, can be compared for a given line speed, *i. e.*, rate of sending of signal elements. Using this formula, it will then be shown that if the line speed can be kept constant and the number of current values increased, the rate of transmission of intelligence can be materially increased.

Comparison will then be made between the theoretical possibilities indicated by the formula and the results obtained by various codes in common use, including the Continental and American Morse codes as applied to land lines, radio and carrier circuits, and the Continental Morse code as applied to submarine cables. It will be shown that the Continental and American Morse codes applied to circuits using two current values are materially slower than the code which it is theoretically possible to obtain because of the fact that these codes are arranged so as to be readily deciphered by the ear. On the other hand, the Continental Morse code, as applied to submarine cables, or other circuits where three current values are employed, will be shown to produce results substantially on par with the ideal. Taking the above factors into account, it will be shown that if a given telegraph circuit using Continental Morse code with two current values were rearranged so as to make possible the use of a code employing three current values, it would be possible to transmit over the rearranged circuit about 2.2 times as much intelligence with a given number of signal elements.

It will then be pointed out why it is not feasible on all telegraph circuits to replace the codes employing two current values with others employing more than two current values, so as to increase the rate of transmitting intelligence. The circuits, for which the possibilities of thus securing increases in speed appear greatest, are pointed out, as well as those for which the possibilities appear least.

Theoretical Possibilities Using Codes with Different Numbers of Current Values

The speed at which intelligence can be transmitted over a telegraph circuit with a given line speed, *i. e.*, a given rate of sending of signal elements, may be determined approximately by the following formula, the derivation of which is given in Appendix *B*.

$$W = K \log m$$

Where W is the speed of transmission of intelligence,
m is the number of current values,
and, K is a constant.

By the speed of transmission of intelligence is meant the number of characters, representing different letters, figures, etc., which can be transmitted in a given

length of time assuming that the circuit transmits a given number of signal elements per unit time.

Substituting numerical values in this formula gives the following table which indicates the possibilities of speeding up the transmission of intelligence by increasing the number of current values.

Number of Current Values Employed	Relative Amount of Intelligence which can be Transmitted with a Given Number of Signal Elements
2	100
3	158
4	200
5	230
8	300
16	400

This table indicates that there is considerable advantage to be secured in going to more than two current values where the circuits are such as to permit it and where the line speed is not lowered as a result. The limitations will be outlined below. It should also be noted that whereas there is considerable advantage in a moderate increase in the number of current values, there is little advantage in going to a large number.

Codes Now in Common Use—Comparison with Ideal

In the case of printer codes, the theoretical results derived correspond closely to practise, as will be obvious from the method of deriving the formula.

In order to compare the theoretical possibilities indicated by the formula with the results which are obtained when non-printer codes are constructed, several codes were assumed, and for each one the number of signal elements required to produce an average letter was deduced. The method of doing this is set forth in Appendix *D*. This work resulted in the following table:

	Signal Elements per Letter	Relative Number of Letters for a Given Number Signal Elements
American Morse (two current values)	8.26	74
Continental Morse (two current values)	8.45	73
Ideal (two current values)	6.14	100
Continental Morse (three current values)	3.77	163
Ideal (three current values)	3.63	169

The column in the above table headed "Relative Number of Letters for a Given Number of Signal Elements" makes possible direct comparison with the results predicted from the formula as given in the table which preceded. It will be noted that the ideal three-current-value code gives an increase in the number of letters for a given number of signal elements as compared with the ideal two-current-value code which is in fair agreement with the theoretical ratio of 1.58:1. It will also be noted that the Continental three-current-value code which is actually in use in the case of submarine cables appears to come quite close to the ideal. In the case of the Continental and American Morse codes, however, where only two current values are used, the results fall short of the ideal, the ratio between the results actually obtained and the ideal being approximately 1.4:1. The reason for this is that a certain proportion of the possible speed is sacrificed in order to make it possible to read the signals by means of a sounder instead of recording them. For instance, the dash has been assumed to be approximately three times as long as the dot. If the signals were mechanically formed at the sending end and recorded at the receiving end, it would be possible to make use of markings 1, 2, 3, etc. signal elements long, as well as corresponding spacings. The ideal codes were so constructed.

It will be seen that the figures deduced for the Continental Morse and the American Morse are substantially identical for two current values. This result probably does not correspond with practise; it is thought that the difference in speed between these two codes is considerably greater, say on the order of 10 or 15 per cent in favor of the American Morse. The discrepancy is due partly to the fact that no account has been taken of figures and punctuation marks in the present computations and partly to the fact that the assumptions as to relative lengths of space is not strictly in accordance with practise.

From the foregoing, it is seen that there is a two-fold gain in changing from the two-current-value American or Continental Morse codes to the three-current-value Continental code. In the first place, there is a theoretical increase in the ratio of 1.6:1 which accompanies the change from the two-current-value to the three-current-value code. In the second place, there is an incidental increase in the ratio of 1.4:1, due to the fact that the present two-current-value codes are longer than would be necessary, if receiving were done by means other than the ear. The total increase in going from the two-current-value Continental or American Morse codes to the three-current-value Continental code is, therefore, in the ratio of 1.6×1.4:1 or 2.2:1, provided the line speed is the same. In this connection it should be noted that in the case of the American Morse, the ratio is probably somewhat less than this for the reasons pointed out above.

Limitations in Applying Codes with More than Two Current Values

Certain inherent limitations which have to do with how much the number of current values can be advantageously increased are as follows:

1. Fluctuations in transmission efficiency of the circuit,
2. Interference,

3. Limitations on the power or voltage which it is permissible to employ.

In addition it may be stated that, in general, whenever more than two current values are employed it is necessary to make the sending and receiving means more complicated and expensive. There may be nothing to gain, therefore, in using codes other than those made up of two current values where the telegraph circuits are cheap.

Considering now the features which limit the number of current values which can be employed, it is believed that the importance of the first factor will be obvious. If the line is subject to fluctuations so that the stronger currents at certain times become less in magnitude than the weaker currents at other times, it will be impossible to discriminate between the different current strengths making up the code, particularly if the fluctuations are rapid.

In connection with interfering currents, it is evident that these may be of such polarity as to add to or subtract from the signaling currents and it is consequently necessary to separate the various current values employed sufficiently so that one current value with the interference added may be distinguished from the next larger current value with the interference subtracted.

The spacing between the current values being determined by the interference and fluctuations in transmission efficiency, it will be seen that the maximum number of current values which can be employed is determined by the maximum power which it is permissible to use.

In the case of land line telegraph circuits operated with direct currents, it is well known that quadruplex circuits are much more seriously affected by fluctuations and interference than are circuits employing only two current values. (A quadruplex telegraph circuit employs four current values for transmission in one direction). In general, it may be said that the possibilities of improving ordinary direct-current operated telegraph circuits in this manner do not appear particularly promising.

In the case of wireless transmission over great distances all three of the above factors are important in limiting the number of current values which can be effectively employed. In the first place, as is well known, large variations take place in the efficiency of the transmitting medium so that the received signals vary considerably in magnitude from time to time. Secondly, the interference, at least at certain seasons, is great enough to make it difficult to distinguish between the current values even when the usual method which employs only two current values is employed. Thirdly, the received power is limited because of the great attenuation suffered by the wireless waves.

In the case of carrier transmission, it may be that there will be a field for the use of more than two current values. The relative cheapness of the line circuits, however, will tend to limit the amount by which it will be economical to increase the cost and complexity of the receiving apparatus. Moreover, it should be borne in mind that no allowance has been made for the effect on the line speed of increasing the number of current values, this being considered outside the scope of the present paper.

Changing an existing network of telegraph circuits so as to employ a code with three instead of two current values would require new types of telegraph repeaters as well as new sending and receiving apparatus, and new operating methods. It is considered to be outside of the scope of this paper to go into a discussion of the details of this matter.

"Sine Wave" Systems

Considerable interest and discussion has been created by suggestions which have been made to use so-called "sine wave" systems of telegraphy. In view of this, a brief discussion of these systems is given below.

A brief analysis of what are the fundamental features of these systems will be given and, based on the results which have been developed in the preceding discussion, comparison will be made of these systems with systems based on other principles. A particular effort will be made to clear up what appears to be fundamentally incorrect assumptions which underlie the arguments which have been advanced in favor of these "sine wave" systems.

Crehore-Squier System. The use of a sine wave envelope to improve the characteristics of telegraph signals was advocated by Crehore and Squier.[3] The words "United States" formed by means of a wave of this type are shown in Fig. 3*d*. The code employed is the same as the ordinary Continental Morse, the only difference being that the signal elements consist of half-cycle sine waves.

In what has preceded, it has been shown that a half-cycle sine wave has a smaller area than a rectangular wave rounded off by passing through an electrical network and, consequently, the sine wave is inferior to the latter from the standpoint of the received signals. From the standpoint of interference into other circuits, it has also been pointed out that the half-cycle sine waves contain more high-frequency components than properly rounded off rectangular waves. Consequently more interference into other circuits will be produced with the wave made up of signal elements consisting of half-cycle sine waves.

Squier System Applied to Submarine Cables. A more recent suggestion by Squier[4] gives the wave shown in Fig. 3*a*. This wave resembles the one advocated by Crehore and Squier in that each signal element consists of a half-cycle sine wave. As has been pointed out, there is no advantage gained by this.

The difference between the two systems lies in the fact that the wave in Fig. 3*a* uses three absolute values

3. Crehore and Squier, loc. cit.
4. Squier, loc. cit. *Proc. Phys. Soc.*

and crosses the axis once every half cycle. The code is the same as the Continental, a space being indicated by a half-cycle sine wave of one unit amplitude, a dot by a half-cycle sine wave of two units amplitude and a dash by a half-cycle sine wave of three units amplitude.

By referring to the figure, it will be seen that the resulting wave resembles a continuous sine wave, except for the fact that successive half cycles differ in magnitude. For this reason, the code may be termed an "unbroken-reversals" code.

In considering the application of this code to submarine cable telegraphy, it is convenient to make use of an analysis which is carried out in Fig. 3. Fig. 3*a* shows the words "United States" written in the code advocated by Squier. Fig. 3*b* shows a constant sine wave whose amplitude is equal to the amplitude of a dot in Fig. 3*a*. Fig. 3*c* shows the result obtained by subtracting the wave of Fig. 3*b* from the wave of Fig. 3*a*. On comparing this last wave with the wave shown in Fig. 3*d*, it will be seen that the two waves are electrically equivalent. They differ only in having the signal elements permuted.

It is thus evident that the wave shown in Fig. 3*a* is

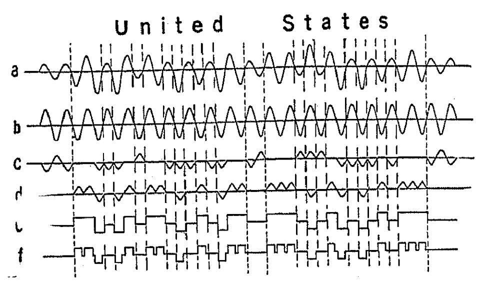

Fig. 3

a - Unbroken reversals code (space = 1 unit, dot = 2 units, dash = 3 units)
b - Constant sine wave, 2 units
c - Wave resulting when substracting *b* from *a*
d - Sine Wave code; note similarity between *c* and *d*
e - Rectangular wave, unmodified
f - Rectangular wave, modified by grounding apex one fourth of the marking time in addition to the spacing time

made up of two components; one being the inert component shown in Fig. 3*b* which transmits no intelligence, and the other the intelligence carrying component illustrated in Fig. 3*c*.

The fact that the component shown in Fig. 3*b* does not carry intelligence from the sending station to the receiving station is made clear when we consider that its value at any moment is predictable and that the component can in fact be produced locally.

The net effect of this component is to reduce the voltage available for intelligence transmission to one-third of the total voltage. For example, if it is permissible to apply 60 volts to a particular cable, 40 volts out of these would be used up in transmitting the inert alternating-current wave and only the remaining 20 volts would be useful for the transmission of intelligence.

Radio and Carrier Telegraphy. Squier has also advocated[5] that the combination of sine wave envelopes, unbroken reversals and a three-current-value code be applied to radio and carrier telegraphy.

The advantages and limitations in applying codes with more than two current values have been fully discussed above, and do not need to be gone into further here. It will be evident that the combining with these of sine wave envelopes and unbroken reversals does no good.

The matter of using sine wave envelopes was discussed above, the discussion pointing out that waves with sine-wave envelopes are inferior to waves produced by sending rectangular shaped signals through suitable networks, both from the standpoint of the received signals, and from the standpoint of interference into other circuits.

The "unbroken reversals" bring in again the use of an inert component. Due to the fundamental difference between cable telegraphy on the one hand, and radio and carrier as usually practised on the other, the inert component in the latter case is somewhat smaller than in the former. In the code advocated by Squier, the current which may be subtracted without greatly affecting the intelligence-carrying capacity of the signals, is about one unit in value, which is the current corresponding to a space. When this current has been subtracted, the space current is reduced from one unit to zero, the dot current from two units to one, and the dash current from three units to two. This subtraction having been carried out, it is seen that the maximum intelligence-carrying component is approximately two-thirds of the maximum current actually employed. (This figure of two-thirds compares with the figure of one-third for the submarine cable.)

In the case of radio, the amount of power which must be radiated from the transmitting station is of particular importance. Since with the system advocated by Squier about two-thirds of the maximum voltage which is radiated is effective in transmitting intelligence, it is evident that about twice as much power must be radiated as would be required if the inert component were not transmitted.

Incorrect Assumptions. Two incorrect assumptions are made in the papers referred to and underlie a considerable portion of the arguments advanced in favor of the systems advocated by Squier.

One of these is that a wave, whose elements are half-cycle sine waves, lends itself to tuning. It is true that in the case of the "unbroken-reversals" code a certain amount of tuning can be secured, but this tuning applies only to the inert unvarying component in the wave, which carries no intelligence. The fact, shown in Fig. 2, that the intelligence-carrying component contains no outstanding narrow range of frequencies to which tuning can be applied should make obvious the error in this assumption.

The other assumption is that a wave, which is ideal for the transmission of power, is also ideal for the transmission of intelligence. As a matter of fact, the transmission of intelligence inherently involves rapid

5. Squier, loc. cit., *Franklin Inst., Jl.*

and unpredictable changes in the current, whereas the transmission of power is best brought about by steady current, either direct or alternating. These two conditions are, of course, incompatible.

Appendix A

Use has been made of the following two principles:

1. In a telegraph circuit in which the line speed is near the maximum, the shape of the received dot is substantially independent of the shape of the impressed dot, and
2. The magnitude of the received current is approximately proportional to the area under the transmitted voltage curve.

The following general discussion of these principles has been furnished by J. R. Carson.

Let the arrival curve, due to suddenly impressed unit battery be denoted by $A(t)$; then the received signal $S(t)$, due to the elementary dot impressed signal $f(t)$ is given by[6]

$$S(t) = \int_0 f(x)\, A'(t-x)\, dx \qquad (1)$$

the upper limit of integration being t for $t < T$ and T for $t \geqq T$. The latter case will alone be considered since the conclusions arrived at in this case are conservative.

Expanding $A'(t-x)$ in (1), we get

$$S(t) = \left[A'(t) - \frac{h_2 T}{2!} A''(t) + \frac{h_3 T^2}{3!} A'''(t) \ldots \right] \int_0^T f(x)\, dx \qquad (2)$$

where
$$h_2 = \frac{\int_0^T x\, f(x)\, dx}{\frac{T}{2!}\int_0^T f(x)\, dx},$$

$$h_3 = \frac{\int_0^T \frac{x^2}{2!} f(x)\, dx}{\frac{T^2}{3!}\int_0^T f(x)\, dx}, \text{ etc.}$$

It follows at once that, provided

$$\int_0^T f(x)\, dx \neq 0$$

and provided the duration T of the signal is sufficiently short, the arrival dot is given approximately by the leading term

$$A'(t) \int_0^T f(x)\, dx$$

and that this approximation becomes increasingly close as the speed of signaling is increased, *i. e.*, as the duration T of the dot is decreased.

6. J. R. Carson. "Theory of the Transient Oscillations of Electrical Networks and Transmission Systems." A. I. E. E. TRANS., Vol. XXXVIII, 1919, p. 345.

The conclusions from the foregoing may be stated in the following propositions:

I. If the speed of signaling is sufficiently high the arrival signal representing the elementary dot is independent in shape of the form of the impressed signal, and is proportional in amplitude to the time integral or "area" of the impressed signal.

It will be evident, however, that if no restrictions are imposed on $A'(t)$ and $f(t)$, the foregoing proposition requires, in general, that the duration T of the dot shall be so small as to make the series expansion rapidly convergent from the start. This, however, requires a speed of signaling very considerably greater than that actually necessary in practise in order that the foregoing proposition shall hold to a good degree of approximation, at least for the types of impressed dot signals specially considered in the present paper. To show this, it is necessary to establish two less general propositions, valid for the types of impressed signals under consideration.

II. If the impressed signal $f(t)$ is everywhere of the same sign, then a value τ exists, such that $0 < / \tau / < T/2$, and such that

$$S(t + T/2) = A'(t+\tau) \int_0^T f(x)\, dx \qquad (3)$$

This proposition follows from the mean value theorem.

III. If $f(t)$ is everywhere of the same sign, and if further it satisfies the conditions of symmetry,

$$f(x) = f(T-x), \; (x \leqq T/2)$$

then a value τ exists, such that $0 < \tau < T/2$ and such that

$$S(t + T/2) = 1/2\,[A'(t+\tau) + A'(t-\tau)] \int_0^T f(x)\, dx \qquad (4)$$

This last equation also follows from the mean value theorem. Furthermore, the conditions stated in proposition III are satisfied by the rectangular wave, the half-cycle sine wave, and the rectangular wave extending through part of the dot provided the reference time $t = 0$ is properly chosen.

Returning to proposition II, let us write

$$S_j(t + T/2) = A'(t + \tau_0 + \tau_j) \int_0^T f_j(x)\, dx,$$

the subscript j indicating the particular type of impressed dot signal, and τ_0 the value of τ for any type of signal, taken as reference. Then

$$S_j(t + T/2) = \left[A'(t+\tau_0) + \frac{\tau_j}{1!} A''(t+\tau_0) + \ldots \right] \int_0^T f_j(x)\, dx \qquad (2a)$$

Now, the condition that proposition I shall hold to a good degree of approximation is that the expansion (2a) shall converge rapidly. Since the maximum possible value of τ_j is $T/2$ and since in practise it is much smaller than $T/2$, the required convergence

obtains for much larger values of T, that is, slower speeds of signaling than that required in the expansion (1). Furthermore, for the three types of signals specifically under consideration τ_1, τ_2 and τ_3 differ from one another by quantities very much smaller than $T/2$ in all actual transmission systems.

If the conditions of proposition III are introduced, the approximation is still closer and proposition I is valid for still lower signaling speeds.

In order to arrive at quantitative ideas of the minimum signaling speeds at which the foregoing proposition is valid, it is necessary, of course, to specify the arrival curve of the transmission system under consideration. An application of the foregoing analysis to representative transmission systems both with and without a "cut-off" frequency has shown that it is valid to a very good degree of approximation for speeds considerably lower than the highest attainable under practical conditions.

Appendix B

Use has been made of the formula

$$W = K \log m$$

where W = the speed of transmission of intelligence

K = a constant

and m = the number of current values employed. The assumptions which underlie this formula and its derivation will now be given.

Let us assume a code whose characters are all of the same duration. This is usually the case in printer codes. If n is the number of signal elements per character, then the total number of characters which can be constructed equals m^n. In order that two such systems should be equivalent, the total number of characters that can be distinguished should be the same. In other words,

$$m^n = \text{const.} \tag{1}$$

This equation may also be written

$$n \log m = \text{const.} \tag{2}$$

The speed with which intelligence can be transmitted over a circuit is directly proportional to the line speed and inversely proportional to the number of signal elements per character provided that the relations above are satisfied. Hence, we may write

$$W = s/n \tag{3}$$

where s is the line speed. Substituting the value of n derived from the equation above, this equation becomes

$$W = \frac{s \log m}{\text{const.}} \tag{4}$$

which may also be written

$$W = K \log m \tag{5}$$

In applying this formula to practical cases it will be found impossible to comply strictly with the condition expressed by equation (1). As an example, consider the comparison between a three-current-value code where each character is made up of three signal elements, and a two-current-value code where each element is made up of five signal elements. It is obvious that the speed with which *characters* can be transmitted in the former case is five-thirds the speed in the latter case for a given line speed. In other words the ratio is 1.67.1 whereas the formula gives the ratio 1.58:1. It should be noted, however, that the former code possesses only 27 characters whereas the latter possesses 32. In other words one *character* of the latter code represents the transmission of more *intelligence* than one *character* of the former. Thus the figure 1.67 for the relative speeds of transmission of *characters* and the figure 1.58 for the relative speeds of transmission of *intelligence* are not incompatible.

It will be noted that the formula has been deduced for codes having characters of uniform duration and that it should not be expected to be anything but an approximation for codes whose characters are of non-uniform duration. To establish the formula for the latter case it would be necessary to make an assumption as to the relative frequencies of the various characters. It seems reasonable to suppose that the formula will give a fair approximation to the facts in this case also, but it should not be expected to be accurate.

Appendix C

The deduction of the curves given in Fig. 2 from the curves given in Fig. 1 requires some explanation. Looked at casually, it would seem as if an isolated dot would not possess any frequency characteristics whatsoever. Nevertheless, if a voltage, such as any of those represented in Fig. 1, is applied to a network capable of being thrown into oscillation, the network will respond to the voltage by oscillating. Suppose, for simplicity, that the network consists of an inductance, a capacity and a very small resistance in series, the response of the network to the application of any of the voltages illustrated is that it oscillates at constant frequency and gradually decreasing amplitude. Further, the response varies when the natural period of the circuit is varied.

There are two ways of looking at this phenomenon. We may say, on the one hand, that the oscillations of the frequency in question are manufactured by the network out of the voltage applied and that the frequency does not exist in the original voltage. On the other hand, we may say that the original voltage contains components at or near the resonant frequency and that the circuit responds to these components because it offers them a small impedance, while it does not respond to other components because it offers them a large impedance. Either of these views is permissible, but it is convenient for the purposes of this paper to use the nomenclature of the second view and to consider the applied voltages to be made up of an indefinitely large number of frequencies. The problem of determining the response of oscillating networks is then solved by deducing the frequency characteristic or the response characteristic of the impressed voltage. This characteristic may be determined by means of the Fourier

integral, whose computation is described in any standard textbook on the subject. The following is intended to outline the considerations, from a physical standpoint, which lead to establishing this integral.

To deduce the frequency characteristic of an isolated dot, it is simplest to start with a long series of dots which are uniformly spaced. If such a series of dots is considered to extend indefinitely, it is possible to analyze the resultant wave into a Fourier series by well known methods. Now, suppose that such a Fourier series has been obtained for a given spacing of the dots. The next step is to increase the spacing between the dots. The result of this is to increase the number of Fourier components in a given frequency range and to decrease the magnitude of each. If this process of increasing the space between the dots is continued indefinitely, we approach the condition of an isolated dot. Moreover, as we approach this condition, the number of components in a given frequency range increases indefinitely and the magnitude of each decreases indefinitely. This limiting result is known as the Fourier integral for the wave in question.

Appendix D

A table has been given in the paper in which the relative efficiency of various codes in transmitting intelligence is listed. The derivation of that table will now be given.

The comparison will include the following codes based on two current values: American Morse, Continental Morse, and the so-called "ideal" two-current-value code. It will also include the following codes based on three current values: Continental Morse and an "ideal" three-current-value code.

The assumption is made that the text is made up of five-letter-words, no allowance being made for punctuation. The following table gives the length of the spaces assumed in terms of signal elements.

	Ordinary Spaces Within Letters	Special Spaces in "Spaced" Letters	Spaces Between Letters	Spaces Between Words
American Morse (two current values).....	1	2	3	4
Continental Morse (two current values).....	1	—	2	3
Continental Morse (three current values)	—	—	1	2

It is assumed that the dashes in the two-current-value codes are of three signal elements, duration except for the letter *l* in American Morse which is assumed to occupy five signal elements. It may be that in practise, the dashes are somewhat shorter than has been assumed but the resulting error is not great. In connection with the relative spacings between letters and words assumed for the Continental and American Morse codes, it is also questionable whether they accord strictly with practise. It may be that these spacings are on the average more nearly equal than the table indicates. However, this assumption affects only the relative speeds obtainable with the American Morse and the Continental Morse and does not materially affect the comparison between codes based on two current values on the one hand and codes based on three current values on the other.

The term "ideal" has been applied to two codes which will next be explained. These codes are constructed on the same principles as the Continental and American Morse codes with an effort to make them as brief as possible without making the reading too difficult. It is thought that the two ideal codes chosen are comparable in the matter of ease of reading. In constructing the two-element code, two steps are involved. In the first place it is assumed that the markings and spacings of any integral number of signal elements' duration can be used so that in addition to the values for markings and spacings assumed above, there may be dashes of two, four, etc., units duration. With these assumptions the 26 shortest characters that can be constructed are next made up. It is found that one character is of 1 unit duration, 1 of 2 units, 2 of 3 units, 3 of 4 units, 5 of 5 units and 9 of 6 units duration. The remaining 5 characters are taken of 7 units duration each. The second step is to ascribe the 26 letters of the alphabet to these characters in such an order that the most frequent letters correspond to the shortest characters. It is most efficient to use the same spacing as was assumed above for the Continental two-current-value code, with the addition that spaces of longer duration than three units may be employed within a letter.

The matter of constructing the ideal three-current-value code is similar. First, the 26 shortest characters are constructed. Two characters can be constructed having a duration of 1 unit, four characters having a duration of 2 units and eight characters having a duration of 3 units. The remaining twelve characters are taken 4 units in duration. Next, the most frequent letters are assigned to these characters in the order of their duration. It is best in this case to use the same assumptions as to spacings between letters and words as was used above in connection with the three-current-value Continental code. The use of spaces within letters is not economical in this case.

A frequency table given by Hitt[7] was used to determine the relative frequency of the various letters. The average duration per letter was computed from this table and corrected for spaces between words and letters. The resultant average duration is as follows:

Code	Signal Elements per Letter
American Morse (two current values)..................	8.26
Continental Morse (two current values)................	8.45
Ideal (two current values)............................	6.14
Continental Morse (three current values)..............	3.77
Ideal (three current values)..........................	3.63

Discussion

Bela Gati (by letter): The following remarks apply to cable telegraphy. Some experiments with a-c. telegraphy have been made by the writer which are of interest in considering telegraph speed. These tests were made on long lines and oscillograph records of two of the tests which are shown herewith. In one case direct current was employed and in the other alternating current at 500 cycles per second.

In each oscillograph the lower line represents the current at the sending point while the upper line represents the received current. The point *b* shows when the current was started at the sending end. Point *c* shows when it started at the receiving end. Point *d* shows when the current was interrupted at the sending end.

From the oscillograms we see that in the case of the alternating current the received current stops sharply at point *e*, but with the direct current, the conductor discharges afterwards at its

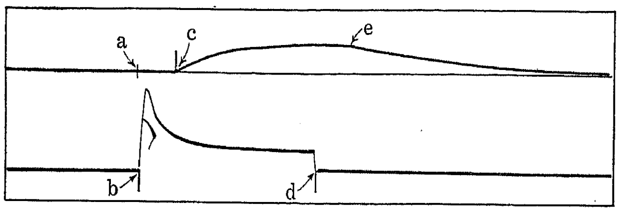

Fig. 1

natural frequency. The signal is lengthened from the point *e* to infinity.

This discharge current is the troublesome feature but there are several ways of lessening the time of discharge. If a cable is not charged to too high a value, especially at the end of the signal, the discharge current will be lessened. The grounding of the circuit at the sending end relieves the sending end of the long discharge and thus makes telegraphy faster.

It is still better to apply an opposing potential. This reduces the strength of the signal but it decreases the charging current. This is the method of Pickard and others.

The best method is to use alternating current. In this case each half cycle counteracts the effect of the previous half cycle. True, the strength of the current is appreciably diminished but the discharge effect is practically eliminated. The first and the

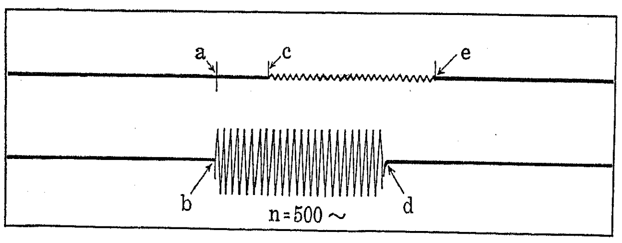

Fig. 2

last half cycles do not have any noticeable effect on the length of the signal.

The received current corresponding to a dot can be obtained from the superposition of two curves, each representing the received current for direct current. One of these curves is displaced along the time coordinate by an amount equal to the duration of the dot and it is plotted with negative values for the ordinate. The result is similar to the ripples obtained with alternating current, if the dot length is made equal to a half cycle. Of course, there are secondary and tertiary phenomena which modify the results and consequently there will be some disagreement between the two curves.

In my opinion the signal should contain ten complete cycles for a dot. This means that telephone frequencies (500 to 2000 cycles per second) are applicable.

The constants used in the experiments from which the oscillograms were taken were as follows: The circuit was 2120 kilometers of bronze wire, 4 millimeters in diameter. For each kilometer: $r = 2.8$ ohm; $l = 1.43 \times 10^{-3}$ henry; $c = 12 \times 10^{-9}$ farad; $g = 10^{-6}$ mho; Zo(= Sending-end impedance as proposed by Dr. Kennelly) = 348.46 (at − 5 deg. 17.85 min.); the attenuation = 41.82×10^{-3} (at 84 deg. 13.09 min.) = $(42.13 + j\,416.07) \times 10^{-4}$; attenuation × length = 8.8; the so-called "cable length" of Dr. K. W. Wagner $= \frac{t}{2}\sqrt{\frac{c}{1}} \times 2120 = 8.57$.

Of course this line is not a cable but it serves to illustrate the phenomena. On a submarine cable the point *e* cannot be exactly distinguished. The conditions are quite complicated and a simple explanation does not apply exactly.

Shunt coils in a cable compensate for the discharge effect and make alternating-current telegraphy possible for a given frequency. There is no reason for the limiting of the frequency to four cycles or ten cycles as is done in the computations of the extremely conservative cable companies. We must apply telephone frequencies giving many cycles for one dot. Only when using such frequencies can the benefits of shunt coils be realizied. The use of shunt coils as applied now at the sending and receiving stations is an entirely different matter from their use with telephone frequency and mounted at proper intervals on the cable. The shunt coils lengthen only the wave length but not the signals. Pupin coils shorten the wave length.

In 1909[2] I first proposed submarine cables with rather high self-induction, 10^{-2} henry. After 15 years, in 1924, the Western Union Cable Company has adopted a cable with such a characteristic.

If but one frequency is considered automatic multiplex printers may be employed (the Murray, for instance) and by this means the cable companies can compete effectively with the new 35-70-cycle channels of the new radio system.

For further information on this subject see the following articles by the present writer: Will the Signal be Lengthened in Alternating Current Telegraphy?—The *Electrician*, London, April 12, 1912; Werdin die Zeichen auch bie Wechselstromtelegraphie verlaengert?—*Elektrotechnik und Maschinenbau*, Wien 1911, Heft, 42.

H. Nyquist: As I understand it, there is very little disagreement between Mr. Gati's results and those obtained in the paper. The principal discrepancy occurs in connection with the matter of improving submarine cable signals by grounding the transmitting end of the cable for short intervals. In the paper the opinion is expressed tentatively that such grounding is not beneficial, whereas Mr. Gati comes to the opposite conclusion. It is to be regretted that his experimental work does not cover this point.

The argument that carrier telegraph at voice frequencies is preferable to direct current for signaling purposes is not, of course, applicable to the subject under consideration, namely, ocean cables as at present constituted. Such cables are incapable of transmitting these frequencies. In the case of the circuits which are capable of transmitting these high frequencies, it is, of course, possible to utilize them for telegraph purposes. In fact, in the case which Mr. Gati considers, namely, where the circuit is assumed to be capable of transmitting 10 cycles of alternating current to form a single dot, it is possible to go even further and to obtain both d-c. telegraph and carrier telegraph simultaneously.

There can further be no question that the introduction of suitable loading extends the frequency range and, therefore, is beneficial, if properly applied. I am under the impression that the reason telegraph companies have not employed loading for submarine cables up to the present is not lack of appreciation of the effectiveness of such loading but rather the lack of suitable methods for accomplishing it.

Measuring Methods for Maintaining the Transmission Efficiency of Telephone Circuits

F. H. BEST

Member, A. I. E. E.
American Tel. and Tel. Company, New York, N. Y.

Review of the Subject.—Maintenance of the transmission efficiency of the telephone plant is conducted by a special force using methods and apparatus that have been developed for this purpose. This paper gives a brief description of the transmission characteristics of some of the common types of telephone circuits, outlines a general method for measuring their transmission efficiency and describes several of the most modern types of transmission measuring sets together with a brief mention of the oscillators which supply the power for testing.

* * * * *

THE circuits involved in the transmission of speech in a modern telephone plant, particularly those designed for long distance operation, necessarily involve a considerable amount of complexity. The use of telephone repeaters, the development of long toll cables, the application of carrier systems, and other developments associated with these, while increasing the efficiency and economy of telephone toll circuits, have also increased their complexity and have required the development of more effective means of insuring that the circuits are maintained at all times in good condition and adjustment.

It is the purpose of this paper to present a brief description of the measuring methods which have been developed and put into use, to enable those charged with the maintenance of such circuits to determine rapidly and conveniently whether the circuits are giving the transmission results for which they were designed.

Talking Tests

To a person who is unfamiliar with telephone transmission measurements, the most obvious method of testing a circuit is to talk over it. Such a method is not suitable for routine testing because of the impossibility of obtaining accurate data without taking elaborate and time-consuming precautions. It is impossible to judge at all accurately the efficiency of a circuit by simply listening to some one talk at the other end. Tests have shown that the most skilled observers cannot detect circuit changes which alter the received power by as much as a factor of three when these changes are made between conversations.

The only method of determining the transmission efficiency of a circuit by talking tests is to compare it repeatedly and directly with another circuit of known and adjustable efficiency. Experienced observers are necessary and much time is required to obtain accurate results. In the case of switchboard cord circuits and other central office apparatus, the total transmission loss is often less than the errors of measurement by this method. On long toll circuits, the errors of observation are small compared with the total loss and by careful tests with experienced observers, results sufficiently accurate for some purposes may be attained. The cost of this testing is, however, too great to permit its use on anything excepting important toll circuits.

Testing Line Circuits

The most accurate method of measuring a line circuit, such as a toll circuit, is to connect it as in Fig. 1 between a source of alternating current and a measuring instrument, both of which have impedances approximating the characteristic impedance of the circuit. With such an arrangement the unknown line becomes in effect part of an infinitely long line of its own type and the ratio of the voltages, currents or powers at the ends of the circuit is a measure of its transmission efficiency. In commercial use the toll circuit may be terminated by switching trunks or other circuits which have different impedances from that of the circuit which is being measured. In these cases terminal

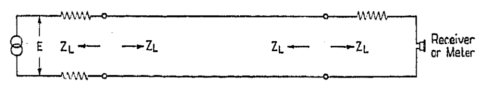

Fig. 1

losses, commonly called reflection losses, will result. As these losses are different for each impedance of the terminating apparatus, it is preferable for maintenance purposes to have them excluded. The measured results can then be readily checked by computations.

The transmission efficiency of the average telephone circuit is not constant with changes in frequency. Because of this a measurement of the transmission efficiency of a circuit with testing current of but a single frequency will not necessarily show the same result as would be obtained if the testing current were supplied by a voice actuated transmitter. In transmission maintenance work we are interested primarily in determining if the circuits are being maintained up to their specified standards. It is possible in many cases to determine this by means of a single frequency measurement or several measurements using testing currents of different frequencies.

Figs. 2 and 3 show the transmission frequency

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

characteristics of two telephone circuits which have been chosen to contrast with each other, and to indicate the variations in type of the attenuation characteristic which may be found in a working plant. Fig. 2 shows the characteristics of a 13-gage, heavily loaded cable circuit. This circuit, while not characteristic of the loaded circuits now being installed, is loaded in accordance with the practise of a number of years ago, and is still in operation. Small irregularities in the spacing of loading coils produce irregularities in the transmission frequency characteristic of the circuit. While these irregularities are not serious in the case shown in Fig. 2, they are sufficient to cause a difference at any one frequency of as much as 2 miles of standard cable in two similar circuits which may have exactly the same equivalents for talking. More accurate results can be obtained by making several measurements at frequencies close together and averaging the results. Averages of such measurements on each of two similar circuits are generally in close agreement.

In addition to the irregularities shown on this circuit, it will be noted that the general trend of the curve from 200 to 400 cycles is downward, while for frequencies above 400 cycles it is upward. In this particular circuit the transmission equivalent for talking currents coincides with the single frequency measurement at about 1000 cycles and in this case a single frequency measurement at 1000 cycles would be a good indication of the talking transmission equivalent. A single frequency measurement at 1000 cycles would, however, not be a complete measure of the characteristics of the circuit including its distorting effect.

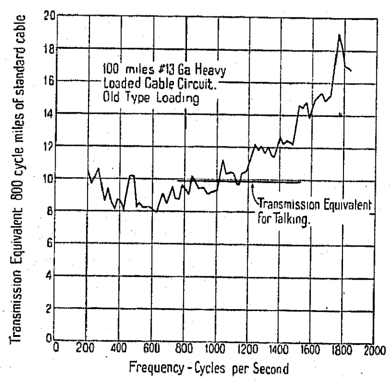

Fig. 2—Transmission Characteristic of 13 Gage Heavy Loaded Cable Circuit

Fig. 3 represents the transmission frequency characteristic of a non-loaded No. 8 B. w. g. open-wire circuit. It will be noted that this curve is quite different from that shown in Fig. 2. This open-wire circuit has no appreciable irregularities in its makeup and its general tendency is to transmit currents of different frequencies much more uniformly than the circuit shown in Fig. 2. In the case of this second circuit a 1000-cycle measurement also agrees with the talking transmission equivalent, but an observer talking over these two circuits would notice a difference in the quality of the transmitted speech. If it is desired to have an accurate picture of the distorting effect of the circuit as well as its volume efficiency, it is necessary to make a number of measurements over the entire voice frequency range.

In a majority of the toll circuits in the telephone plant a single frequency measurement is sufficient for routine purposes, the construction of these circuits being such that any defects which materially increase the transmission loss for talking will be evident at

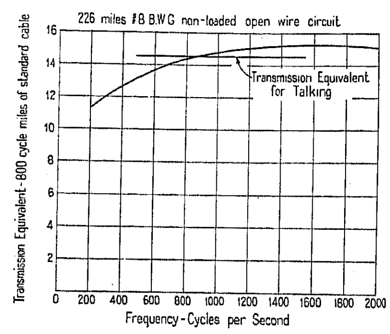

Fig. 3—Transmission Characteristic of No. 8 B. W. G. Non-Loaded Open Wire Circuit

nearly any single frequency in the voice range, although because of irregularities, it is not possible in many cases to determine the loss more closely than 2 or 3 miles of standard cable. However, there are some types of circuits, particularly the most modern types, in which it is possible by the opening of a single wire in a network or filter, or by some one piece of apparatus becoming defective to materially change the transmission-frequency characteristic for part of the frequency range only. In such cases as these, the talking volume as well as the distortion would be altered, although at certain single frequencies the circuit would appear to be normal. For such circuits, it is necessary for routine maintenance purposes, to make measurements at several widely separated frequencies in the voice range.

Testing Central Office Apparatus

The arrangement shown in Fig. 1 and described for line circuit testing can also be used for determining the transmission loss caused by a cord circuit or other piece of central office equipment under service conditions. If the generator and measuring instrument are connected directly together and then are connected by means of the cord circuit, the ratio of the currents in the measuring instrument for the two cases will indicate the effect of the cord circuit on transmission. By making the impedance of the generator and measuring instrument equal to the characteristic impedance of toll circuits of various types, the loss in received power caused by the cord circuit under different conditions can be readily obtained.

While in the case of line circuits it is necessary in some

cases to make several measurements using testing currents of different frequencies in order to determine the condition of the circuit, it is seldom necessary in central office apparatus to use more than one frequency of testing current. The reason for this is clearly shown in Fig. 4, which is the transmission frequency characteristic of a subscriber's operator's cord circuit. Curve A represents a normal circuit and shows the equivalent to vary only a small amount over the entire frequency range, the variation being gradual. If a large number of similar circuits were measured in this manner the same type of curve would be obtained for all of them which were not defective. Because of this, it is reasonable to assume that if two similar cord circuits have the same transmission equivalents for a single frequency of testing current, the two circuits will have approximately the same equivalents for voice frequencies.

Curve B represents the same cord circuit after one of the four windings of the transformer has been short-circuited, thus simulating the condition of a breakdown of the insulation between windings. This curve is also a smooth curve similar to curve A but higher at each point, the equivalent being approximately doubled at the more important frequencies. Because of the fact that a defect in one of the parts of a cord circuit usually increases the equivalent of the circuit at all frequencies, it is evident that a measurement of the equivalent at any one frequency of testing current is sufficient to indicate whether the cord circuit is normal or defective.

Practically all switchboard cord circuits and other central office apparatus such as phantom coils and composite sets have transmission frequency character-

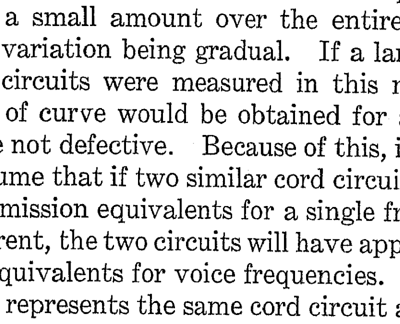

FIG. 4—TRANSMISSION-FREQUENCY CHARACTERISTICS OF SUBSCRIBER'S OPERATOR'S CORD CIRCUIT

istics which vary in the gradual manner of the circuit in Fig. 4 and are affected at nearly all frequencies by a change in the electrical constants of any part.

TESTS WITH ARTIFICIAL CABLE

Although talking tests with artificial cable have not been in general use for a number of years, the method was applied for some time to important circuits and a brief description will be given.

The arrangement generally used is shown in Fig. 5. In this arrangement two telephone sets are connected by means of switches to the ends of the circuit under tests or to an artificial cable, the "length" of which is adjustable. In testing, one observer talks to the other at the opposite end of the circuit, talking alternately through the artificial cable and through the unknown circuit. The artificial cable is adjusted until the same volume of sound is received over each circuit. The number of miles of cable required to obtain a balance is said to be the transmission equivalent of the unknown circuit.

This method requires that both ends of the circuit

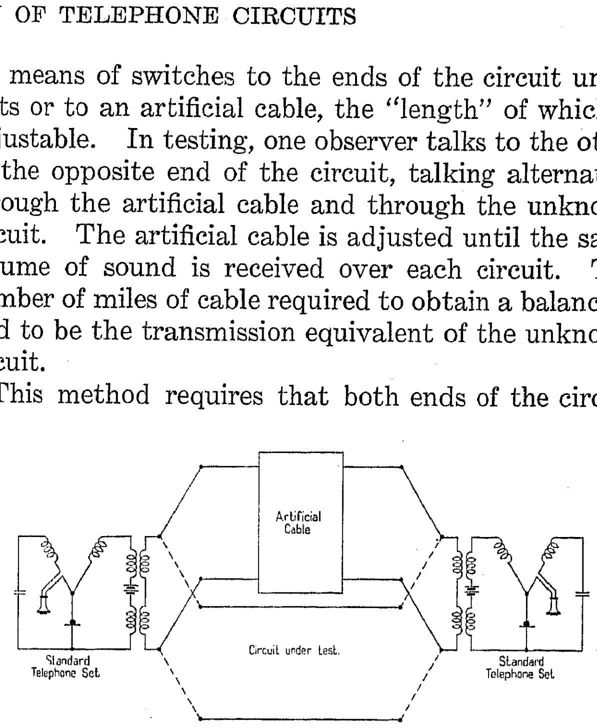

FIG. 5—ARRANGEMENT FOR TALKING TEST USING ARTIFICIAL CABLE

under test be available at the testing point. Long circuits can then only be tested by connecting two of them together at the distant end and measuring them as one circuit. The amount of artificial cable when a balance is obtained represents not only the attenuation in the unknown circuit, but also includes reflection losses which occur at the junction of the unknown line and the substation instruments.

As toll circuits are seldom terminated directly by telephone sets, the reflection losses which occur in practise are generally not those occurring when tests are made by this method. One of the chief advantages of modern testing sets lies in the elimination of these reflection losses by the substitution for the telephone set of terminating impedances which approximate the characteristic impedance of the unknown circuit.

It is difficult to compare, from the standpoint of volume, two circuits which distort the speech in a different manner. Artificial cable has approximately the same distorting effect as some telephone circuits, particularly the oldest types, but it differs considerably from the latest types. In many cases, it is, therefore, difficult to obtain an accurate comparison of circuits by a talking test.

1-A TRANSMISSION MEASURING SET

This was the first successful routine transmission measuring set to be developed to obviate difficulties and delays incidental to tests with artificial cable. Substation sets were eliminated as terminals and replaced with impedances adjustable to the characteristic impedances of representative circuits thus approximating the ideal of Fig. 1. The avoidance of reflection losses by characteristic impedance terminations also

enables the testing to be simplified by the use of single frequencies instead of the voice. This piece of apparatus and the alternating-current generator which supplies the testing current, are readily portable and entirely self-contained, being capable of operation without external batteries. It was designed, primarily, for the purpose of measuring the transmission loss under normal operating conditions of switchboard cord circuits and apparatus, and inter-office trunks. It was not intended for measurement of long toll circuits,

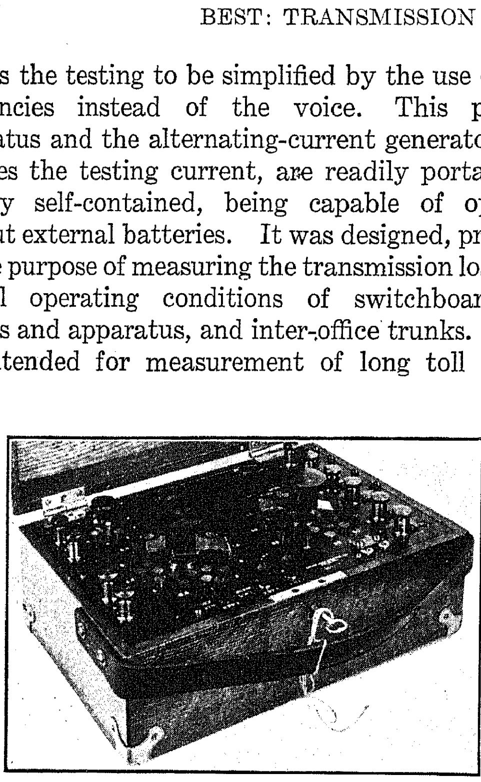

FIG. 6—1-A TRANSMISSION MEASURING SET

although with limitations, it can be used for this purpose. An illustration of this set is shown in Fig. 6.

As shown in Fig. 7, the circuit consists of two branches which are permanently bridged together at one end. An alternating-current source is connected to the junction of these branches and the same voltage is, therefore, impressed upon each. The two branches are similar, except that in the upper one is connected the apparatus or circuit to be measured, while the lower one

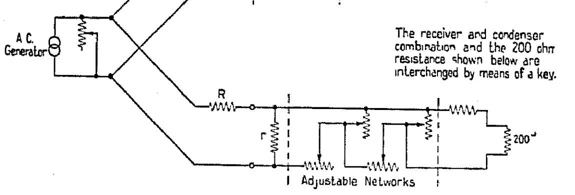

FIG. 7—SIMPLIFIED CIRCUIT OF 1-A TRANSMISSION MEASURING SET

contains an adjustable network for producing different transmission losses. A transmission measurement is made by adjusting the loss of this network until it is equal to that caused by the apparatus to be measured as determined by an equality of sound in a receiver when switched from one branch to the other. As the receiver is switched from one branch a 200-ohm resistance is substituted for it, this arrangement keeping the load on the alternating-current source and, consequently, the voltage at the junction of the two branches constant as the receiver is connected alternately to them.

Each branch is divided into two parts: A sending impedance designated R and a receiving impedance composed of r in multiple with the network to the right of r. The apparatus to be measured is connected between the sending and receiving impedance in the upper branch. The sending and receiving impedances in both branches can, by means of a key, be given any one of three values: 600, 1300 or 2200 ohms non-inductive, corresponding approximately to low, medium and high-impedance circuits, respectively. For transmission measurements, these values are sufficiently close to the characteristic impedance of telephone circuits.

The 1-A transmission measuring set cannot be used for testing circuits between offices, unless they are measured two at a time, the distant ends being connected together, as described in talking tests using artificial cable.

The adjustable network for producing different transmission losses is distortionless and consists of a series-shunt, non-inductive resistance arrangement of constant impedance as viewed from the source of power. It is so designed that the transmission loss can be adjusted in steps which cause the same change in the current as is caused by one mile of standard cable at a frequency of 800 cycles per second. This unit of transmission loss is known as the "800-cycle mile." The distortionless network is advantageous for transmission measuring purposes as it facilitates comparisons of the transmission efficiency of a circuit or piece of apparatus at different frequencies. Tests with artificial cable do not permit this.

The use of a single-frequency alternating current instead of the voice for testing enables comparisons to be made rapidly and quite accurately, it being possible to detect differences in currents as small as 2 per cent. (Approximately 0.2 mile of standard cable.)

The adjustable resistance connected across the junction of the two sending impedances and the alternating-current generator is for the purpose of controlling the sound in the receiver. It has no effect, from an impedance standpoint, on the results.

The two large dials shown in Fig. 6 adjust the loss of the distortionless network in half-mile and 5-mile steps. Directly above these are 3 smaller dials which control the volume of the testing current and the value of the sending and receiving circuit impedances. The binding posts and jacks are for the purpose of connecting the generator, receiver and circuits to be tested.

The actual operation of measuring consists simply in operating a key which connects the receiver alternately to its two positions and adjusting the network dials until the volume of sound is the same for both positions. The transmission equivalent of the apparatus or circuit under test is read directly from the dials.

3-A Transmission Measuring Set

At the time the 1 - *A* transmission measuring set was developed there were no alternating-current measuring instruments available for measuring the power received at the end of a telephone circuit which were sufficiently rugged or practicable to withstand the service required of them. The amounts of power at both the transmitting and receiving ends of a telephone connection are small. The sound energy produced by the voice during a telephone conversation varies over wide limits, an average figure expressed in electrical power units being of the order of 10 microwatts. Only a small part of this power reaches the transmitter, nevertheless, the transmitter being an amplifier, the power generated by it for this case is about 300 microwatts. The received power for an average connection is less than 1 microwatt and conversations may be carried on when the received power is as little as 0.01 microwatt.

The development and commercialization of the three-electrode thermionic vacuum tube made available a means for amplifying these weak currents sufficiently to enable them to be accurately read with standard types of meters. This tube also plays an important part in generators of alternating current for testing purposes. With suitable alternating-current generators and amplifiers available the problem of designing a transmission measuring set consists in arranging the apparatus in such a manner that it may be operated conveniently and rapidly and will measure accurately.

The transmission efficiency of a circuit may, as previously stated, be determined by measuring the currents or voltages at the two ends of the circuit. The ratio of these voltages or currents can then, if desired, be expressed in terms of standard cable. It is, however, much more convenient to have the result obtained directly, without computations. The principles used in the 1 -*A* transmission measuring set have, therefore, been followed in the more recent sets using vacuum tubes.

The 1 -*A* transmission measuring set requires for its operation, the maintenance of equal voltages on the two branches. As no voltmeter is provided, it is necessary to bridge the branches together to obtain equal voltages. This requirement prevents the measurement of circuits between offices unless two circuits are connected together at the distant end. The 1 - *A* set could be used for measuring such circuits if the branches were separated and equal voltages applied to them. In this case the upper branch R of Fig. 7 would be removed and connected to the distant end of the line under test and testing current supplied through it from a generator having a voltage equal to that of the generator connected to the lower branch.

The transmission measuring sets which employ vacuum tubes are arranged so that the voltage across the sending circuit impedances may be maintained at a definite value, a meter being connected in the oscillator circuit. It is, therefore, possible to make measurements on a circuit, in either direction, when a measuring set is connected to each end.

Several types of transmission measuring sets which make use of vacuum tubes have been developed but only the latest types of portable and non-portable sets will be described. The 3 - *A* transmission measuring set, a view of which is shown in Fig. 8, is a portable set designed to replace the 1 - *A* transmission measuring set in common battery central offices where a direct-current supply is available to operate the vacuum tubes. Like the 1 - *A* set, it is intended primarily for measuring central office apparatus and switching trunks. The maximum transmission equivalent which can be measured is 30 800-cycle miles.

Fig. 9 shows the circuit arrangement used in measuring the transmission equivalent of a circuit between two offices, this type of test being commonly called a "straightaway" test, as differentiated from the "loop"

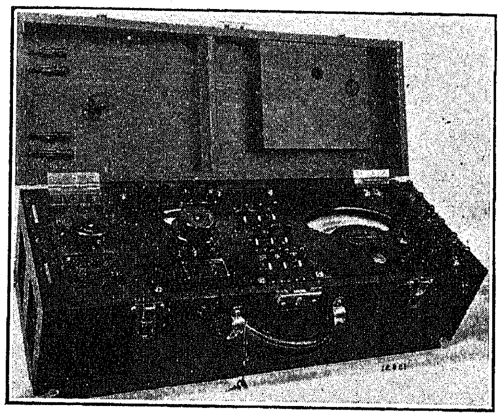

Fig. 8—3-A Transmission Measuring Set

test used with the 1 - *A* set and with talking tests. At the sending end of the circuit only part of the apparatus is in use, as shown. The sole purpose of this apparatus is to impress a voltage across the terminals $C_1\,C_1$. The impedances D_1 together approximate the characteristic impedance of the unknown circuit. The a-c. meter shown in this drawing is a thermo-milliammeter which can, of course, be used in measuring voltage if the resistance of the circuit is known. If the milliammeter were in series with the resistance H_1, shown connected across terminals $C_1\,C_1$, the reading of the meter would be proportional to the voltage. But such an arrangement is undesirable because the impedance of the meter would be important. For practical reasons it is desirable to have the meter where the total current through both H_1, and $D_1\,D_1$, is measured. However, the resistance of H_1 is so small, with respect to $D_1\,D_1$, and the unknown circuit, that practically all of the current is in H_1, and changes in the impedance of the unknown circuit produce a negligible effect on the voltage across

$C_1 C_1$. H_1, then serves the purpose of a generator of low impedance, this arrangement being referred to as a "point source" approximation.

At the receiving end of the circuit the complete transmission measuring set is required. The principal parts of the set are shown in the dotted rectangle to the right of the unknown circuit. They consist of an amplifier-detector unit for amplifying the weak received testing current and converting it into direct current, a meter which is actuated by the rectified current, a sending circuit identical with that used at the sending end of the unknown circuit, and two branches containing networks known as the "calibrating" and "measuring" networks.

The purpose of some of these parts, particularly the calibrating network, will not be evident to those unfamiliar with vacuum tubes. The vacuum tube, while an excellent amplifier and rectifier, cannot be relied on to maintain unvarying characteristics. The characteristics of a tube change slightly with time for several moments after the filament is energized. There is also the effect of long continued use. A still greater change in an amplifier is occasioned by replacing tubes, even in the case of tubes used in telephone circuits where a high degree of uniformity is required. Because of these variations a vacuum tube amplifier acts in a manner similar to that of a meter in which the resistance of the meter and the tension of the springs are subject to variations.

Transmission measuring sets must be designed to operate on power available at a central office. The voltages of the batteries used for telephone work are allowed to fluctuate between fairly broad limits, the difference between the maximum and minimum voltages being about 25 per cent. This change in voltage usually takes place slowly as the batteries are charged, nevertheless the effect of voltage change in the plate circuit of a vacuum tube is shown directly in its amplification.

It should not be inferred that a vacuum tube amplifier is a continuously fluctuating instrument for this is not the case. After the tubes have been operating for about 15 minutes, and at times when the battery voltage is constant, the amplification factor of an amplifier will remain practically constant for some time. The changes experienced are more of an hour to hour or day to day change, but are sufficient to require the provision of an arrangement whereby the amplifier may be regulated.

The amplifier-detector unit is adjusted by connecting the sending circuit directly to its own receiving circuit, the switches being thrown as indicated by the solid lines of Fig. 9, thus bringing the calibrating network into the circuit. The impedances $D\,D$ and H in the sending circuit are set for the same values as $D_1\,D_1$ and H_1 of the sending circuit at the distant end of the unknown line. As previously stated, $D_1\,D_1$ together approximate the characteristic impedance of the unknown line. The sending circuit currents are both adjusted to the same value. The calibrating network is designed to cause the same loss as is caused by 30 800-miles of standard cable, this being the maximum transmission equivalent for which this set is designed. The reduced voltage from the output terminals of the calibrating network is applied to the input of the amplifier-detector unit, is amplified and rectified and produces a deflection on the meter. By means of the "adjusting dial" the deflection is brought to mid-scale. When this condition holds the apparatus is said to be "calibrated", which means that when a given e. m. f. is applied to the terminals $C\,C$ in the sending circuit, and the resulting current attenuated by the calibrating network, a mid-scale deflection is obtained on the meter.

The receiving circuit now being in a condition to measure the unknown circuit, the switches are operated to the dotted position. By this operation the receiving end of the unknown circuit is connected to the transformer K and the calibrating network is replaced by the adjustable measuring networks. While the power in the unknown circuit at the sending end is the same as that supplied to transformer K in calibrating, the unknown circuit attenuates this power so that the power supplied to the adjustable networks is less than that supplied to the calibrating network. Consequently, to obtain a mid-scale deflection on the meter as in calibrating, the loss in the adjustable networks must be reduced, from that of the calibrating network, by an amount equal to that caused by the unknown

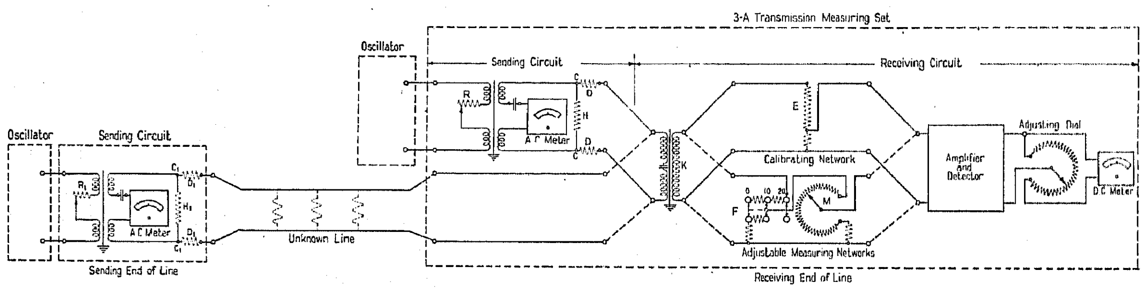

FIG. 9—3-A TRANSMISSION MEASURING SET

Simplified Diagram Showing Arrangement for Straightaway Tests.
Solid Position of switches show corrections for calibrating. Dotted position of switches show corrections for measuring.

circuit. By calibrating the adjustable networks to indicate this reduction, the transmission equivalent of the unknown circuit can be read directly.

As long as the amplification of the tubes remains constant other circuits may be measured without recalibration, the only operation required being the adjusting of the measuring networks until a mid-scale reading is obtained. It is evident that this method of measurement is more rapid and more satisfactory than a method which requires the reading and calculation of currents and equivalents.

In the transmission measuring sets the amplified current is converted into direct current by means of a rectifier or detector, it being customary to use a standard amplifying tube for this purpose. For a given amplifier the deflection obtained on a sensitive d-c. meter using rectified currents is about the same as would hold with a thermal meter if the current were not rectified. The d-c. meter operating on rectified current has an important advantage over a thermal meter in that it operates more rapidly and it is chiefly for this reason that it is used.

There are numerous other details of the 3-*A* transmission measuring set which are of interest and a few of them will be mentioned. Among the most important of these are the transformer *K* and the transformer in the sending circuit. Each of these transformers has an electrostatic shield between the windings, the shield being connected to ground. The purpose of these shielded transformers is to furnish paths of equal admittance to ground from the two wires of the testing circuit, thus preserving the balance of that circuit. The transformer in the sending circuit prevents any unbalanced current being sent into the line, due to unbalances which may exist in the oscillator. The transformer *K*, in the receiving circuit prevents any unbalance currents which may be induced in the unknown circuit from acting on the unbalanced networks and amplifier. It also prevents the receiving circuit from unbalancing the line.

The adjustable network *F* is a constant impedance non-inductive resistance network. The impedance of *F* is 600 ohms at all times as viewed from transformer *K*. This transformer has an impedance ratio of approximately unity, the departure from unity being such that the combination of network and transformer impedance is 600 ohms when measured from the terminals to which the unknown circuit is connected. The impedance of the receiving circuit is normally 600 ohms but can be made 1200 or 1800 ohms by connecting resistances between the transformer and the switch. The impedances in the sending circuit can be given these same values. Two of these impedances differ from those of the 1 - *A* transmission measuring set, being based on conditions now existing in the telephone plant.

The adjustable network *M* is a potentiometer of unusual design. It is made in the form of a circular slide wire, the resistance wire being wound on a mandrel of non-uniform cross-section so that the change in resistance when rotating the drum on which the mandrel is mounted will be logarithmic. The attenuation of a long uniform telephone circuit is represented by the expression $e^{-L\alpha}$ in which L is the total length and α the attenuation per unit length. This is a logarithmic expression and requires a logarithmic variation of the resistance on a slide wire if uniform divisions are to be obtained.

Both networks *E* and *M* are designed on the assumption that the impedance of the amplifier is so high with respect to the networks that it may be considered infinite. This condition is met by the amplifier, the input transformers having high-impedance windings.

The 3 - *A* transmission measuring set operates entirely from the 24-volt central office battery as a source of power for both the filament and plate circuits of the tubes. The energy required by the meter is so small that tubes operating on this low voltage will carry it without danger of overloading them. However the circuit of the amplifier is so arranged that the maximum energy which the tubes will deliver is not sufficient to damage the meter.

Although two meters are shown in Fig. 9 only one is used in the 3 - *A* set. This meter is a microammeter which measures direct current in the detector circuit of the amplifier and, in conjunction with a thermocouple measures, in milliamperes, the current in the sending circuit. It also is used with a shunt to measure filament current. Arrangements are provided so that in case a thermocouple is replaced the combination of meter and couple can be calibrated without the use of an additional meter.

The actual operation of the 3 - *A* set is simple and rapid. The 9 keys shown in Fig. 8 control the sending and receiving circuit impedances, switch from the measuring to calibrating condition, and perform several other minor operations. The two dial handles, mounted concentrically, control the adjusting dial used in calibrating and the network *M* used in measuring. The scale on dial *M* is shown directly above the dial handles.

The dial handle at the extreme left controls a rheostat which regulates the oscillator current in the sending circuit, being designated as R and R_1 in Fig. 9. The vacuum tubes and filament rheostat are in the compartment below this dial handle.

The binding posts and jacks at the extreme right are for the purpose of connecting the circuits to be tested to the measuring set. The jacks are used for cord circuits which terminate in plugs.

4-A Transmission Measuring Set

The 4 - *A* transmission measuring set is a non-portable set designed for routine measurements on toll circuits. It will measure transmission losses as great

as 60 800-cycle miles and will also measure the gain of a telephone repeater. A view of the set is shown in Fig. 10.

The 4 - *A* set resembles the 3 - *A* set electrically in so many details that it is unnecessary to show any schematic circuit. It consists of an identical sending circuit and a receiving circuit which differs only in two important respects, both of these being in the amplifier.

The range of the set being double that of the 3 - *A* set makes it necessary to provide an additional stage of amplification. This extra range means also that the magnitude of the power received from many of the circuits under test is much less than that which is received in the case of the 3 - *A* set. Toll circuits are often exposed to induction from power circuits, sometimes resulting in induced currents of a magnitude which in the case of high transmission equivalents, approaches that of the testing current. Even when the equivalent of the toll circuit is low, such as is usually the case, these induced currents may cause serious errors. The induced currents add to the testing current and cause the toll circuit to appear to have a

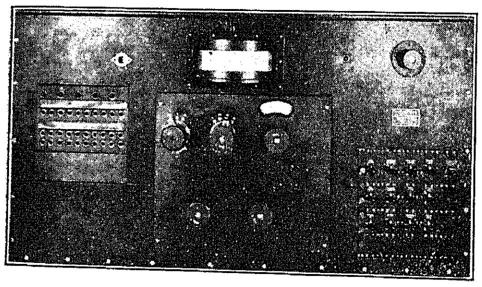

Fig. 10—4-A Transmission Measuring Set

smaller transmission equivalent than it actually has. In order to minimize the effect of induced currents a network of condensers and inductances, known as an electrical "filter" is provided in the amplifier circuit. This filter greatly attenuates all frequencies except those within a narrow band used for testing purposes and enables measurements to be accurately made on nearly all circuits. Special filters may be required when measurements are made over a wide range of frequencies. However, for routine measurements where a single frequency or narrow band of frequencies is employed, little difficulty is experienced when the filter in the 4 - *A* set is used. The filter is located between the first and second tubes in the amplifier. With this arrangement the filter can be changed at will without the resulting changes in impedance appreciably affecting the impedance of the amplifier as a whole, considered from the terminals to which the measuring and calibrating networks are connected. The 3 - *A* set having no filter, is not well adapted to testing circuits which are subject to induction.

In addition to the increased range the 4 - *A* transmission measuring set differs chiefly from the 3 - *A* set in having facilities for enabling the tester to talk over circuits and to the toll operator whose duty it is to establish a connection between the measuring set and the toll circuits.

The vacuum tubes operate from the central office battery as a source of power for the filaments. The plate potential is supplied by the central office battery and an 18-volt flashlight cell battery.

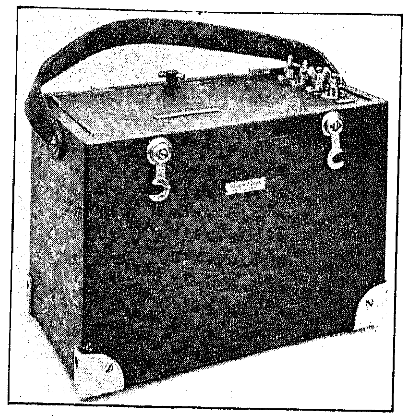

Fig. 11—2-A Oscillator

Oscillators Used with Transmission Measuring Sets

While it is not the purpose of this paper to give a detailed description of the oscillators used with transmission measuring sets a brief statement about each will enable a more complete picture to be obtained. Fig. 11 shows a photograph of the 2 - *A* oscillator which furnishes testing current for the 1 - *A* transmission measuring set. This oscillator contains three dry cells which supply power to operate a vibrating reed type of carbon button generator. A single-frequency current of 800 cycles is obtained.

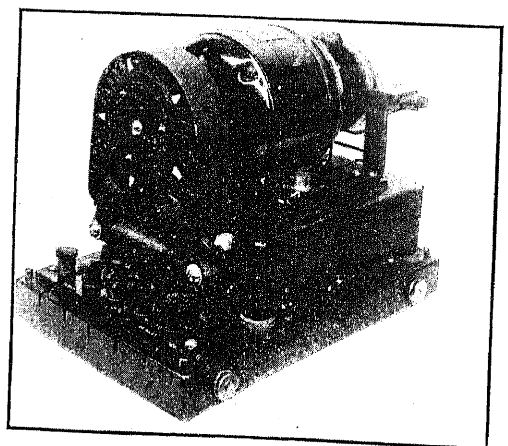

Fig. 12—3-A Oscillator

Fig. 12 shows a photograph of the 3 - *A* oscillator used with the 3-*A* transmission measuring set. This is a motor-driven inductor-alternator which operates

from the 24-volt central office battery as a source of power. It generates a single-frequency current of 1000 cycles. The speed of the motor is regulated by a governor.

Fig. 13 shows a photograph of the 4 - *B* oscillator which is used with the 4 - *A* transmission measuring sets in making measurements at frequencies between 100 and

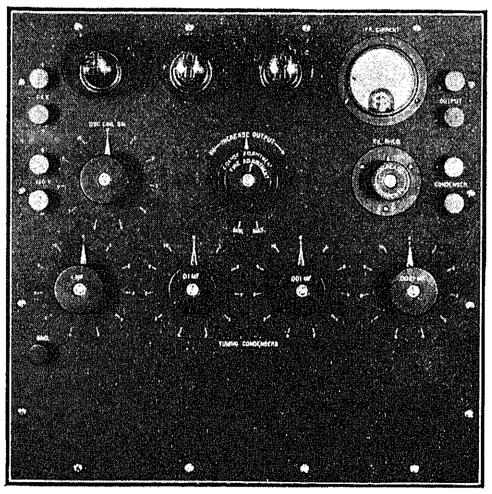

Fig. 13—4-B Oscillator

3000 cycles. This oscillator is of the vacuum tube type and is conveniently arranged so that any frequency may be easily obtained.

Fig. 14 is a photograph of the 5 - *A* oscillator which has been designed for routine measurements on toll

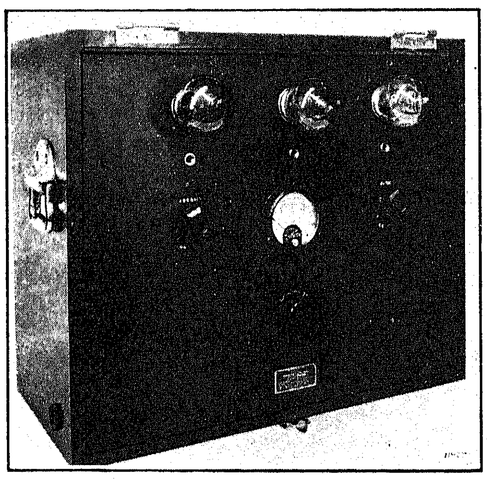

Fig. 14—5-A Oscillator

circuits in cases where it is not necessary to make measurements over a wide range of frequencies. This oscillator is of the "frequency-band" type, the generated current varying in frequency continuously and periodically between 900 and 1100 cycles per second in a manner similar to a siren. The results obtained with this oscillator are the same as the average of a number of single-frequency measurements between these same frequency limits. This oscillator is of particular value in the case of circuits of the type shown in Fig. 2. The frequency is varied by changing the inductance of an inductometer in the oscillating circuit, the shaft on which the moving part is mounted being rotated by a motor.

Conclusion

The development of these transmission measuring sets and associated oscillators has placed in the hands of telephone operating forces convenient and practical tools which enable them to properly maintain the talking efficiency of telephone circuits. Widespread use has demonstrated that the resulting transmission savings and improvements in service are worth many times the cost of doing the work.

Discussion

W. H. Harden: Mr. Best's paper in dealing with the development of telephone-transmission testing apparatus describes three of the common forms of instruments and mentions the oscillators employed to supply the testing current. It may be of interest to outline briefly some of the more important applications which are being made of these testing devices in maintaining the efficiency of telephone circuits in the Bell System.

The three types of instruments considered are the *1-A* and *3-A* transmission-measuring sets which are portable and the *4-A* transmission-measuring set which is designed for permanent installation. The *1-A* type of set has been used extensively during the past eight or nine years and prior to the advent of instruments employing vacuum tubes a majority of the important exchange area circuits in the System were tested with this set. There are at present approximately 150 sets of this type in the Bell System.

When the *3-A* type of set came into use two or three years ago it replaced the *1-A* type for certain classes of work but not all classes. The *3-A* set employing vacuum tubes and visual means of indicating transmission losses allows transmission tests to be made more quickly and accurately than the older type of set. It finds its principal application in testing the larger units of plant, such as common-battery central offices, both manual and machine switching. It is also used to some extent in testing toll circuits. For the smaller units of plant, such as private-branch exchange switchboards, magneto switchboards, etc., where the power necessary for operating the *3-A* set and its oscillator is not available locally, the *1-A* type of set is still generally used. There are at present approximately 100 sets of the *3-A* type in the Bell System.

The testing work using these two types of sets is usually carried on by teams of two men each who travel from office to office. For average conditions involving both large and small central office areas one team can test from 30,000 to 40,000 circuits a year clearing all troubles which are found.

The *4-A* transmission-measuring set, or permanent type, is used extensively in maintaining the transmission efficiency of toll circuits. There are at present some 40 or 50 of these instruments installed at important toll centers about the country. Tests are made straight-away or looped between these centers at frequent intervals and also on the loop basis to the smaller outlying toll centers. The transmission efficiency of toll circuits of all types, such as, 2-wire, 4-wire or carrier, can be quickly checked with the arrangement as outlined.

One thousand-cycle measuring current is now used for all

routine tests on toll circuits and on all tests of exchange area circuits where the *3-A* type of set is employed. The 800-cycle oscillators which are now in the field are still being used for exchange-area testing with the *1-A* type of set and are satisfactory for this work. Whenever it is necesary to check the transmission-frequency characteristics of any circuits the *4-A* type of set is used in conjunction with the *4-A* type of oscillator which can be made to give any desired frequency within the voice range.

This line of transmission-testing apparatus has enabled troubles which cannot be detected by ordinary tests, to be quickly located and cleared. Short-circuited turns in transformers, retardation coils and relays, incorrect wiring of certain equipment and certain defective equipment are examples of the kinds of trouble which require transmission tests for detection. The application of this testing apparatus has gone beyond the experimental stage and routine transmission tests are now an important factor in the maintenance of the telephone plant.

H. H. Nance: At the beginning of the war period there had come into general use vacuum-tube telephone repeaters and toll cables carrying many circuits of different gages and types of loading. The range of telephone transmission was rapidly increasing, and longer and more complicated circuits were being established. Also, at that time the heavy demands for additional circuits, many of which were for the Government's use, necessitated the hurried installation of additional facilities, heavy growth in many instances being to outlying points where comparatively little traffic previously existed. Ofttimes it was a matter of putting together such facilities as could be obtained. All of these factors combined to present a serious problem from the standpoint of transmission maintenance and a heavy burden was placed on the forces maintaining the several thousand circuits then in operation in the plant of the long-lines department of the American Telephone and Telegraph Co. The situation was further complicated, of course, by the fact that skilled personnel required for this work was at a premium.

The development of the *3-A* and *4-A* types of measuring sets brought about a decided improvement in transmission-testing methods. From a practical standpoint the use of a single-frequency measuring current and direct meter readings were of particular benefit and greatly relieved the work of the trained observer. These methods eliminated to a large degree the personal equation, and more accurate and quicker results were obtained and at a very considerable saving in circuit time and testing labor.

The first sets of the *4-A* type were installed at New York and Washington, as these were two long-distance telephone centers of great activity at that time. By means of these sets, the two offices together could measure approximately 200 circuits in a night period of about seven hours, including the directing of repeater adjustments at intermediate points and clearance of trouble found, whereas by the older methods, which had consisted mainly of talking tests using artificial cable, this would have required many nights' work and a testing force several times as large, even if it had been practicable under the conditions to follow the older methods.

Since then, additional measuring sets of the *4-A* type have been installed at a considerable number of points well distributed throughout the long-lines plant and the methods and routine have been systematized to a point where the large number of circuits in this plant is now measured periodically.

A great many circuits, of course, terminate at points where these sets are not installed but measurements on such circuits can be obtained by connecting them through to a testing point by means of other circuits of known equivalents. In some cases the *3-A* or portable type sets, which are likewise well distributed throughout the plant, are used for measuring circuits which cannot conveninetly be measured from the nearest station at which a *4-A* type is installed.

The results obtained in accordance with the present methods and routine have been highly satisfactory, and it has been practicable to maintain the circuits within relatively close limits of variation from the computed equivalents.

The particular work mentioned, that is, the measuring of circuit equivalents from one terminal to the other is, of course, only a part of the transmission maintenance work, since a great many other measurements in connection with that work are made on individual repeaters, networks and sections of circuits at intermediate stations.

R. L. Simpson: The New York Telephone Company is making considerable use of the transmission measuring apparatus which is described in Mr. Best's paper. In each of our seven Plant Divisions we have one or more specially trained forces whose function it is to maintain our circuits up to the proper grade of transmission efficiency. They conduct tests on all of our central-office and private-branch-exchange circuits and equipment.

In general, these forces are equipped with *1-A* and *3-A* transmission measuring sets; and, in addition, we have one of our divisions equipped with a set of the *4-A* type for the maintenance of toll lines which are equipped with through-line repeaters. Periodic transmission measurements are made on a 1000-cycle basis. The *1-A* set is used on small magneto switchboards and P. B. X. switchboards where 24-volt battery supply is not readily available. In our larger central offices where a considerable amount of apparatus is concentrated at one point, and battery supply sufficient to operate the *3-A* set is available, we use this instrument. The *3-A* set, being a visual reading type eliminates to a great extent the personal equation and by eliminating the necessity for personal judgment makes the test quicker.

Before the development of the transmission measuring sets, as described in Mr. Best's paper, a transmission investigation on one of the larger offices in the Metropolitan division of our Company would require an expenditure of both time and money which would probably be out of proportion with the results obtained, but the facility with which circuits can be measured with both the *1-A* and the *3-A* set, makes it possible to accomplish this work both economically and quickly even though the investigation of one of our larger offices would mean the testing of something in the order of 5000 individual circuits, such as cord circuits, operators' telephone circuits, trunks, etc.

These instruments are so designed that they not only indicate the amount of excess loss present when trouble is encountered as compared to the known transmission standard of the particular circuit under investigation, but also make it possible in a large majority of cases to definitely locate the trouble and eliminate it while the circuit is under observation by the transmission tester.

Many of the troubles eliminated by this means are not obvious, nor is their location possible by the usual maintenance methods which are followed by the central office forces. It sometimes happens in the course of the installation of a large number of core circuits involving repeating coils and relays that, due to the amount and complexity of the work required in the installation, some of these coils are installed with one winding reversed. The effect of this would not be apparent on any of the routine tests which are made as these are all on a d-c. basis, but since the repeating coil acting as it does as a transformer with one winding reversed is very inefficient, the effect on the transmission efficiency of the circuit would be detrimental. A transmission measurement of the circuit, together with an investigation, will readily clear up this trouble.

The results of the tests which have been carried out in the New York Telephone Company have been invaluable to us not only due to the fact that we have been able to eliminate some rather obscure troubles, but also due to the fact that we can in many cases anticipate and prevent the reoccurrence of conditions which transmission measurements have shown to react unfavorably on

the performance our circuits are designed to give, through analysis of the reports.

Bela Gati: I always had the opinion that the resulting transmission savings and improvements in service are worth many times the cost of doing the work.

The European government telephone practise has not followed the excellent example of the American Telegraph and Telephone Company as yet; consequently, it is believed to be a great success to speak over the territory of three States in Europe. Government employees are cheap in Europe (about $25 monthly salary for telephone engineers, in Hungary) thus the talking tests are not so expensive.

I agree with Mr. F. H. Best regarding the talking tests. I am glad that the American Telegraph and Telephone Company does not favor it any more, although the company was a great defender of this system and it is the sin of this company (Germans not excepted), that this American method has firm root in our poor Europe.

I wish to complete Mr. Best's objections in one direction. The talking tests do not count in the resonance question. Each 100 kilometers of line has different resonance effects for some speech frequencies, hence the incalculable results obtained by such investigations. In the TRANSACTIONS of the A. I. E. E., Vol., XXX, part II, pages 1679-1680, Multiplex Telephony and Telegraphy by means of Electric Waves Guided by Wires, George O. Squier, Discussion at Chicago, 1911 June 28, I pointed out clearly the resonance effect. If the outgoing current is not in phase with its voltage, then in that case we do not measure the attenuation, but we construct the resonance curve only. I believe this resonance effect disturbs also the results obtained by the various transmission measuring sets. In measuring long lines, the applied filter substitutes in some degree the necessary resonance state at the sending end.

The testing method of central office apparatus is an ingenious one. I quote but one example. Bucarest, the capital City of Roumania was unable to call Budapest, the capital City of Hungary directly, but always needed the intermediation of Brasso. This went on for years. The line signal coils and the clearing-out drop coils were changed by mechanics in Brasso's and this caused the inconvenience. I measured the fault from Budapest, which is a distance of 700 kilometers.

Our subscriber and city lines need measurements also. Paris could not reach Rome because of the interconnecting lines in Lyon. The French administration is not in favor of the secondary lines at all.

In the transmission measuring sets Mr. F. H. Best uses, according to the figures, ohmic resistances only. Kennelly's sending end impedance is needed at the end of the line and this always in the $a - j\,C$ form, $z_0 = \sqrt{\dfrac{r + j\,u\,l}{g + j\,u\,c}}$ compression means a resistance in series with leakance-free condensator. This condensator is missing, therefore the attenuation values differ from the actual ones.

In chapter *3-A*, Transmission Measuring Set, Mr. F. H. Best writes that "no alternating-current measuring instruments were available for measuring the power received at the end of a telephone circuit, which were sufficiently rugged or practicable to withstand the service required of them." I don't know whether there is an instrument which measures the phase displacement at the end of a long telephone line, but I measured the attenuation with my barretter apparatus 15 years ago. I modified Kennelly's barretter, using it in compensation bridge. I measured 100 microamperes telephone-current with Robt. W. Paul's pointer instruments. In loop, I used the same barretter for the outgoing and incoming currents; the d-c. microampere-meter readings were proportional with the square of the current. Keeping the outgoing current always at the same level (50 deg. deflections) from tables previously made the attenuation × length could be read at once.

I measured with these instruments at the bottom of the poles in moonlight, in rainy weather also. We had many auto-accidents, but Paul's microampermeter and the set remained intact.

F. H. Best: As it is not clear as to just what is meant by some of the points raised by Mr. Bela Gati, it may be that his comments can best be answered by referring to the general principle of the method used in the transmission measuring apparatus described in the paper. The measuring apparatus is designed to measure the transmission equivalent of a telephone circuit in such a way that the answer obtained represents the equivalent which this circuit would have were it connected in the center of a long line of its own type. For this reason the apparatus which is connected to the two ends of the circuit under test approximates in impedance the impedance of the circuit under test. For the most precise results this impedance should, of course, be exactly equal to that of the circuit under test. However, the complexity of the testing apparatus necessary to permit an exact impedance match is not warranted. The values of the three impedance terminations included in the testing apparatus have been selected so that in testing any of the circuits in common use in this country some one of these terminations will meet the impedance of the circuit under test sufficiently closely to make the error introduced by the approximation so small as to be negligible. It has not been found necessary to have a reactance component in the impedance of the termination. Loaded circuits are so designed that the reactance component of the impedance at the end of the circuit is small. Non-loaded open-wire circuits have small reactance components. Even in the case of non-loaded cable circuits where the phase angle of the impedance may approach 45 deg. the error introduced by the use of non-reactive terminations is small.

As mentioned on page 4 of the article, the apparatus described is arranged to read the transmission loss or equivalent in terms of the loss in standard cable at a frequency of 800 cycles, the unit being commonly called the "800-Cycle Mile." This cable is the standard cable used for some time in this country, having a resistance of 88 ohms and a capacity of 0.054 $\mu f.$ per mile with $G = 0$ and $L = 0$. This "800-cycle mile" of standard cable, which was a somewhat arbitrary unit, has recently been replaced in the Bell System by a "Transmission Unit," which is described in a paper by Mr. W. H. Martin, published in the June, 1923, JOURNAL of the A. I. E. E. While of approximately the same size as the 800-cycle mile, this new unit is founded on a more logical basis, one unit causing a power attenuation of $10^{0.1}$. New testing apparatus will be calibrated in terms of this unit.

It is not evident what Mr. Bela Gati had in mind in the third paragraph of his comments in which he mentions "talking tests." Such tests have played an important part in development work and have been well justified, but because of the elaborate nature of such tests the American Telephone and Telegraph Company have never used or recommended the making of such tests as a routine method of determining the condition of operating circuits.

In connection with the Barretter mentioned by Mr. Bela Gati for measuring attenuation, it might be of interest to note that the current at the receiving end of a telephone circuit when it is being tested with apparatus described in this paper is in some cases as small as 2 microamperes. The output of the sending apparatus is one milliwatt. For received currents as small as 2 microamperes, it is, of course, necessary to use apparatus employing vacuum tubes. The current levels used in testing are selected to be of the same order of magnitude as the currents impressed on the lines and associated apparatus in telephoning.

Regarding the question as to the proper impedance of receivers, it should be noted that the most efficient receiver is one which matches the impedance of the circuit to which it is connected.

Radio Telephone Signaling

Low Frequency System

By CHARLES S. DEMAREST MILTON L. ALMQUIST

Department of Development and Research
American Telephone and Telegraph Company

LEWIS M. CLEMENT

Research Laboratories of the American Telephone and Telegraph Company, and the Western Electric Company, Incorporated.

Review of the Subject.—*A signaling system is described which serves to extend to the field of radio telephony the same sort of calling facilities as are now available in wire telephony. By its means the radio attendants or subscribers are enabled to signal each other without requiring that the called party should have to listen with a receiver. The system is intercommunicating with a capacity for a large number of stations on one wave length. It has a range of operation extending as far as a radio channel suitable for the commercial transmission of speech can be reliably maintained, and offers a very satisfactory degree of freedom from interference. Furthermore, it employs simple, standard types of telephone apparatus. Some possible fields of usefulness of the system, its outstanding characteristics, and the apparatus which it employs are described.*

Introduction

In any system of communication, it is desirable that means be provided whereby an attendant or subscriber may be called without requiring that he should have to listen on a particular line. In wire telephone systems, as is well known, means are provided whereby the central office operator may ring a subscriber's bell. In addition, signaling equipment is provided which permits calling the attention of the central office operator at either station on a line to a particular circuit, without requiring her to listen on that circuit. Thus, it is possible for the operator, after she has established the desired connections between certain circuits, to give her attention to others.

The need of such independent signaling facilities for radio systems has not in the past been an important factor, on account of the fact that licensed operators have been required by law to stand watch at all transmitting stations. However, in certain of the various commercial applications of radio telephony which are now being considered, it is undoubtedly true that the licensed operators on continuous watch could be dispensed with, without detriment to the public safety, and, in these instances, signaling facilities would be a distinct advantage.

To anticipate these needs, the development of signaling arrangements suited to practical use with radio systems has been undertaken and much progress has been made. The problem involves the difficulty that the communication channel provided by radio may be less easily maintained in a stable condition than a wire channel. However, it is now felt that it will be practicable to provide signaling facilities adapted to any type of radio telephone service for which a channel suitable for the commercial transmission of speech can be reliably maintained. This will be of considerable advantage, it is thought, in the commercial development of such service.

One promising possibility for the use of this signaling system would seem to be in the field of marine radio telephony. In ship-to-shore radio telephony automatic signaling would serve to lessen the radio operators' duties. Undoubtedly, there would be considerable operating advantage from a commercial standpoint, in placing the ship-to-shore radio telephone service on the same signaling basis as wire lines. This might be expected to become particularly important if the volume of such radio telephone traffic became large.

Among other commercial applications of radio telephony in which signaling facilities are expected to prove advantageous might be mentioned the point-to-point service. A radio telephone system for such a service is being installed by certain interests in Persia as a means of communication between points not reached by wire systems. An automatic signaling system of the type described in this paper is to be employed in this case, and a number of intercommunicating stations are expected to be involved eventually. In the United States there has not, thus far, been much field for the commercial application of point-to-point radio telephone systems. However, where conditions do not favor the installation of wire lines, as in the Persian case, point-to-point radio systems may be expected to find application.

Description of Basic System

The experimental work has indicated that a low-frequency signaling system employing a mechanically tuned alternating-current receiving relay is well adapted to operation in connection with radio systems. Such an arrangement has been shown to be both highly selective and sensitive. These qualities result in giving a very satisfactory degree of freedom from interference, while at the same time the signaling energy level required is so low as to permit operation directly from a radio set employing the smallest available types of vacuum tubes.

With such a system, standard types of apparatus may be employed for the signaling equipment, which is not expensive as compared with the cost of the remainder of the radio equipment. Furthermore, the ordinary

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

types of radio transmitting and receiving circuits may be used, without modification.

In testing the system over short distances a simple radio transmitter was used, employing one modulating and one oscillating tube, each of the so-called E type. This transmitter had an output capacity of about 5 watts at wave lengths between 200 and 450 meters.

Any type of radio receiver which is suitable for receiving speech over the particular radio system employed may be used. In the tests, one having two stages of radio-frequency amplification, a detector and one stage of audio-frequency amplification, all of which utilized the small N type vacuum tubes, was employed. The signal-receiving apparatus was operated either from the detector tube or the audio-frequency amplifier, depending upon the signaling range desired.

Fig. 1 shows this scheme in its most simple form which may be made to serve as the basis for a variety of systems, suited to different purposes. As seen in this figure, the outgoing signal is produced by applying an alternating current of a particular frequency to the radio transmitter in the same manner as the speech currents are applied. Modulation of the radio carrier wave at the signaling frequency results. In this particular system, the signaling current frequency employed is 135 cycles.

At the receiving end the radio carrier wave, modulated by the signaling current, is detected in the radio receiver in the usual manner. The output of the detector thus includes a component similar to the signaling current originally sent into the radio transmitter at the outgoing end.

This received signaling current is sent into an alternating-current relay of a type particularly adapted to the purpose, which serves to close a sensitive direct-current relay in a local circuit. This combination of relays acts as a mechanical rectifier.

Fig. 2 represents very roughly the form of the signaling currents at the various stages in the process of operation of the basic system. In this figure, the operation at the transmitting end is shown at A, B and C, while that at the receiving end is shown at D, E, F, and G. Such a graphical representation of these currents cannot, of course, be made accurate in a quantitative sense, but it permits visualizing the character of the signal at different steps in the process of operation.

At A in this figure is shown the direct-current impulse through the sending key and direct-current signal-transmitting relay, which occurs when the key is closed.

The operation of the signal transmitting relay, which occurs when the sending key is closed, supplies 135-cycle current to the radio transmitter as shown at B.

The modulation of the radio carrier wave by the 135-cycle current results in antenna current of the form shown at C. This consists of the radio frequency current varying in amplitude at a rate dependent upon the frequency of the impressed signaling current.

The form of the incoming current in the antenna or loop at the radio receiving station, as shown at D, is the same as that of the transmitted antenna current previously shown at C, but is of course greatly attenuated.

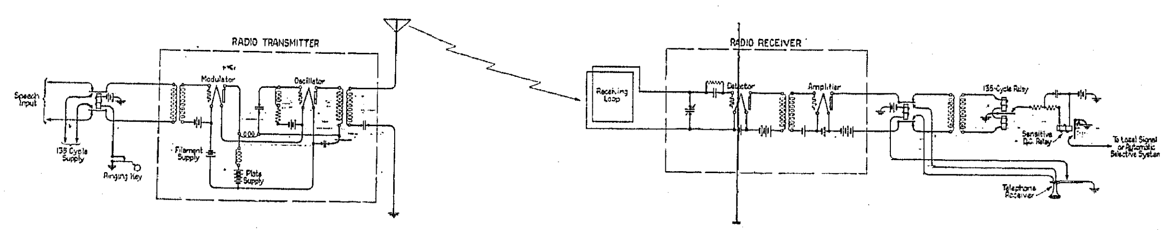

FIG. 1—SIMPLIFIED DIAGRAM OF BASIC SYSTEM FOR 135-CYCLE SIGNALING

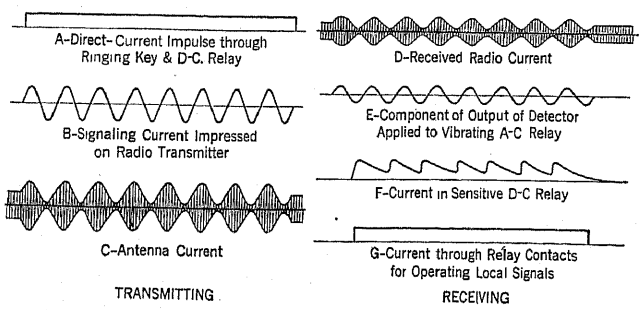

FIG. 2—FORM OF TRANSMITTED AND RECEIVED SIGNALING CURRENTS IN OPERATION OF BASIC SYSTEM

This radio-frequency current, varying in amplitude at a rate dependent upon the modulating frequency of 135-cycles, is impressed upon the detector in the radio receiver. The detector functions in the usual manner, giving as one of the components of its output, 135-cycle current as shown at E. This is similar in form to the signaling current originally sent into the transmitter, as shown at B.

The 135-cycle component of the detector output is sent into the alternating-current relay and causes its mechanically tuned reed to vibrate at a corresponding rate. The vibration of the reed closes the local circuit through its contacts and the sensitive direct-current relay intermittently. This results in a uni-directional pulsating current through the sensitive direct-current relay, as shown at F, and holds the latter closed.

The sensitive direct-current relay, thus operated through the contacts of the vibrating reed, serves to close the circuit through a secondary relay suited to operate directly the local signal. The form of the

current at this point, as shown at G, corresponds closely to the original signal-transmitting impulse through the sending key and direct-current relay, as shown at A. The operation of the secondary direct-current relay in this manner constitutes the conclusion of the final step in the functioning of the basic signaling system. Subsequent steps depend upon the type of signaling facilities desired, as will be described later.

Operation of Alternating-Current Relay

The reliability and range of operation of this system are due in a large measure to the characteristics of the particular type of alternating-current relay used.

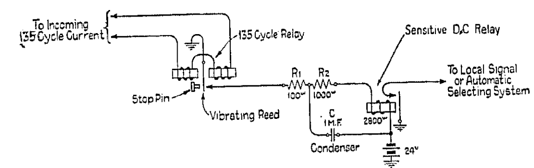

Fig. 3—Secondary Circuit of 135-Cycle Relay

This relay is unusually sensitive, as it will operate on as little power as 30 microwatts corresponding to a current of about 0.25 milliampere. The selectivity of the relay is such that a 4 per cent change in the frequency of the signaling current necessitates doubling the current to give equally effective operation of the relay.

Fig. 3 shows the arrangement employed in associating the vibrating reed relay with the local circuit. It is seen from this diagram that the vibrating reed intermittently closes a circuit associated with a sensitive direct-current relay in such a way that the latter is held closed. The direct-current relay is held operated without vibration, as long as the reed of the a-c. relay is vibrating at the frequency of the signaling current.

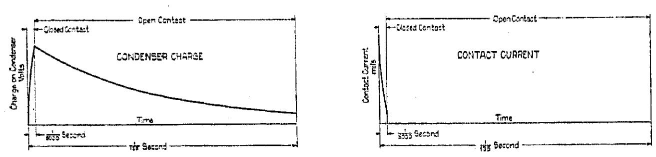

Fig. 4—Characteristic Curves Showing Operation of Secondary Circuit of 135-Cycle Relay

The action of this particular local circuit is such that effective operation of the a-c. relay may be obtained with a very small 135-cycle current. The condenser connected in parallel with the sensitive direct-current relay and the resistance in series with the condenser are so chosen in value that the condenser will take an effective charge from the local battery in a short period of time. Thus, but a small amount of work is required to be done in the form of contact pressure by the vibrating reed to charge the condenser to the degree necessary to operate the sensitive direct-current relay by discharging through the winding of the latter.

The curves shown in Fig. 4 indicate approximately the relation between the condenser voltage and contact current over a period of time corresponding to one cycle, that is 1/135 of a second. From these curves it is seen that the contacts need be closed for only a small fraction of the cycle. Thus, little energy need be expended to effect the operation of the local relay.

Fig. 5 is a typical curve showing the performance of the relay in relation to the frequency of the signaling current under average conditions of adjustment. The mechanical tuning of the reed is largely responsible for

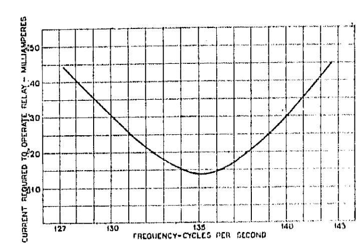

Fig. 5—Typical Curve Showing Frequency Characteristics of 135-Cycle Relay Under Average Conditions of Adjustment

its selectivity. The reed is adjusted so that the natural period corresponds closely to the frequency of the signaling current. It is thus very selective and is relatively free from the ordinary sources of electrical interference such as those caused by telegraph signals, static, voice currents, etc.

Fig. 6 shows the general structure of the relay. The relay is provided with plug connections so that it may be inserted in the circuit or removed from it readily, without requiring soldering of connections. Thus, it is convenient to make necessary adjustments of the

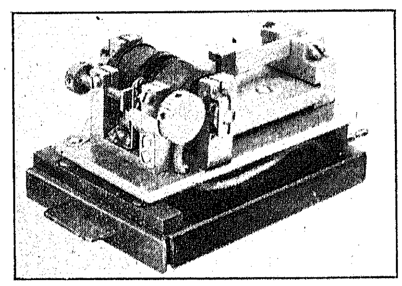

Fig. 6—Structure of 135-Cycle Relay

relay separate from the circuit with which it may be associated in service. The relay is well protected from interference due to mechanical vibration by padding in the mounting. This eliminates rigid mechanical connection between the relay and its external support thereby preventing loss of energy. A stop-pin is also provided which prevents undue vibration of the reed due to transient impulses or excessive currents.

Signaling Current Frequency

The signaling current frequency used in the practical application of this system, as previously mentioned, ha

been 135 cycles. This has had the advantage of being a frequency which is low enough to be relatively free from the various kinds of interference experienced in radio systems and at the same time permit the use of simple and reliable apparatus. The fundamental features of the system, however, are such as to permit its being adapted to use with other low frequencies, if such should be desired.

The inherent advantages in the use of a frequency well below the ordinary voice range for telephone signaling, may be readily made effective in a radio telephone system, since there is ordinarily nothing in such a system to discriminate against the lower frequencies. In fact, as far as the radio characteristics of the system are concerned, what difference there may be is in favor of the lower frequencies, because of the close approach of the modulated carrier wave, in this case, to the carrier frequency itself. While this factor may not be practically important with the short-wave systems now commonly used in radio telephony, it is more likely to be of account with longer waves.

The high degree of freedom from interference which is obtained with this system is in a measure due to the use of a frequency as low as 135 cycles for signaling. This is particularly true with respect to the interference caused by spark and I. C. W. telegraph. The tones from these sources, being within the audible range, are likely to interfere with any system tuned to a normal voice frequency. 135 cycles, however, being well below these frequencies, permits the effective use of both electrical and mechanical tuning in the signal-receiving apparatus to discriminate against interfering currents. This point was well demonstrated in the signaling tests in which it was found that radio telegraph signals similar to those from an I. C. W. or spark transmitter would cause the received speech to become unintelligible when the energy level of the interference was only 20 or 30 per cent of that required to cause the signaling system to fail.

Another advantage in low-frequency signaling occurs when the signaling apparatus is desired to be bridged across the talking circuit. In this case greater efficiency results in the use of 135-cycle signaling, by reason of the fact that it is possible with this low frequency to pass a large proportion of the received signaling energy into the signaling circuit. If a much higher signaling frequency were used, such that it occupied a more important part of the speech range, an undesirable loss might be caused by an efficient signaling circuit.

135-Cycle Supply

The highly selective signal-receiving apparatus which is used in this system permits a greater sensitivity in reception when the outgoing signaling currents are kept closely to the desired frequency. This has been accomplished practically by the development of a 135-cycle interrupter capable of maintaining close regulation and an output of good wave form.

Fig. 7 shows the circuit arrangement of the interrupter which has been developed for commercial use. This employs a tuned vibrating reed actuated by an electromagnet when direct current is applied. The contacts on the reed being in series with the battery circuit, vibration of the reed is effected in the manner of an ordinary buzzer. The actuating circuit of the

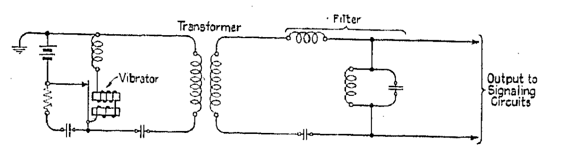

Fig. 7—135-Cycle Interrupter Circuit—Simplified Diagram

vibrator is bridged by the primary side of a transformer in series with a condenser, the secondary side of the transformer being connected to a filter for suppressing harmonics in the output.

Fig. 8 shows the structure of the vibrator for the interrupter. Since the output frequency of the interrupter for a given applied voltage depends upon the

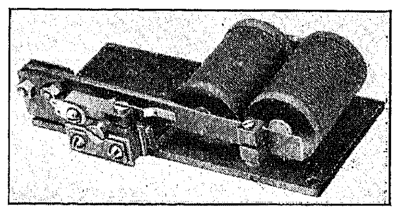

Fig. 8—Structure of Vibrator for Interrupter

natural period of the reed, means are provided for closely adjusting the latter. It will be noted that this consists of a weight, the position of which along the reed is adjustable. This weight is used in making the initial adjustment of the vibrator to give 135 cycles at the normal battery voltage, but variations in adjustment are not required in subsequent operation of the interrupter.

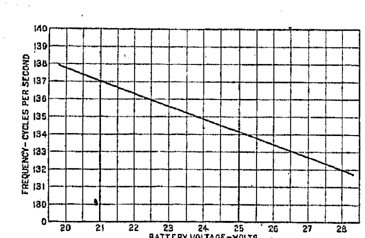

Fig. 9—Typical Curve Showing Relation between Frequency of Output and Applied Voltage for 135-Cycle Interrupter

This matter of frequency regulation is a most important one in the performance of the interrupter. As shown in Fig. 9, the frequency of the output may vary several cycles for a variation in the applied voltage of 20 to 28 volts. This voltage variation represents the maximum which might be expected to occur with an 11-cell storage battery operated on a charge and dis-

charge basis, without any regulating device. If the battery voltage is maintained within closer limits than 20 to 28 volts, as may be accomplished by various means, it is seen from the curve in Fig. 9 that correspondingly closer regulation of the output frequency

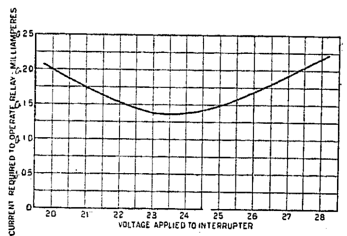

Fig. 10—Typical Curve Showing Effect of Change in Frequency Due to Variation in Voltage Applied to 135-Cycle Interrupter on Current Required to Operate 135-Cycle Relay Under Average Conditions of Adjustment

may be obtained. For example, if duplicate batteries of adequate capacity are available, the applied voltage may be kept within limits such that the output frequency will vary only about one cycle.

average conditions, affect the current requirements of the receiving relay. By keeping the battery voltage within fairly close limits, reliable operation on smaller currents may be depended upon. Where desired, advantage may be taken of the closer frequency regulation obtained in this manner to secure greater signaling range.

The maximum output capacity of this interrupter is about three-fourths of a watt. The output voltage varies from about 25 volts at no-load, to 20 volts when the load is 35 milliamperes and 12 volts for a load of 60 milliamperes.

In certain of the signaling tests over short distances, a simplified form of the above interrupter was used. Under the testing conditions in this case, a smaller 135-cycle output was sufficient for the purpose and it was possible to reduce the size of the filter for the interrupter and to operate it with a 6-volt battery instead of a 24-volt battery.

Automatic Selective Signaling System

This signaling system may be adapted readily to automatic selective operation, whereby any one out of a

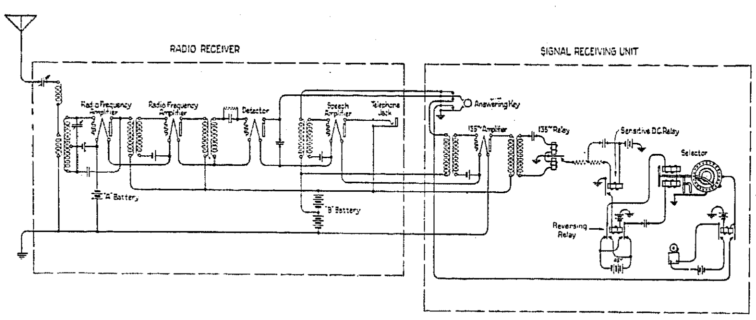

Fig. 12—135-Cycle Selective Signaling System—Circuit Arrangement of Receiving Apparatus

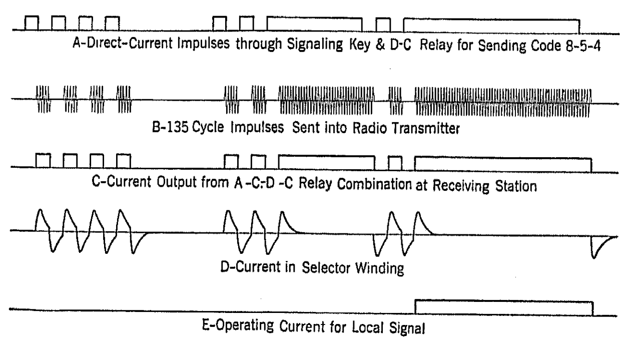

Fig. 13—Form of Transmitted and Received Currents in Operation of Selective Signaling System

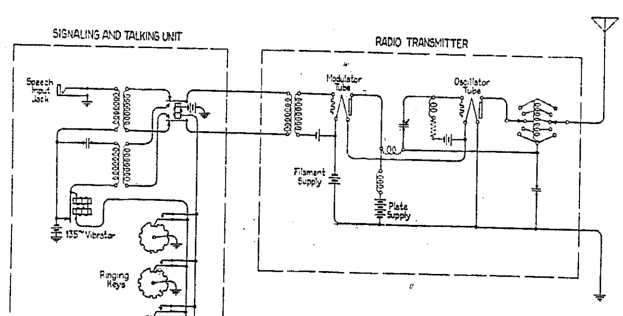

Fig. 11—135-Cycle Selective Signaling System—Circuit Arrangement of Transmitting Apparatus

Fig. 10 combines the voltage-frequency curve for the interrupter and the frequency-current characteristic of the relay to indicate directly how variations in the voltage applied to the interrupter and the consequent changes in output frequency may, under

number of stations on the same wave length may be signaled individually, or all may be signaled simultaneously. This form of the system is expected to be particularly useful in radio telephony, since a number of intercommunicating stations may often be involved as in the marine and point-to-point services. The illustrations which follow will give a picture of a typical arrangement of the automatic selective system.

From Fig. 11 the operation of the circuit at the transmitting end is seen to be as follows: The signaling key for the station which it is desired to call is operated and serves to produce a series of direct-current impulses in the form of a code corresponding to that assigned to the called station. For example, if a certain station is desired whose code signal is 8-5-4, a series of direct-current impulses suitable to indicate this number are sent out. These direct-current impulses operate at first a direct-current signal-transmitting relay which connects to the radio transmitter corresponding impulses of 135-cycle current, in such a manner as to modulate the outgoing carrier wave with current of this frequency

in a coded series of impulses each similar to the single impulse described in connection with the basic system.

As shown in Fig. 12, at the receiving end the radio receiver serves to detect the 135-cycle signals in the manner described in connection with the basic system, and these signals are sent into the alternating-current relay which operates in accordance with the code originally transmitted. This causes the sensitive direct-current relay to operate in accordance with the code and to produce in a local circuit direct-current impulses corresponding to the original impulses sent out at the transmitting end. These impulses then serve to operate a reversing relay which reverses the potential applied to a condenser in series with a stepping mechanism known as the selector, such that when the proper combination of impulses is received, the mechanism closes a circuit arranged to operate the desired local signal.

The functioning of the selective system may be followed in greater detail, by considering the form which the signal takes at various stages. Fig. 13 shows graphically the general form of the signaling currents in the successive steps necessary to transmit a typical code signal, such as 8-5-4.

The form of the original code signal, as applied by means of the sending key to the winding of the direct-current signal-transmitting relay, is shown at *A*. It is seen from this that the number of impulses sent is equal to each of the numbers in the code, either the making or breaking of the current (and consequently either the closing or opening of the signal-transmitting relay) counting as one impulse. This is due to the use of reversals in the final receiving operation, as will be explained later.

Each time the signal-transmitting relay is closed by the direct current applied through the sending key, 135-cycle current is supplied through the contacts of this

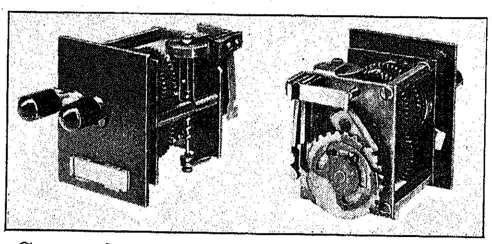

FIG. 14—CODE SENDING KEY FOR PARTICULAR STATION

relay to the radio transmitter, thus the signaling currents impressed on the radio transmitter for the code signal 8-5-4 are as shown at *B*.

These coded impulses of 135-cycle current serve to modulate the transmitted radio wave so that the antenna current is similar to that previously shown for the basic system, excepting that the 135-cycle modulation of the carrier is interrupted in accordance with the code.

The incoming current at the receiving station is similar in form to the transmitted antenna current.

The component of the detector output which is useful in transmitting the signal consists in 135-cycle impulses which are similar in form to those sent into the radio transmitter, as previously shown at *B*.

The operation of the alternating-current relay, as previously explained, serves to operate the sensitive direct-current relay in accordance with the transmitted code. The contacts of this relay close and open the circuit through the reversing relay. The current in the winding of the reversing relay is as shown at *C*.

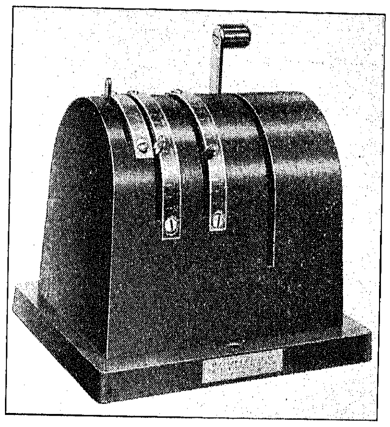

FIG. 15—MASTER CODE SENDING KEY

The reversing relay reverses the potential applied to the condenser in series with the selector winding. The selector is arranged so that it operates on the charge and discharge of this condenser. The operation of this relay reverses the battery connections to the condenser and selector, causing the condenser to discharge and charge to the opposite polarity whenever the relay picks up or releases, and it is this charging current which operates the selector. These reversals take place in accordance with the original code and produce a current in the selector winding as shown at *D*. When the proper code is transmitted, the selector closes a local circuit causing direct current, as shown at *E*, to operate a signal. The final impulse of the series of impulses shown at *D* causes the selector to release and return to normal.

The apparatus employed in this typical arrangement of the system is of a type which has been used in connection with railway dispatching systems and is consequently available in a reliable commercial form. The selecting apparatus consists of the code sending key and the receiving selector mechanism.

Fig. 14 shows the structure of one type of sending key used for this purpose. This key is set to give the desired code for a particular station. Thus, at the sending end it is necessary to have a separate sending key for each station to be signaled.

Fig. 15 shows the structure of a master sending key. This is arranged so that it may be adjusted by the operator to send out any desired code in the system.

Thus, where this type of key is used, but one is required at the sending end for signaling all stations.

Fig. 16 shows the structure of the receiving selector mechanism with the cover removed. This piece of apparatus consists essentially of a polar relay with a ratchet attachment so arranged that successive operations of the relay, at the proper speed, cause the stepping around of a contact wheel. Stop-pins are provided at certain points to prevent the contact wheel from returning to its normal position when the regular sequence of stepping is interrupted at these points. Any interruption of the regular sequence of stepping when the contact wheel is at any other point causes it to release. When the contact wheel has operated over 17 steps a contact is made which operates a signal. Thus, it is seen that to operate the selector so as to give a signal, the direct-current pulses must occur in the proper sequence and the pauses between the groups of pulses must occur at points where stop-pins are located.

The apparatus which has been described is arranged so that as many as 78 stations on one wave length may be signaled separately. The same apparatus can also be arranged so that at each one of the 78 stations, four separate supplementary stations can be individually signaled. For example, if a marine radio telephone system is involved, any one of four stations on each of 78 boats could be signaled separately. With a further slight modification in the apparatus, the same system is capable of being extended to permit the separate signaling of any one out of more than 200 stations. In each of these cases it is also possible to signal all of the stations simultaneously, when desired.

Fig. 17 shows how a system like that which has just been described may be arranged for two-way operation. This embodies a duplication at both ends of the features of the one-way system. With such an arrangement, any one station of a number operating on a given wave length may signal any other station in the same system, without calling in stations not desired. Such a system might be used, for example, between ships equipped with radio telephone systems or between the ships and the shore, where signaling any one of several shore stations might be desired. It might also be used for intercommunication between a number of fixed stations in a point-to-point system.

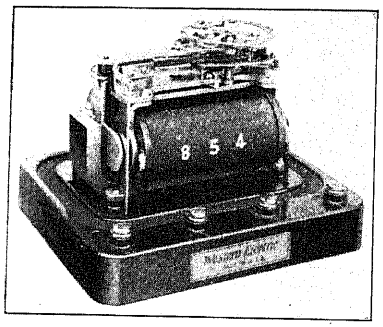

FIG. 16—RECEIVING SELECTOR MECHANISM

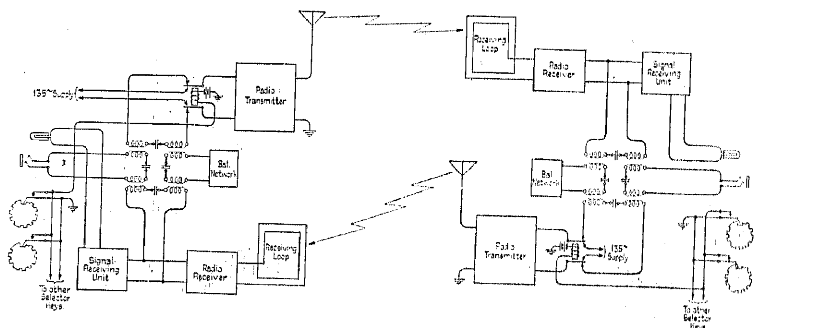

FIG. 17—SIMPLIFIED DIAGRAM OF TWO-WAY RADIO SYSTEM ARRANGED FOR AUTOMATIC SELECTIVE SIGNALING

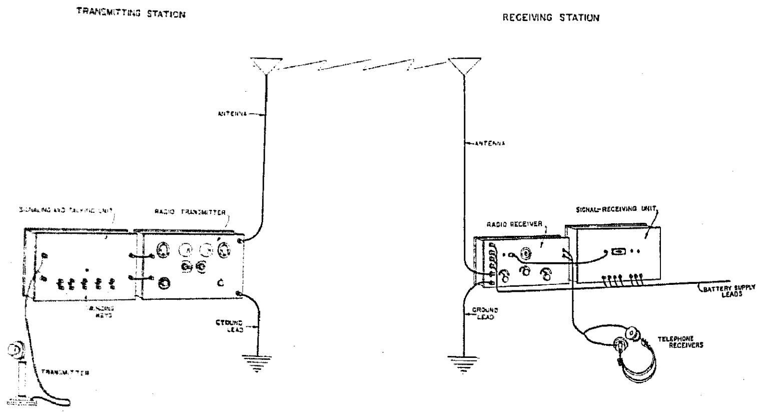

FIG. 18—135-CYCLE SELECTIVE SIGNALING SYSTEM—TYPICAL ARRANGEMENT OF APPARATUS FOR ONE-WAY OPERATION

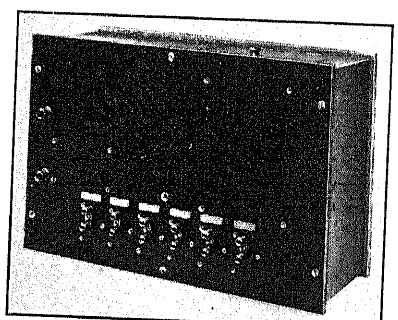

FIG. 19—SIGNALING AND TALKING UNIT

FORM AND ASSEMBLY OF EQUIPMENT

In the possible uses of this signaling system which have been mentioned as likely to have the most immediate commercial application, the signaling apparatus is a part of the radio attendant's equipment rather than the telephone subscriber's apparatus. The apparatus chosen for the purpose is, therefore, in a form which is well suited to central station use, although it has no features which would prevent its being used conveniently at a subscriber's station if the service required it.

In assembling the signaling equipment a uniform panel arrangement has been developed, with the idea that the various units might be used interchangeably in meeting the requirements of different types of installations. To this end, all apparatus has been mounted on panels

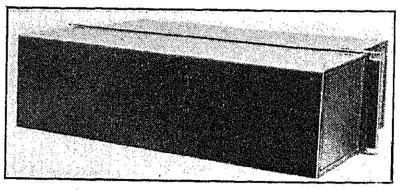

FIG. 20—ASSEMBLY OF 135-CYCLE INTERRUPTER

of a uniform length of 19 inches. The height of the different panels has varied according to the amount of apparatus in each unit, but this vertical dimension has in each case been a whole multiple of the basic dimension of 1¾ inches.

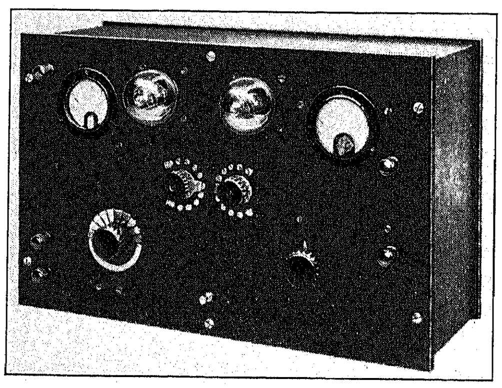

FIG. 21—EXPERIMENTAL RADIO TRANSMITTER UNIT

By this means it is possible to mount the units in any desired manner. If, for example, it is desired to locate the radio and signaling apparatus on a desk or table, each equipment unit constitutes the front panel of a separate box. Fig. 18, shows the various units required

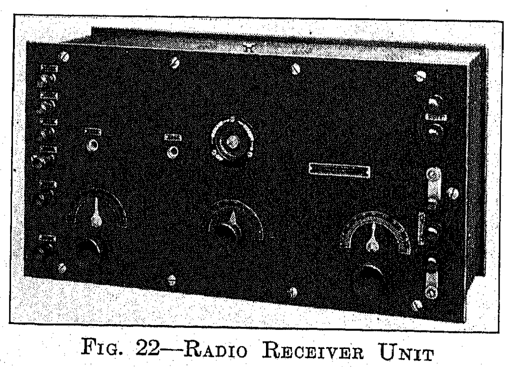

FIG. 22—RADIO RECEIVER UNIT

to make up a complete one-way system mounted in this manner.

Fig. 19 shows in more detail the signaling and talking unit of this group. This unit includes the sending keys, a simplified form of 135-cycle interrupter suited to use with the experimental set, and a six-volt dry cell battery for operating the interrupter and signal-transmitting relay. It also includes an induction coil and talking battery for use with a telephone transmitter.

Fig. 20 shows a separate 135-cycle interrupter unit which also employs the standard panel assembly. Removable covers are provided on both the front and back of the panel to protect the apparatus from

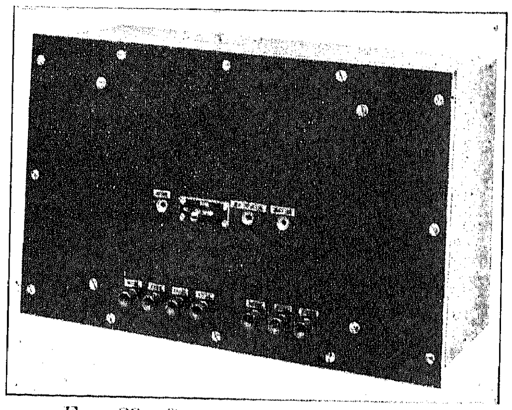

FIG. 23—SIGNAL RECEIVING UNIT

mechanical injury. This interrupter is of a type adapted to commercial use with radio transmitters of various forms and output capacities. It employs the circuit arrangement previously described in the section on "135-cycle Supply."

Fig. 21 shows an experimental radio transmitter unit of the type which was used in making certain of the

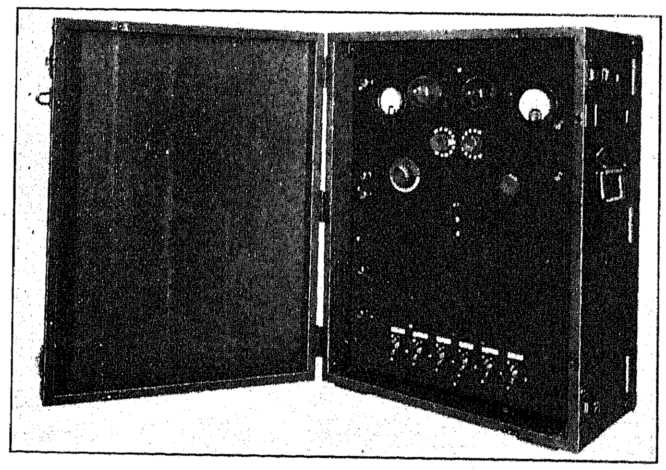

FIG. 24—ASSEMBLY OF EXPERIMENTAL RADIO TRANSMITTER WITH SIGNALING AND TALKING UNIT IN CABINET

signaling tests over short distances. As explained in the section describing the basic system, this transmitter has an output of about 5 watts at 200 to 450 meters.

Fig. 22 shows the assembly of one of the radio receiver units used in the tests. This is of the radio frequency amplifier type employing *N* tubes, such as would be employed in a commercial installation as in the Persian point-to-point system.

Fig. 23 shows the signal-receiving unit for automatic selective signaling. This includes the alternating-current relay, the selector mechanism and the necessary associated relays to respond to the incoming signal when connected to the detector tube of an ordinary radio receiver. This unit also includes an N tube amplifier for use when it is desired to secure the maximum signaling range. In this unit, terminals are provided on the rear of the panel in addition to the binding posts on the front, so that when the panel is removed from the box, rear wiring can be used if desired.

If it is desired to associate several panels together in one cabinet, each panel is detached from the box and mounted on the vertical supports which are provided in the standard cabinets. Fig. 24 shows the experimental radio transmitter together with the signaling and talking unit assembled in one of these standard cabinets which are designed to house equipment of any type mounted on standard panels. Fig. 25 shows the radio receiver and signal-receiving unit in a similar cabinet.

In some cases it may be desirable to mount the radio receiving apparatus, signal-receiving unit, signaling and talking unit and other associated apparatus together on one rack, without employing cabinets. Fig. 26 shows how this might be accomplished, the various panels of standard length being assembled on a standard rack suited to mount many different types of units employing

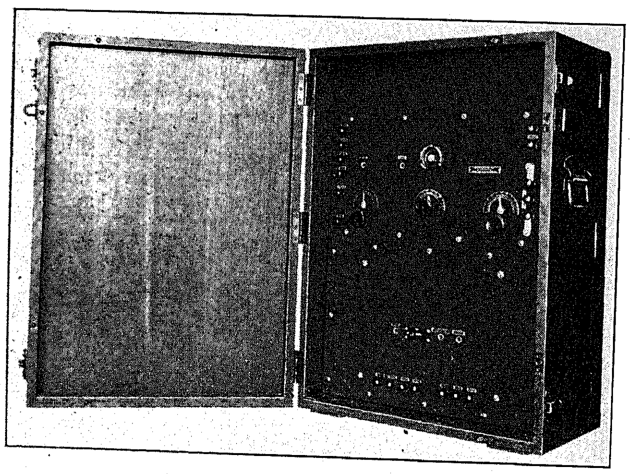

Fig. 25—Assembly of Radio Receiver and Signal Receiving Unit in Cabinet

this type of design. In this case, the radio transmitter is not included with the receiving apparatus, as it is assumed that in a commercial installation it may be of a larger and more powerful type than the experimental one previously shown for purposes of illustration. The 135-cycle interrupter is also shown as a separate unit, since such a separate interrupter may be required if the output of a small interrupter of the type which was included in the signaling and talking unit for convenience in the experimental work, is insufficient.

Review of System Characteristics

In considering the application to radio telephony of the signaling system which has been described, it is of interest to review certain of its outstanding characteristics. These may be briefly summarized as follows:

(1) The selectivity of the signaling system is such that interference of the kinds ordinarily experienced in radio telephony will make speech unintelligible before it will cause the signaling system to fail. Due to this high degree of selectivity, the signaling apparatus will operate if the radio system is adjusted so as to permit commercial transmission of speech, when the field strength is as low as it is desirable to use for the latter. With the types of radio apparatus which have been described, reliable operation of the signaling system has been secured with a field strength as low as 100 microvolts per meter.

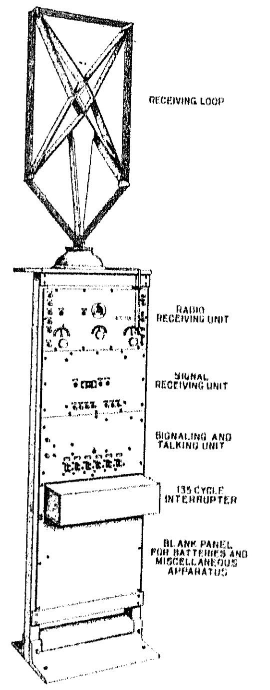

Fig. 26—Typical Assembly Arrangement for Panel Mounted Radio Receiving and Signaling Apparatus on Standard Rack

(2) The sensitivity of the signal-receiving apparatus is such that the energy output obtainable from the smallest available types of vacuum tubes is more than sufficient to operate it satisfactorily. The type N vacuum tube can give an output of several hundred microwatts when operated as an amplifier, while the sensitive 135-cycle relay used in this signaling system will operate with as little as 30 microwatts.

(3) The system readily permits automatic selective signaling, whereby any one station out of a number on the same wave length may be signaled separately, as well as being adapted to use where only one sending and one receiving station are concerned. Seventy-eight stations on one wave length may be signaled separately with the apparatus which has been described while by employing other apparatus of a similar type which is at present available, over 200 stations may be signaled separately. The system is also adapted to permit the simultaneous signaling of all of the stations which may be included in the system on one wave length.

(4) The form and arrangement of the signaling apparatus are practically independent of the type of radio service, the power capacity of the radio system and the wave length used. It is applicable to ordinary radio transmitters and receivers without requiring modification of the radio equipment, and at the same time is simple in form and not high in cost as compared with the remainder of the radio equipment.

Telephone Transformers

BY W. L. CASPER

Research Laboratories of the American Telephone and Telegraph Company, and the Western Electric Company, Incorporated.

Review of the Subject.—In the communication art transformers are used to transfer inductively the energy of speech currents from one electric circuit to another. In addition to this primary function which must be efficiently performed without distorting the speech significance of the transmitted energy, there is a variety of secondary functions such as making possible the super-position of phantom circuits on ordinary telephone circuits, discriminating between speech and telegraph or signaling frequencies, isolating circuits carrying direct current, and preventing inductive interference between adjacent circuits.

A discussion is presented of the frequency range over which telephone transformers must operate efficiently in transferring energy between two circuits and the three most common limiting impedance combinations of these circuits, namely, both circuits resistances, one circuit a resistance and the other a positive reactance and one circuit a resistance and the other a negative reactance. The efficiency with which energy is transmitted is measured by comparison with an ideal transformer which is one that introduces no losses and has the best ratio to connect the two circuits. In studying its action the transformer is replaced by its equivalent T network which affords a ready means of analyzing its losses. The variation of the transformer losses with frequency is discussed for the three above mentioned combinations of circuit impedances and characteristic curves are shown for transformers of different mutual impedances. Characteristics are also given showing the operation of the input transformer into the vacuum tube as the mutual impedance and the transformer ratio are varied. The circuit conditions of the input transformer represent a common special case of the third combination of circuit impedances.

The mechanical construction of various transformers is shown, namely, that of the ordinary battery supply repeating coil, of the telephone induction coil, and of three more recent types of transformers used principally in various vacuum tube circuits such as telephone repeaters, carrier frequency and radio circuits. These transformers are all constructed so as to give the desired accuracy of speech transmission under their particular circuit conditions. The climatic conditions present in the widely distributed telephone plant have been carefully considered and the transformers designed to maintain their initial efficiency over a long period of years.

INTRODUCTION

THE transformers used in the telephone plant are required to transmit speech or signaling currents from one electrical circuit to another in such a way as to obtain maximum transfer of power. They differ in their required action from power transformers in two main respects. They have to transmit milliwatts efficiently instead of kilowatts and must operate efficiently under a variety of conditions of voltage, frequency, etc., instead of under single fixed conditions. These various requirements of operation make it necessary in designing a telephone transformer to proportion it differently from a power transformer.

The requirements of circuits in which telephone transformers are used make it necessary to consider their efficiency in detail over a wide range of frequency and at the same time make sure in each particular case that they have characteristics apart from this efficiency which will enable the circuits to function properly. Such other characteristics, one or more of which may be required of a transformer, are:

1. The efficient transmission of telephone currents while carrying super-posed direct current as in the cord circuit battery supply repeating coil.

2. A high degree of impedance balance between the windings in order: (1) to avoid unbalancing the circuit and rendering it subject to noise or cross-talk troubles; (2) to limit cross-talk in closely associated circuits as in the case of the phantom circuit repeating coil in which the balance required is very precise, the two phantom circuit windings being balanced to about 0.01 per cent; or (3) to prevent sustained oscillations or singing in a two-way telephone repeater as in the case of the repeater output transformer.

3. High efficiency as a low-frequency power transformer, for example, at 16⅔-cycle signaling frequency, as well as high efficiency as a telephone speech frequency transformer.

4. Low efficiency as a power transformer at the frequencies of interruption of direct current used in Morse telegraph as well as high efficiency as an audio frequency transformer. This low power efficiency is necessary in order to reduce troubles, such as, noise interference, false operation of relays and acoustic shock when the same lines are used for both telephone and telegraph.

5. Impedance transformation closely approximating that obtained with an ideal transformer as in the line transformers in circuits in which two-way telephone repeaters are employed. By impedance transformation is meant the modification of the line or network impedances when viewed through the transformer.

6. Impedance transformation for a pair of transformers alike over the transmitted audio frequency range for use as the line and network transformers in two-way repeater operation.

7. Stable impedance transformation even when having been subjected to large magnetizing forces as in the line transformers in two-way telephone repeater circuits in order to maintain the required balance between line and network under all conditions of service.

8. Minimum production of harmonics due to the magnetization characteristics of the iron which would cause interference in the normal transmission frequency range, as in the line transformers on circuits which are used for the transmission of Morse telegraph in addition to speech.

9. To isolate conductively one portion of a circuit from another as in transformers used to connect grounded to metallic lines or to isolate subscriber sets

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

from the telephone lines which parallel high-tension power lines and which may therefore be exposed to large inductive disturbances.

10. To maintain the usual conductive isolation and furnish a path to ground for longitudinal currents as may be obtained with a transformer with a shield between primary and secondary windings. By a longitudinal current is meant one which flows along a circuit and returns by some path exterior to that circuit.

As the primary function of the telephone transformer is to transmit telephonic speech efficiently, this paper will be limited to this part of the subject, although the complexity of the telephone plant rarely permits a transformer to be free from the necessity of meeting one or more secondary requirements such as those mentioned above. Two winding transformers only will be discussed.

Frequency Requirements

In the ordinary telephone circuit a range of frequency of about 200 to 2500 cycles is allotted to the transmission of speech, both of these limits varying somewhat with the type of circuit. In the case of long distance lines in which it is desirable to utilize the circuits to the best economic advantage, the frequency range below 3000 cycles is allotted to speech, signaling and telegraph and above that frequency to the transmission of carrier telegraph and telephone. A transformer used for the transmission of speech currents is required to operate efficiently over the entire range of frequency transmitted.

With the present intensive use of the telephone lines, transformers may be required to transmit low-frequency signaling of 16⅔ or 20 cycles, composite ringing of 135 cycles, speech from 200 to 3000 cycles and carrier from 3000 to 30,000 cycles. This carrier frequency is divided into a number of frequency channels which are used for separate telegraph or telephone circuits. A carrier range from 3000 to 10,000 is generally used for telegraph while with carrier telephone a frequency range from 6000 to 30,000 is used.[1] In certain radio telephone circuits transformers are required to operate at frequencies of the order of 50,000 to 100,000 cycles and in radio frequency amplifiers at approximately 1,000,000 cycles. Telephone transformers may be required to operate at any one of these frequencies or frequency bands or they may be required to transmit efficiently two or more of them. Illustrations of this are the ordinary phantom circuit repeating coil which transmits low-frequency (16⅔ cycles) signaling and composite ringing (135 cycles) as well as speech, and the transformers which connect the Key West-Havana cable to the shore lines and which are designed to transmit carrier telegraph up to about 6000 cycles as well as ordinary telephonic speech.

1. Colpitts and Blackwell: "Carrier-Current Telephony and Telegraphy," Trans. A. I. E. E., Vol. 40, page 301.

In radio transmitters used for broadcasting and in Public Address Systems[2] where it is desired to transmit music and to reproduce accurately the exact quality of the speaker's voice, it is necessary that any transformers in the circuit operate efficiently at frequencies at least as low as 50 cycles and as high as 5000 cycles.[3]

In the following the operation of transformers over the voice range of frequencies only will be discussed but it is to be noted that the principles involved apply to transformers for carrier and radio frequencies as well.

Impedance Requirements

Another important factor in determining the design and operation of the transformer are the impedances of the circuits which the transformer connects. The circuit impedances, which are the impedances as measured from the place where the transformer is to be located, may be but a few ohms in magnitude or may be several megohms. They may also vary appreciably in magnitude or phase angle over the frequency range.

The circuit impedances met in the telephone plant are seldom either substantially pure resistances or reactances over the entire frequency range and in considering the action of a transformer between two such circuits at any frequency the actual impedances of the circuits at that frequency must be employed. It is impossible to discuss all possible combinations of circuit impedances here. However, with a knowledge of the action of transformers between three limiting combinations of circuit impedances an indication will be given of their operation under all conditions of importance. These three limiting impedance conditions are:

1. Sending and receiving end impedances both resistances.
2. Sending end impedance a resistance, and receiving end impedance a positive reactance.
3. Sending end impedance a resistance, and receiving end impedance a negative reactance.

It is, of course, to be understood that the sending and receiving end impedances may be interchanged. There are, in addition, three other possible limiting circuit impedance conditions—the sending and receiving end impedances both positive or negative reactances and the sending end impedance a positive reactance and the receiving end impedance a negative reactance. These three impedance conditions are less usual than the first three and it is felt to be unnecessary here to discuss in detail the action of telephone transformers in circuits of this type.

Transformer Efficiency

The telephone transformer is generally used for transmission in both directions and the usual definition

in power work for the primary as the winding which receives the energy from the supply circuit does not hold. The terms primary and secondary are therefore used simply to distinguish between the two windings without regard to the energy flow.

It can be shown that maximum power may be delivered from one circuit to another if the impedances of the circuits are equal in magnitude and opposite in phase, that is, if the resistances are equal and if the reactances annul each other. Maximum power may be delivered from one circuit to another in which the reactances annul each other and in which the resistances are not equal provided an ideal or perfect transformer of proper ratio is used to connect the circuit resistances. In the ordinary case it is not possible to annul the reactances over the entire frequency range to be transmitted and no attempt is therefore made to modify them. Under these conditions transformers are used to connect the two circuit impedances and without annuling reactances the greatest amount of power will be delivered by connecting these impedances by means of an ideal transformer of the best ratio.

By an ideal transformer is meant one which neither dissipates nor stores energy. Such a transformer has infinite primary and secondary self-impedances, infinite mutual impedance, unity coupling factor or zero leakage impedances, and zero d-c. resistances. An ideal transformer for any given circuit condition also has the best ratio to connect the circuit impedances.

It may be stated that when the circuit reactances are not annulled by the addition of reactances of the opposite sign, it is possible to deliver more power to the load impedance at certain frequencies by the use of an actual than by an ideal transformer as the transformer impedances may tend to annul the circuit reactances.

It has long been customary in dealing mathematically with a transformer to use in its place some equivalent network such as a π or a T network.[4] The use of an equivalent T network changes a coupled circuit into a simple circuit in such a way as to make it easier to see the effect of changes of the transformer constants on the transmission of the circuit. The equivalent T network of a two-winding transformer is shown in Fig. 1. in which the junction point of the three arms is considered not accessible and in which P, S and M are respectively, the primary, secondary and mutual impedances.

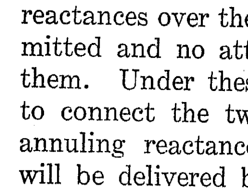

FIG. 1

The series arms a and b of the T network consist respectively of the differences of the primary and mutual impedances and the secondary and mutual impedances. The equivalent T network of the transformer is sometimes shown having series arms $P + M$ and $S + M$ and shunt arm $- M$. These two T's may be derived from the transformer impedances depending on whether the secondary is connected to give a received current in one direction or the other. The T shown here is the most convenient for ordinary considerations. Considering for the present a unity ratio transformer, the arm a will contain the d-c. resistance of the primary and the arm b the d-c. resistance of the secondary. In addition, the leakage impedance will be divided between them. Whether the leakage impedance should properly be considered

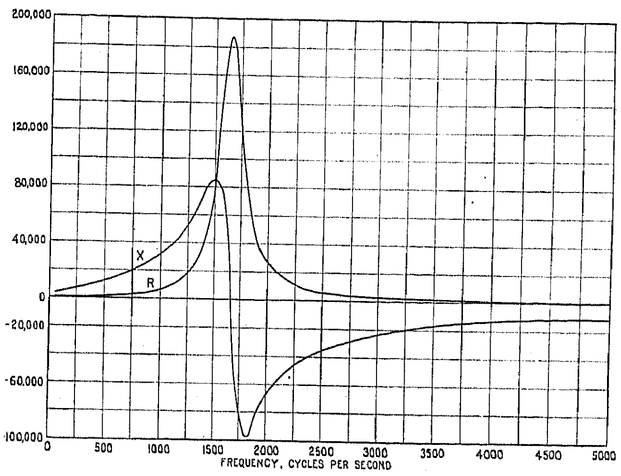

FIG. 2—MUTUAL IMPEDANCE M OF A PHANTOM CIRCUIT REPEATING COIL
X Effective reactance—ohms
R Effective resistance—ohms

principally in the arm a or principally in the arm b or divided equally between them depends on the relative location of the primary and secondary windings. However, in the ordinary case the coupling factor is so near unity and the leakage impedance is so small in comparison with the primary, mutual and secondary impedances that practically no error is introduced if it is assumed to be divided equally between them.

The shunt arm c of the equivalent T network contains the mutual impedance M. This mutual impedance equals $K \sqrt{P_0 S_0}$ where P_0 and S_0 are the primary and secondary impedances less their respective d-c. resistances, and where K is the coupling factor. The coupling factor K has a phase angle in actual transformers but where the coupling factor is nearly unity the angle may usually be disregarded. The mutual impedance is a complex quantity as are also the primary and secondary impedances of all usual transformers. As the mutual impedance is dependent on P_0 and S_0, any factors which enter into P_0 and S_0 will also enter into M. The reactance components of these impedances depend on the number and distribution of turns in the windings and the dimensions and permeability of the core. The resistance component is made up of an effective resistance due to hysteresis, eddy current and dielectric losses.

The distributed or lumped capacities of the windings are best considered in their effective values. These

4. Campbell: "Cissoidal Oscillation" TRANS. A. I. E. E., Vol. 30, Part 2, page 873.

effective capacities may be regarded as shunted across the primary or secondary of the transformer or may be considered as located across M of the arm c of the equivalent T of the transformer. If this effective capacity is considered in shunt with M and combined in it, both the resistance and the reactance of M will have components due to the effect of this capacity. The effective resistance and effective reactance of M will then go through the usual curves for parallel resonance as shown in Fig. 2 for a typical phantom circuit repeating coil.

One other factor frequently enters into the determination of the effective value of M as well as P_0 and S_0. In some circuits, in order to economize on the amount of apparatus necessary, a direct current is allowed to flow through the primary or secondary windings of the transformer. This causes a uni-directional magnetizing force in the core in addition to the a-c. magnetizing force of the speech current. This d-c. magnetization causes a decrease in M from the initial value or value with no d-c. magnetization, depending upon the strength of this magnetization and the reluctance of the magnetic circuit.

The series arms of the equivalent T of the unity ratio transformer are thus impedances consisting of the d-c. resistances and the leakage impedances and are usually relatively small compared with the circuit impedances while the shunt arm is the mutual impedance which is usually large compared with the circuit impedances. The simplicity of the equivalent T network of the unity ratio transformer is very useful and convenient in studying the effect of the transformer in producing losses. With an inequality ratio transformer, however, the arms a and b which equal $P-M$ and $S-M$, respectively, do not appear as small impedances. For instance, if P is larger than S, $P-M$ will be a large positive impedance and $S-M$ will be a large negative impedance and the T network has no decided advantage, from a mathematical standpoint over the ordinary transformer network.

Fig. 3 shows a transformer operating between the sending end impedance Z_1 and receiving end impedance Z_2. Z_2 may be considered less than Z_1. The actual sending and receiving circuits in telephone work are usually quite complex, each consisting of numerous series and shunt elements. According to Thévenins theorem[5] any electromotive force acting through any circuit no matter how complex will produce the same current in any receiving impedance as will some other electromotive force bearing a definite relation to the first electromotive force and acting directly in series with the impedance which would be obtained by a measurement of the circuit looking away from the terminals from which the receiving circuit has been disconnected. From this theorem it may be shown that the complex sending and receiving circuits may be replaced respectively by simple series impedances Z_1 and Z_2 which are the impedances of the complex sending and receiving circuits looking away from the place where it is desired to join them, and a transformer or any other structure studied between these impedances will act identically as if connected between the more complex actual circuits.

5. Comptes Rendus for 1883, Vol. 97, page 159.

If the transformer shown in Fig. 3 were the ideal transformer to connect the circuit impedances Z_1 and Z_2, the best impedance ratio could be found as follows: The current received through the impedance Z_2 is

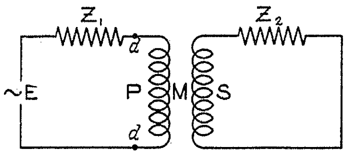

Fig. 3

$$I = \frac{E\,M}{(Z_1 + P)\,(Z_2 + S) - M^2}$$

But since in the ideal transformer P, S and M are infinite pure reactances and the coupling factor is unity and $M = \sqrt{P\,S}$

$$I = \frac{E\,M}{Z_1\,S + Z_2\,P}$$

This expression may be shown to be a maximum when the ratio P/S is equal to the absolute magnitude of Z_1 / Z_2.

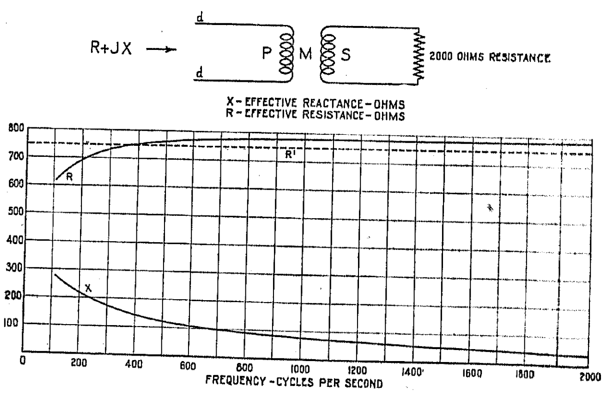

Fig. 4—Impedance Measured at d-d Ratio of Impedances P:S = 1:2.66

A transformer designed for the circuit of Fig. 3 should, therefore, have an impedance ratio $R = P/S = Z_1/Z_2$. With an ideal transformer of such a ratio the impedance at d, d looking toward the receiving end with the sending end open at d, d will equal Z_1. Such an impedance characteristic as measured with an actual inequality ratio transformer having an impedance ratio of 1:2.66 and a receiving end impedance Z_2 of 2000 ohms non-inductive resistance is shown as $R+j\,X$ in Fig. 4. The corresponding characteristic for an ideal transformer of the same ratio is shown as R^1. These characteristics show that an actual transformer in transforming or

modifying the circuit impedance adds both a resistance and a reactance component to the value of the circuit impedance divided by the transformer impedance ratio except at low frequencies where the transformer has a considerable shunting effect on the circuit impedance as explained later on, and where the resistance falls below the value obtained with an ideal transformer and the reactance is increased over its value at higher frequencies.

It may be stated that under certain circuit conditions it is quite important that the transformer give a transformation of the circuit impedance which is nearly ideal in order to limit the impedance irregularity introduced in the line.

For analysis or design work involving inequality ratio transformers the circuit of Fig. 3 may be reduced to a circuit in which the impedances Z_1 and Z_2 have the same absolute magnitude and the equivalent T network of the transformer may be reduced to an equivalent T of an equivalent unity ratio transformer. In this way the disadvantages of the equivalent T network of the inequality ratio transformer are avoided. This transformation is made by multiplying the circuit impedance Z_2 and the secondary impedance S by the impedance ratio R and multiplying the mutual impedance M of the transformer by $\sqrt{R}$ as shown in Fig. 5. As $P_0 = M\sqrt{R}/K$, $P - M\sqrt{R}$ will be a small positive quantity, and as $S_0 = M/K\sqrt{R}$, $S R - M\sqrt{R}$ will be a small positive quantity. $M\sqrt{R}$ will be a large positive quantity. This treatment of the transformer presupposes that P_0 and S_0 have the same phase angle. This is not necessarily precise in the case of all transformers but will hold with sufficient accuracy for the usual type of iron core transformers.

The series arms a and b and the shunt arm c of the equivalent unity ratio T network consist respectively of the d-c. resistances of the primary and secondary plus the leakage impedance, and the mutual impedance, all reduced to terms of the sending end impedance Z_1. In this transformation a circuit such as is shown in Fig. 3 is changed to an equivalent circuit as shown in Fig. 5. This equivalent circuit gives a received current which is less than the received current of the circuit of Fig. 3 by the factor $I/\sqrt{R}$ but the received power is the same in each case. This equivalent T of the equivalent unity ratio transformer consisting of relatively small impedances in series with the circuit and a relatively high impedance as a shunt across the circuit, furnishes an easy means of studying the losses produced by a transformer.

The telephone engineer as well as the power engineer is concerned with the delivery of power. In power work the efficiency of a device is usually expressed in per cent as the ratio of the power delivered to the power supplied or the watts output divided by the watts input. In telephone work it is customary to consider the losses caused by the device rather than its efficiency. These losses are determined by the change in received power caused by the insertion of the device in the circuit. They are expressed in terms of the attenuation of a length (in miles) of standard cable (*M. S. C.*). This unit is such that if two currents I_1 and I_2 flow through the same impedance (load) delivering powers W_1 and W_2 respectively, the number of miles corresponding to the current or power ratios is given by the relation $M\,S\,C = 21.12 \log_{10} I_1/I_2 = 10.56 \log_{10} W_1/W_2$. It can be shown from the above that for small losses a change in current ratio of 1 per cent corresponds approximately to 0.1 mile of standard cable.

In inserting an ideal transformer of best ratio between two circuits of different impedance an increased current is obtained through the receiving end impedance and a transmission gain is effected. If an actual transformer were used in place of the ideal transformer a somewhat lesser gain would usually be obtained due to the losses of the transformer. The transformer loss is determined by the ratio of the received current with the transformer in circuit to the received current with the ideal transformer in circuit.

It is to be noted that the above mentioned ratio of received currents which is used as the basis of the transmission loss of the telephone transformer takes no account of the phase angle of the load impedance and bears no direct relation to the ratio of the power output to the power input. There is, therefore, no very simple relation between the miles loss and the power efficiency. For example, a telephone transformer might have equally low losses when operating into a pure reactance as when operating into a resistance, whereas, the power efficiency approaches zero when the phase angle of the load approaches 90 deg. When operating into a resistance load the current ratio of the telephone transformer approaches the square root of the power efficiency for very efficient transformers.

Transformer Operating Between Resistances

From the circuit of Fig. 5, it can easily be seen that provided the circuit impedances approximate resistances, the smaller $P - M\sqrt{R}$ and $S R - M\sqrt{R}$ are and the larger $M\sqrt{R}$ is, the smaller will be the loss caused by the transformer. The speech current used in most telephone circuits is so minute that the permeability of the transformer cores remains at approximately its initial value regardless of what winding is placed on the transformer. An increase in the mutual impedance will lower the shunt losses, but will also cause an increase in the series losses, as there will be an increase in the d-c. resistance and the leakage impedance in practically the same ratio as the increase in the mutual impedance. If the capacity in the transformer windings is neglected, it will be noted that both the series and shunt arms of the

transformer T contain components of impedances which increase with the frequency and that at zero frequency the shunt loss will be infinitely great and at infinite frequency the series loss will be infinitely great while at intermediate frequencies these losses will be finite. It is, therefore, evident that for a given transformer there will be some frequency at which the transformer operates with minimum losses, and that for operation at a given frequency there is a value of mutual impedance for any given transformer structure at which the losses are a minimum.

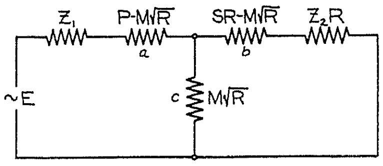

Fig. 5

The transformer of Fig. 5 when operating between non-inductive resistance impedances will produce a loss-frequency characteristic, as shown in Fig. 6, in which the various curves are for a fixed circuit condition and for several different windings or values of mutual impedance. In these characteristics the d-c. resistance of the winding produces a loss which is practically independent of frequency. There is an increase in loss at the lower part of the frequency range due to the increased shunting effect of $M\sqrt{R}$ at the lower frequencies. This loss decreases as the frequency

increases. Although in any actual case the departure of the angle of $M\sqrt{R}$ from 90 deg. may cause an appreciable part of the shunting loss it is usually possible to obtain greater reduction in loss by increasing the absolute magnitude of this impedance than by increasing the phase angle. If the transformer has sufficient capacity in and between the windings to affect appreciably this impedance, it may also affect the loss due to it. In some transformers, the effective capacity may be large enough to cause resonance within the frequency range which is transmitted efficiently. This would cause $M\sqrt{R}$ to have a maximum value at the resonance frequency, and the loss due to the shunt arm would go through a minimum value at this frequency. If the capacity is large enough to produce this resonance near the lower end of the transmited frequency range, its effect at the higher frequencies in decreasing the magnitude of $M\sqrt{R}$ might be sufficient to cause an appreciable loss at these frequencies.

The magnitude of the leakage impedances, which, together with the d-c. resistance, make up the series arms of the T, also tends to increase the loss at the upper frequencies, as this impedance increases with the frequency. In cases where both the leakage and the capacity are high, the effect of one may to some extent tend to lessen the loss produced by the other at some frequencies.

It is to be noted that as the leakage impedance generally consists of a larger reactance than effective resistance, this impedance has far less effect in determining the value of received current through Z_2 when the circuit impedances are resistances than does the d-c. resistance.

In the design of telephone transformers to operate with little distortion between resistance impedances, it follows that the transformer impedance ratio is determined as the ratio of the circuit impedances between which the transformer operates, the loss at the lower frequencies is determined principally by the impedance of the shunt arm of the T network, $M\sqrt{R}$, and the loss at the higher frequencies is determined principally by the leakage impedance and the effective capacity. The d-c. resistance adds a loss which is practically constant over the frequency range.

The determination of the windings of such a transformer would be made as follows, assuming for the present that the transformer construction has already been decided upon. The impedance ratio of the transformer is calculated as the ratio of the circuit impedances. Using this ratio, the winding is calculated, choosing such sizes of wire as will make the ratio of d-c. resistance of primary and secondary the same as the impedance ratio, and will completely fill the winding space with an allowance for commercial variations in the winding space, dimensions, wire diameter, winding and insulation. As the transformer dimensions and core permeability (initial or low magnetic density value) are known, the inductance for a given number of turns may be calculated as proportional to the square of the turns or from a trial winding the relation between impedance and number of turns may be obtained. The coupling factor and effective capacity are best obtained by a trial design using the arrangement of winding which is expected to be used in the final design. All the information for determining equivalent T networks is thus available.

The loss curves for different values of mutual impedance may be predetermined from these equivalent networks and the desired winding chosen from these characteristics. Such a series of curves for a transformer operating between resistance impedances is shown in Fig. 6. In the table in this figure is shown the ratio of the shunt arm, $M \sqrt{R}$, of the equivalent T network of the equivalent unity ratio transformer at 1000 cycles, to the sending end impedance Z_1.

Fig. 7 shows the transmission loss characteristic of

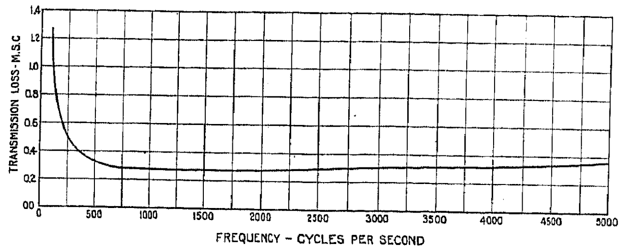

FIG. 7—TRANSMISSION LOSS CHARACTERISTIC OF PHANTOM CIRCUIT REPEATING COIL OPERATING BETWEEN 1830-OHM RESISTANCE LINES

a phantom circuit repeating coil operating between non-inductive resistance lines of 1830 ohms. The mutual impedance-frequency characteristic of this repeating coil was shown in Fig. 2 from which it may be noted that the reactance component of this impedance is negative above a frequency of 1700 cycles per second. Although above this frequency the mutual impedance decreases, its magnitude is so great as compared with that of the line impedance that the loss due to it is practically negligible at a frequency of 5000 cycles per second.

TRANSFORMER OPERATING BETWEEN A RESISTANCE AND A POSITIVE REACTANCE

The case of a transformer operating into a pure positive reactance is, of course, hypothetical and no energy would be delivered unless the reactance had a resistance associated with it. In any actual case, there is always a resistance component to this impedance, but for this discussion it is assumed that the resistance component is practically zero.

In this circuit condition we have one impedance which is independent of the frequency and another which is directly proportional to the frequency. By properly choosing the transformer ratio it is possible to match the circuit impedances at any particular frequency and deliver maximum energy at this frequency. At other frequencies there would be a transmission loss due to this failure to match impedances, and it follows that even with an ideal transformer, it is not possible to obtain uniform efficiency over a range of frequency, and that by selecting the proper ratio, maximum efficiency may be obtained at any desired frequency.

Fig. 8, curve A, shows the transmission loss, in miles due to the introduction of an ideal transformer of fixed ratio between the sending end resistance Z_1 and the receiving end reactance Z_2. This transformer serves to match these impedances at the frequency F_1 and the curve shows the loss above what would be obtained if the impedances were matched at any other frequency. Curve B is a similar characteristic for an ideal transformer, matching impedances at frequency F_2.

Fig. 5 may be considered to represent the equivalent unity ratio circuit (Z_2 being less than Z_1) with the T network of the equivalent unity ratio transformer in the circuit. If, for the present the effect of capacity in the mutual impedance is neglected, the losses produced by the components of the series arms of the transformer operating under these circuit conditions, that is the d-c. resistance and the leakage reactance, are approximately of equal importance. The d-c. resistance causes a loss which is finite at low frequencies and decreases to zero at infinite frequency while the leakage reactance causes a loss which is finite at infinite frequency and reduces to zero at zero frequency. The mutual impedance produces a loss which is infinite at zero frequency and decreases to a relatively small finite value at infinite frequency.

If the mutual impedance contains a capacity component, a reduction of loss may be produced at certain frequencies due to resonance of the capacity reactance with the mutual, leakage and receiving end reactances. This may even give a gain over the characteristic of the ideal transformer for a limited frequency range, but

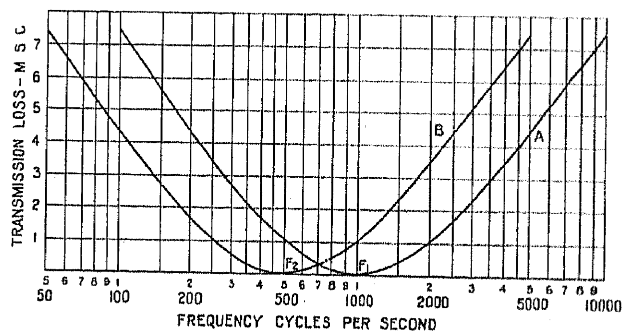

FIG. 8—TRANSFORMER CONNECTING A RESISTANCE TO A POSITIVE REACTANCE

"A" and "B" ideal transformers of impedance ratio R/X at frequency "F_1" and "F_2" respectively.

above the resonant frequency an increased loss is produced which approaches infinity.

Characteristics A, B, C and D of Fig. 9 show measurements of actual transformers having different values of mutual impedance and the proper ratio to match impedances at 1000 cycles. The transmission losses shown are the losses of the actual transformers compared with the corresponding ideal transformer of the same ratio. The ideal transformer, itself, has a loss characteristic causing distortion which varies with the frequency as shown in Fig. 8. The ratio of

$M\sqrt{R}:Z_1$ at 1000 cycles is shown in the table. These transformers are the same as those shown in Fig. 6 as operating between resistances. The losses at the upper frequencies are reduced somewhat by the winding capacity. It may be noticed that of the transformers whose characteristics are shown in Fig. 9, transformer B introduces minimum loss.

In designing a transformer to connect a resistance to a positive reactance, the impedance ratio of the transformer is determined as the ratio of the circuit

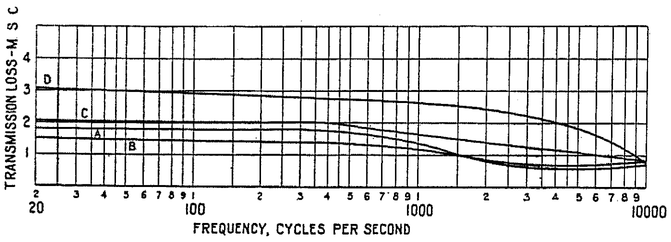

FIG. 9—TRANSFORMERS OPERATING BETWEEN A RESISTANCE AND A POSITIVE REACTANCE

Transmission loss above that of an ideal transformer of the same ratio.
Sending end impedance $Z_1 = 6000$ ohms.
Receiving end impedance $Z_2 = (R + j L)\,\omega$ ohms $= 20 + j\,2000$ ohms at 1000 cycles.

impedances at the frequency at which it is desired to deliver maximum power. The choice of best mutual impedance may be made by assuming windings of different impedance and predetermining their loss characteristics as has been described under transformers working between resistances.

Transformer Operating Between A Resistance and A Negative Reactance

Where a transformer operates between a resistance and a negative reactance, a condition exists where one impedance is independent of and the other is a function of the frequency, although in this case the reactance varies inversely with the frequency. Here again in order to deliver power it is necessary to assume that the receiving end impedance has a small resistance component. The transformer ratio may be made to match these impedances at any frequency, delivering maximum energy, but causing an increasing loss above and below this frequency. The loss characteristic of such a transformer is shown in Fig. 10 which gives the increase in transmission loss of the ideal transformer of fixed ratio over the ideal transformer of the actual ratio of the circuit impedances at all frequencies.

Referring to Fig. 5 and considering Z_2 a negative reactance, there are two frequencies at which resonance takes place. At the first frequency parallel resonance occurs between the impedance $M\sqrt{R}$ and $Z_2 R$ and at the second, series resonance occurs between the leakage reactance components of $P - M\sqrt{R}$ and $S R - M\sqrt{R}$ and the receiving circuit impedance $Z_2 R$. The d-c. resistance causes a loss which, in general, is finite at zero frequency and becomes zero at infinite frequency. The leakage reactance produces a loss which, in general, increases from zero at zero frequency to infinity at infinite frequency going through a minimum, however, and in some cases causing a gain over the ideal transformer at the second resonance frequency. The mutual impedance, in general, produces a loss which decreases from infinity at zero frequency to a finite value at infinite frequency, going through a minimum, however, at the first resonance frequency and possibly even causing a gain over the ideal transformer at this frequency.

Input Transformer

The usual case of a transformer operating under these circuit conditions is the input transformer of the vacuum tube amplifier, the vacuum tube approximating a condenser in its grid-filament impedance.

With the receiving end impedance an ordinary capacity of constant phase angle, it is necessary in order to deliver uniform power over a range of frequency to match impedances at all frequencies or supply a voltage which decreases inversely as the square root of the frequency. In a vacuum tube amplifier, when the output or plate-filament current is proportional to the input or grid-filament voltage, uniform output

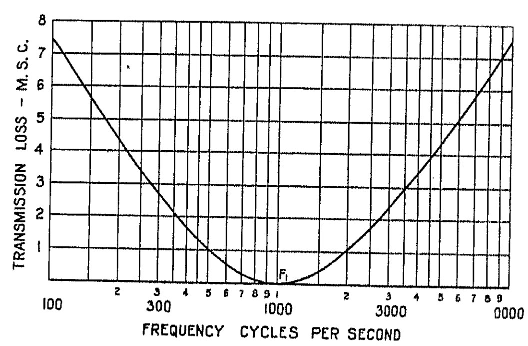

FIG. 10—TRANSFORMER CONNECTING A RESISTANCE TO A NEGATIVE REACTANCE

Ideal transformer of impedance ratio R/X at frequency "F_1" = 1000 cycles.

power will be delivered at varying frequency provided the input voltage is kept constant. When operating into a vacuum tube, therefore, it is not required to match the circuit impedances at all frequencies to limit distortion. An ideal input transformer of fixed ratio will tend to cause the vacuum tube to deliver uniform power over a range of frequency but only throughout that part of the frequency range in which it can maintain constant voltage across the grid-filament impedance.

The receiving end circuit impedance Z_2 is usually larger than Z_1. The equivalent unity ratio circuit and the equivalent T network of the equivalent unity ratio transformer are, therefore, obtained by dividing S and Z_2 by R and M by $\sqrt{R}$ instead of multiplying as in Fig. 5. Such an equivalent unity ratio circuit is shown in Fig. 11.

In considering the losses introduced in the circuit by the input transformer it is not convenient to compare the received current through the actual transformer

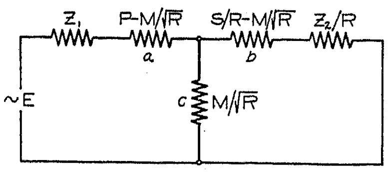

Fig. 11

with that of the ideal transformer of either variable or fixed ratio as neither ideal transformer delivers uniform input voltage to the vacuum tube at all frequencies or causes the amplifier to deliver uniform power. A more satisfactory basis of comparison, particularly for input transformers of different ratios which are intended for the same circuit conditions, is obtained by comparing the ratio of the potential produced across the grid-filament impedance Z_2 (see Fig. 3) to the potential E impressed on the circuit. This ratio gives the amount of effective amplification produced in the amplifier by the input transformer.

The losses of the input transformer have the same general frequency variations as the losses of the transformer operating into an ordinary negative reactance except that at the first resonance frequency the losses produced by the mutual impedance $M/\sqrt{R}$ of the input transformer may be zero but never negative. It is to be noted that the d-c. resistance of the secondary produces zero loss at zero frequency while the loss due to the d-c. resistance of the primary is finite.

Input transformers designed for audio frequencies operate into the high negative reactance of the vacuum tube and therefore the secondary and mutual impedances are necessarily of large magnitude. The capacity of the transformer windings under these conditions becomes of considerable importance and even when limited by careful design usually causes parallel resonance in the arm c of the transformer network in the transmitted frequency range. The same is the case with input transformers designed for carrier frequency operation although the impedances involved are usually not so large. Above this resonant frequency both the arm c and the impedance Z_2/R are negative reactances and their impedances tend to be annulled by the leakage reactance of the arms a and b. The combined effect of the leakage reactances of these arms produces resonance with the transformer and tube capacities which may increase the transformer amplification characteristic even above the value given by the ratio of secondary to primary turns.

Amplification characteristics produced by transformers of different ratio operating from a sending end impedance of 20,000 ohms into a 216-A vacuum tube are shown in Fig. 12. It will be noted that as the impedance ratio of the transformer is lowered, the amplification characteristic flattens out and the frequency distortion is reduced. In the characteristics of some of the lower ratio transformers, a gain in amplification above the ratio of turns of the transformer may be noted at the higher frequencies.

It is to be noted that in the circuit of Fig. 11, a and b are positive reactances while at the high frequencies c and Z_2/R are negative reactances and the circuit approximates a low pass filter. As a filter, it has a cut-off frequency above which it tends to limit transmission and the amplification characteristic falls off quite rapidly.

The d-c. resistance of the primary is of more importance than the d-c. resistance of the secondary. In the

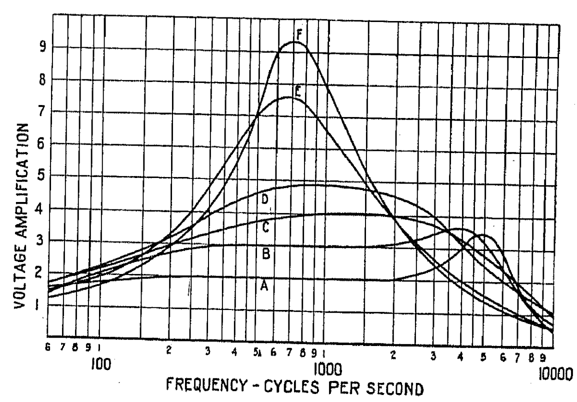

Fig. 12—Voltage Amplification Characteristics of Input Transformers of Various Turns Ratios Operating from 20,000 Ohms Resistance into a 216-A Vacuum Tube

Coils	Turns Ratio
A	1:2

C	1:4
D	1:5
E	1:8
F	1:10

well-proportioned input transformer, the value of the arm c particularly at the resonance frequency becomes very large as compared with the sum of the impedance Z_1 and the impedance of the arm a and at these frequencies the transformer gives practically the amplification represented by the ratio of secondary to primary turns. However, at the lower frequency range, where the impedance of the arm c becomes more nearly equal to the sum of the impedances of Z_1 and the arm a, the d-c. resistance of the primary produces a loss in amplification. The d-c. resistance of the primary is, therefore, a factor in the distortion at the lower frequencies.

For the rapid analysis of an input transformer, it is

customary to consider the d-c. resistance of P as added directly to Z_1 to form Z_0; to consider the total leakage reactance, $+ j X_l$, located entirely in the arm a; to neglect the d-c. resistance of S; to combine the capacity of the vacuum tube and effective capacity of the transformer as determined as located across S to form the reactance $- j X_c$ and to consider the mutual impedance M as the impedance due to the transformer windings exclusive of capacity. Such a circuit as shown in Fig. 13, approximates the actual circuit conditions quite closely in the ordinary case and is useful in design work.

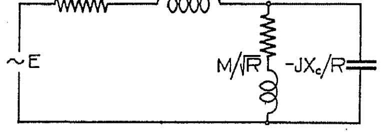

FIG. 13

For an audio-frequency input transformer of a given ratio, the losses or the departure from full amplification depend at low frequencies, principally on the value of the mutual impedance, while at high frequencies the effective capacity of the tube plus that of the transformer has a considerable influence. As the mutual impedance is a function of the number of turns, while the capacity is practically independent of the number of turns, it follows that, in general, for an input transformer operating over a wide band of frequencies, the higher the mutual impedance, the wider will be the transmitted frequency band.

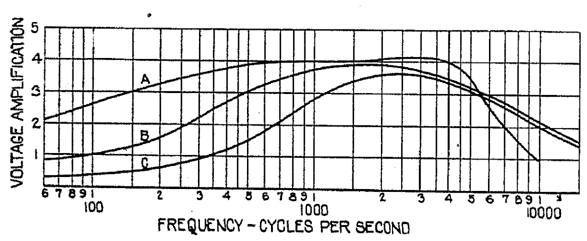

FIG. 14—VOLTAGE AMPLIFICATION OF INPUT TRANSFORMERS OF DIFFERENT MUTUAL IMPEDANCES HAVING AN IMPEDANCE RATIO OF 1:16 AND OPERATING FROM 15,000 OHMS RESISTANCE INTO A 216-A VACUUM TUBE.

Transformer	Ratio $\frac{M \sqrt{R}}{15,000}$ at 1000 cycles
A	1:1
B	1:4
C	1:10

Fig. 14 shows the variation in amplification obtained with input transformers of the same ratio but of different mutual impedances operating between a resistance of 15,000 ohms and a 216-A vacuum tube. It will be noted that as the mutual impedance is increased the width of the transmitted frequency band is increased and the mid-band frequency is lowered. The upper slope of the frequency characteristic is determined principally by the leakage reactance of the transformer and the transformer and vacuum tube capacities. In transformer C the leakage reactance is so proportioned that resonance with this capacity extends the flat portion of the amplification characteristic upward in the frequency range. The lower slope of the characteristic is determined principally by the mutual impedance of the transformer.

This advantage of high mutual impedance explains the use of No. 40 and No. 44 A. w. g. enameled wire for the secondaries in most audio frequency input transformers, as giving the highest impedance secondary windings that can be commercially applied with different methods of winding. With the gage of wire and the secondary impedance thus determined, the possible amplification characteristic will depend on the transformer ratio. With a number of predetermined characteristics of different ratio transformers prepared as shown in Fig. 12, the required windings for the input transformer may be determined to give a desirable compromise between the amplification and the transmission distortion permissible.

From the standpoint of minimum distortion, it

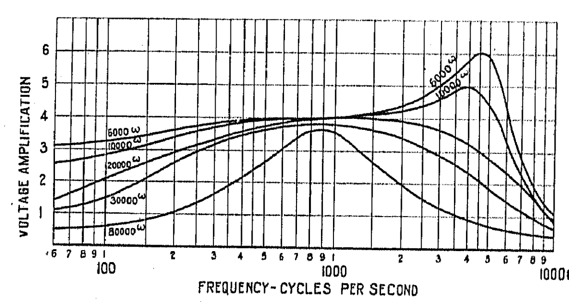

FIG. 15—VOLTAGE AMPLIFICATION CHARACTERISTICS OF AN INPUT TRANSFORMER OF IMPEDANCE RATIO 1:16 OPERATING FROM VARIOUS RESISTANCES INTO A 216-A VACUUM TUBE

should be mentioned that it is desirable to use vacuum tubes of low plate-filament impedance in the amplifier, particularly if this can be done without sacrificing the tube amplification factor. The effect on the input transformer characteristic of operating it from tubes of different plate circuit impedance is shown in Fig. 15.

In the earlier telephone repeaters,[6] a resistance was shunted across the secondary of the input transformer and the grid-filament impedance of the vacuum tube. This resistance was of sufficiently low magnitude to determine the impedance into which the input transformer operated and the transformer was given the proper impedance ratio to match this impedance with the impedance from which the transformer was operated. This resistance served to aid in obtaining a flat amplification characteristic and to fix the impedance measured on the primary of the transformer with the secondary connected in circuit. An impedance characteristic was produced as shown in Fig. 4 instead of the characteristic of the type shown in Fig. 2, which

6. Gherardi and Jewett: "Telephone Repeaters," TRANS. A. I. E. E., Vol. 38, part 2, page 1287.

represents simply a transformer with appreciable effective capacity in the windings. Later on an improvement was made by shunting the primary of the input transformer with a resistance of a value equal to the resistance formerly used across the secondary divided by the transformer impedance ratio. It will be noted that in the first case, the transformer operates into a circuit which is principally a resistance while in the second case, it operates into a capacity.

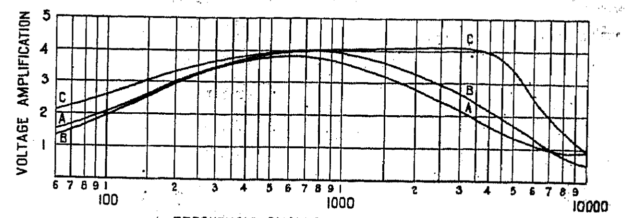

FIG. 16—VOLTAGE AMPLIFICATION CHARACTERISTICS OF INPUT TRANSFORMERS UNDER DIFFERENT CIRCUIT CONDITIONS

Curve	Transformer Impedance Ratio	Resistance Across Low Side	Resistance Across High Side
A	1:64	∞	64 × 15,000
B	1:64	15,000	∞
C	1:16	∞	∞

Measured amplification characteristics of an input transformer operating under both circuit conditions are shown in Fig. 16 which gives, in addition, the characteristic of an input transformer of the same size and construction designed to give the same value of amplification as in the first two cases but without the shunting resistance. The superiority of the latter type of circuit in giving a uniform amplification characteristic is easily seen. This last circuit connection does not have an input impedance characteristic which is practically independent of frequency and it is, therefore, more limited in its uses.

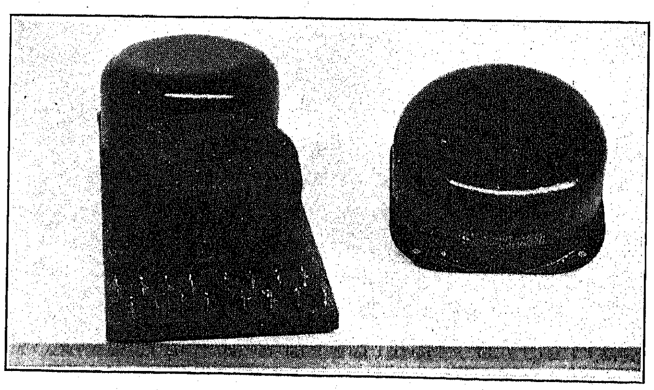

FIG. 17—TOROIDAL REPEATING COIL

In the foregoing, the transformer has been treated from the standpoint of the transmission of telephone currents and those features have been presented which appeared to the writer to be of special interest and usefulness to those interested in its application to this problem. In conclusion, the writer wishes to acknowledge his indebtedness to Mr. Thomas Shaw of the American Telephone and Telegraph Company and to Mr. K. S. Johnson of the Western Electric Company, Inc., with whom he has been associated for a number of years on the general problem of telephone transmission and in the application of the principles described herein.

Appendix

The construction of telephone transformers is covered in an appendix not printed here.

TRANSFORMER CONSTRUCTION

The type of transformer most used in the telephone plant is a toroidal core transformer usually called a repeating coil. This type of transformer has a ring-shaped core of soft magnetic iron wire or silicon steel laminations completely covered with the primary winding over which is applied the secondary winding. Such a transformer, when the dimensions are properly proportioned and the winding is applied so as practically to fill the central hole in the core, is a very efficient structure. The symmetrical distribution of winding limits the stray field, thus preventing cross-talk

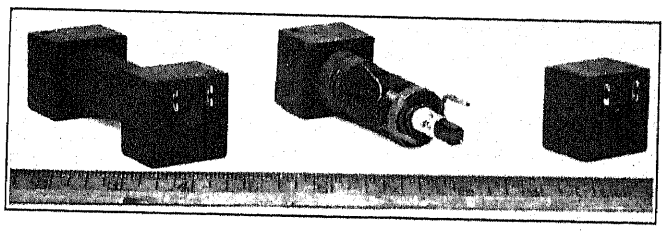

FIG. 18—TELEPHONE INDUCTION COIL

trouble in neighboring circuits. The cost of winding has been reduced to a low value by the development of a winding machine in which a circular shuttle threading through the center of the core is used to hold the wire which is wound on the core by a motor-driven annular part of the machine. The windings are accessible and permit of easy adjustment. This type of transformer is used in telephone installations where the impedances of the circuits in which the transformer is operated are less than 20,000 ohms and where the frequency is relatively low. The usual type of mounting of two repeating coils on a common base is shown in Fig. 17. The case has been removed from the front coil unit to show the construction.

The telephone induction coil used in all subscribers sets is an open magnetic circuit core type transformer. The impedance and frequency requirements of the circuit in which this form of transformer is used are not severe and the value of the transmission is relatively low due to the fact that any one transformer is used a relatively small part of the time and only for conversations from a single station. This, together with the facts that the transformer must be designed to operate with direct current through the windings and

stray magnetic field is of no particular disadvantage permits the use of this relatively inefficient type of transformer shown in Fig. 18. It is to be noted that in this transformer the winding is located about the center portion of the core only as in this location the highest ratio of inductance to d-c. resistance is obtained giving maximum efficiency.

For portable test sets, considerably lighter and smaller types of transformer than are generally used in

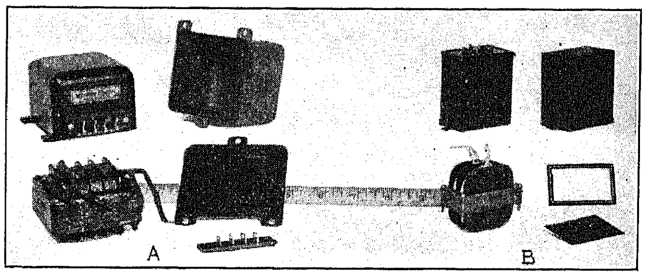

Fig. 19—Shell Type Transformers

the telephone plant are required. Transformer A of Fig. 19 shows the type of transformer used in sets such as the S. C. R. 72 amplifier developed for the Signal Corps of the United States Army. This amplifier set was intended to operate on 1000-cycle telegraph signals transmitted through the ground. The transformers used in this set were required to operate efficiently only in the neighborhood of 1000 cycles and transmission at other frequencies was sacrificed to obtain

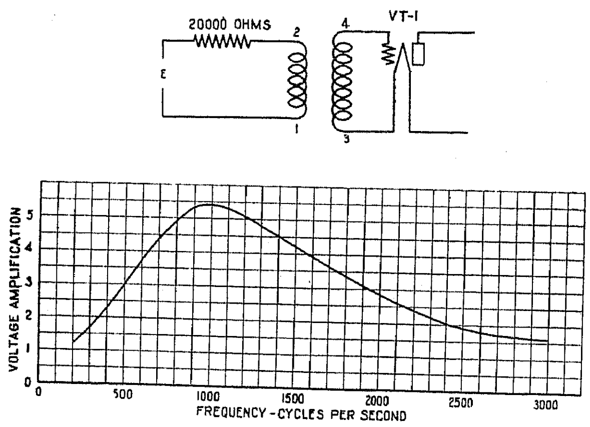

Fig. 20—Amplification Characteristic, 201-A Input Transformer

maximum amplification at this frequency. An amplification characteristic of the input transformer of this set is given in Fig. 20. This type of transformer was widely used in both Signal Corps and Navy radio transmitting and receiving sets throughout the war and weighed about two pounds.

The type of transformer shown as B in Fig. 19 is also of shell type construction and is used in portable telephone field test sets and weighs 12 ounces.

One of the latest designs of shell type transformer and the one which was used for most of the experimental characteristics given herein is shown in Fig. 21. The construction of this input transformer, the No. 224 type, is such that winding and assembly can be readily accomplished and repair easily effected if necessary. The winding space and the core have been proportioned to obtain minimum cost of manufacture. The core consists of I and E shape laminations riveted together to form an I and E part which butt together forming the core. The winding is placed on a spool which fits over the central limb of the E. The two core parts are held together by means of two brackets which are held in place by four machine screws. The terminals are arranged on insulated mounting plates held under the screws of the mounting bracket and serving as mechanical protection to the lead wires.

It may be noted that whereas the form of toroidal repeating coils is core type, that of the transformers employing spool windings is shell type. The core type is used for the toroidal repeating coils as it permits ready adjustment of the windings and the shell type is used in the transformer having spool windings as it permits the use of a winding of small effective capacity.

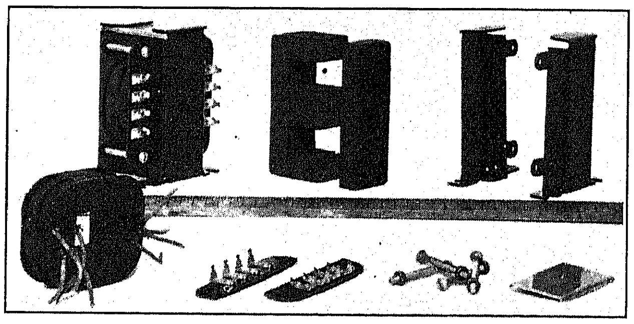

Fig. 21—224-Type Input Transformer

The size of the transformer is governed by three factors, the amount of space available, the cost permissible and the ratio of inductance to d-c. resistance which is required to give the desired freedom from transmission loss.

In the windings of telephone transformers, cotton or cotton and enamel is used for the insulation of the heavier gages of wire while for the smaller gages, enamel or enamel and silk is used. The gage sizes used range from No. 18 A. w. g. or heavier to No. 44. In input transformers, the d-c. resistance of the secondary winding usually causes an inappreciable loss and it is, therefore, desirable to have it take up as little space as possible and the smallest size of wire which can be used with the different commercial methods of winding is employed. The quality of the enamel insulation generally used for this winding is a determining factor in the minimum size of winding which can be used. With the best enamel, it is possible to wind No. 40 A. w. g. wire with little or no interleaving paper and with little special machinery, and have the resulting windings reasonably free from short circuits. How-

ever, with inferior enamel, it is necessary to use a covering of silk in addition to the enamel, or to use interleaving paper between each two layers of the winding. This extra insulation, needless to say, causes a considerable increase in the space taken up by the winding, which is undesirable.

In transformers in which the effective capacity is an important factor, it is frequently necessary to apply the winding in such a way as to reduce the capacity to a minimum. The effective capacity depends on the size of the transformer winding, more care being required to reduce it to a reasonable value in a large than in a small transformer. The capacity of the winding may be conveniently considered as composed of four parts, part one being the sum of the capacities between each two adjacent turns all connected in series from one terminal of the winding to the other, part two the sum of the capacities between adjacent layers

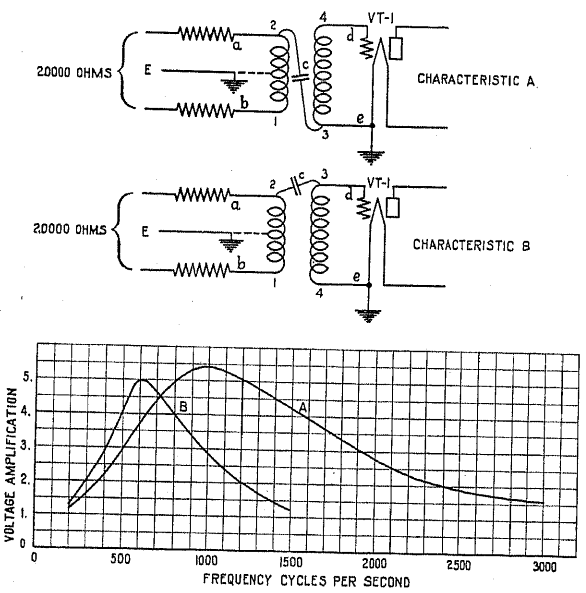

Fig. 22—Transformer Amplification Characteristics with Different Winding Connections

in series, part three the capacities between adjacent winding sections in series and part four due to the capacities between the winding and any other metal or other windings in the neighborhood. These capacities may be considered in effective values as connected across the winding terminals. Of these component capacities, the first may usually be neglected entirely, as it consists of a large number of small capacities in series, this number being only slightly less than the total number of turns. The fourth part is usually the most important as it seldom consists of more than two capacities in series. The second and third parts of the effective capacity are of importance depending on the number of sections and layers and the capacity between adjacent ones. In high ratio transformers, it is usually sufficiently accurate to consider the lower impedance winding as an equi-potential plate and to consider the capacities with regard to the high impedance winding only.

The effect of inter-winding capacities in affecting transmission is given in Fig. 22. This figure shows how sometimes these capacities may be connected between approximately equal potential points in the circuit and thus lessen the effective capacity of the winding. The transformer on which these characteristics were taken is the same as that shown in Figs. 19 and 20. Characteristic A represents the normal connection of windings with the interwinding capacity C located between the parts of the circuit a and e in which it is effectively across one half the impedance of the primary, 1-2. Characteristic B shows the amplification obtained with the secondary winding, 3-4, reversed, terminal 3 being connected to the grid of the vacuum tube instead of the filament. In this case the capacity C is across the entire secondary impedance in addition to one-half the primary impedance, the combined impedance being approximately 200 times the impedance under the circuit connection A. The effect of this inter-winding capacity being connected across points of widely different potential in the circuit in lowering the frequency of the amplification peak is clearly shown.

Transformers are subjected in service to conditions of temperature and humidity which vary greatly. Conditions in exchanges in the tropics and in certain sets for outdoor use are particularly severe while in some other locations there is but little chance of trouble. Under conditions of humidity electrolytic corrosion will take place provided salts which might form an electrolyte on the addition of moisture are present in the completed windings. Corrosion will be accelerated in circuits in which there is a direct-current potential between some point in the winding and another neighboring metallic part. It frequently causes the windings of the transformer to open-circuit particularly when they are wound with the smaller gages of wire. It is rather difficult to obtain materials which are free from slight amounts of salts and to keep the transformer winding free from them during the operations incident to manufacture. Perspiration from the operators hands or the use of soldering salts are common causes of corrosion. To reduce this trouble the windings are imbedded in a moisture resisting compound of oils or waxes which is in itself chemically inert. The moisture-proofing process is usually effected under vacuum after a baking period. The advantages of a carefully worked out moisture-proofing treatment in prolonging the useful life of transformers is so great that it has been universally adopted in all carefully designed transformers.

Discussion

Wm. Fondiller: Mr. Casper has described the ideal transformer, one which would introduce zero loss in a telephone circuit, as represented by an equivalent network having zero impedance series arms and an infinite impedance shunt arm.

In any practical transformer the factor which most largely determines the extent to which this ideal can be approached is the magnetic material used for the core. The ideal core material obviously would be one having infinite permeability and zero losses, as this would make possible 100 per cent coupling, practically zero winding resistance and infinite mutual impedance. Fortunately, however, a magnetic material having characteristics altogether finite in value will permit the construction of quite satisfactory transformers. It may be of interest to indicate what the desirable properties of the magnetic material should be and the extent to which they are attained in materials at present commercially available.

As Mr. Casper has indicated, the speech frequency magnetizing forces operating in these transformers are of low values, generally ranging from 0.001 to 0.05 c. g. s. units. These values are less than 1/100 of those ordinarily employed in power work. On account of the extremely low magnetizing forces, the part of the usual permeability characteristic which is of importance in material to be used in this apparatus is a small portion near the origin. Over this part of the curve the change in permeability with magnetizing force is not very large, consequently, what is commonly called the "initial" permeability may be used to define the relative merits of different materials. The requirements of a desirable magnetic material for the telephone transformer, so far as its action in transmitting speech frequency currents is concerned, are therefore, high initial permeability and low core losses at the corresponding flux densities.

The material which at present meets these requirements most satisfactorily is what is known as high silicon steel transformer sheet. This is a low carbon iron having from 3.5 to 5.0 per cent silicon and is supplied in sheets of 0.014 in. in thickness.

So far as I am aware, no steel mill is at present equipped to make the required tests at very low magnetizing forces. Due to this condition, the product supplied at present by the different manufacturers varies a good deal in respect to some of these magnetic characteristics. The initial permeability ranges from about 400 to 600. Frequently, however, values as low as 250 are observed. The maximum of these permeability values is, of course, desirable, although a steel consistently having an initial permeability of about 500 would be quite satisfactory. Eddy current loss is fairly uniform at about 1.0 erg per gram at a frequency of 1000 cycles per second and a maximum density of 15 gausses. The hysteresis loss under the same test conditions varies from about 1.0 to 5.0 ergs per gram in different samples. When the value of this loss is above 3.5 ergs the results are unsatisfactory. As brought out in the paper by Speed and Elmen, on "Compressed Powdered Iron" in 1921, the hysteresis loss is less in hard than in soft material for the same flux density at very low magnetizing forces. It will be evident from this that some conflict in requirements exists in that it is desired to secure high initial permeability in combination with low hysteresis loss. Until substantially lower hysteresis loss values can be obtained, there is little to be gained from reducing the values at present obtainable for eddy current loss at audio frequencies. The latter can, of course, always be reduced by employing thinner laminations.

The variations just cited make the problem of the design and manufacture of telephone transformers to consistently uniform standards of performance rather difficult. It is hoped that developments, which have been recently instituted in conjunction with some of the suppliers of magnetic materials, will in the comparatively near future make it possible to obtain such materials under suitable magnetic specifications. An important factor contributing to the attainment of this end would be the recognition of the performance requirements of magnetic materials for such uses as Mr. Casper's paper describes, in standardized tests such as those adopted by the American Society for Testing Materials. The present standardized tests for transformer sheets are applicable only to power frequencies and flux densities. What is needed to meet the requirements of communication engineering is a test for permeability and core loss at a flux density of about 15 gausses. This test could be made at a frequency of say, 1000 cycles with a bridge type of testing circuit using an ordinary telephone receiver as an unbalance detector. Simultaneous readings of inductance and effective resistance can be taken in this way from which the permeability and core losses are readily calculated.

I believe that the adoption of a uniform practise for specifying the characteristics of magnetic materials at low magnetizing forces would result not only in a more satisfactory condition as regards the production of telephone transformers, but would also lead to improvements in these characteristics due to a new appreciation by steel manufactures of the effect of their processes on the magnetic behavior of this material.

W. L. Casper: Mr. Fondiller has dealt with the use of silicon steel for the magnetic core material of the speech-frequency transformer giving figures for the initial permeability and the eddy-current and hysteresis losses. The much higher permeability and lower losses of permalloy as brought out in the paper by Arnold and Elmen before the Franklin Institute in 1923 naturally raises the question as to whether permalloy will not supersede silicon steel for this purpose. Obviously, wherever the circuit conditions are such as to require the transformer core to operate only at this initial value and not to require the introduction of gaps in the magnetic circuit these characteristics of permalloy will be of great advantage. For instance, the phantom-circuit repeating coil which is a toroidal-type transformer wound on a silicon-steel core and which weighs about 3½ lb., has been duplicated experimentally in efficiency to talking currents by a transformer of similar construction but having a permalloy core and weighing under two ounces.

As brought out in the paper, telephone circuits, as a rule, have to perform more functions than simply to transmit speech currents and the phantom-circuit repeating coil is required, in addition to this primary function, either to transmit 20-cycle signaling current or be inefficient to Morse telegraph currents. As the amount of energy transmitted under either of these two conditions is vastly larger than the speech-current energy in addition to the frequency being considerably lower, it becomes an involved problem in design as to whether permalloy would prove good, depending largely on the cost of the core material.

Another case where the complex circuit conditions prevent full advantage being taken of the large difference in initial permeability of permalloy over silicon steel is that of the transformers which operate with direct current through their windings as, for instance, the input transformer. The design of such a transformer involves proportioning the core in such a way as to give maximum permeability under the operating conditions which is done by the introduction of an air gap of suitable length. Obviously, the greatest gain by the use of permalloy will be made in input transformers operating from low-space-current tubes. Whereas the economic advantage of permalloy is marked in transformers operating from tubes employing one or two milliamperes space current, its superiority is reduced when this space current is 10 or 20 milliamperes, requiring the cost of permalloy to be not greatly above the cost of its constituents in order to prove satisfactory.

Permalloy is being used at present in a number of those transformers which operate under conditions where maximum advantage may be taken of its high initial permeability and economic studies are in progress to determine under just what other circuit conditions it will prove advantageous.

An Electrical Frequency Analyzer

BY R. L. WEGEL and C. R. MOORE

Research Laboratories of the American Telephone and Telegraph Company and the Western Electric Company, Incorporated

Review of the Subject.—*An apparatus has been developed by means of which it is possible to measure and obtain a permanent record of the frequency components of an electric current wave. The device has two frequency ranges: 20 to 1250 cycles and 80 to 5000 cycles; the amount of power required does not in general exceed 500 microwatts; and the time necessary for making a record is about 5 minutes. An attachment is provided which permits of the making of simultaneous harmonic analyses of two complex waves in the same length of time.*

In principle, the process consists in feeding the complex wave to be analyzed into a selective network, the essential feature of which is a sharply tuned circuit whose frequency of tuning is controlled by varying the capacitance in small steps with a pneumatic apparatus similar to that in a player piano. A maximum of response of the circuit occurs at each frequency of tuning which coincides with a component of the complex wave. An automatic photographic recorder of the response to each frequency of tuning is provided by means of which the frequency and magnitude of each component of the complex wave may be obtained. For convenience of operation, an automatic control apparatus is provided, so that it is only necessary to connect the complex source or sources to be analyzed and press a starting button. The completed record of the analysis is delivered after the machine has passed through the entire range of frequencies.

The application has so far been principally to problems in the communication field such as the analysis of performance and distortion at audio frequencies of vacuum tube and mechanical oscillators and amplifiers, analysis of complex telephone waves and speech sounds, and the effect on a complex wave of transmission through electrical and acoustic apparatus. In the power field many applications are obvious, such as for example, quantitative comparison as to frequency content of the voltage and current supplied to and delivered by transformers, voltage and magnetic flux studies in generators and motors, commutation, and the effect of wave-shapes in power transmission line problems and control apparatus.

INTRODUCTION

THE harmonic analyzer described in this paper consists of a variable tuned circuit into which the complex current wave to be analyzed is introduced, and an automatic recording apparatus to register its response as the frequency of tuning is changed.

The first recorded use of a tuned circuit as an analyzer was by Pupin in 1894[1]. He analyzed power waves by measuring the response of circuits tuned to each of the harmonic frequencies. It has been the practise for a number of years to determine the frequency characteristics of currents and voltages on power circuits and noise on telephone lines by means of a variable resonant circuit which includes a telephone receiver for listening.

During the recent war a rapid automatic method was developed for varying the tuning of a circuit in such an analyzer in connection with the analysis of sounds radiated by submarines. The analyzer described in this paper is in principle the same as this apparatus but includes such improvements as were found desirable by experience to increase the speed, dependability and convenience of use. The present apparatus is capable of recording the frequency and magnitude of each component in a complex wave between 20 and 1250 cycles or 80 and 5000 cycles in about five minutes. This analyzer does not measure the phase of the various components but has the advantage that the frequencies need not be simple multiples of the fundamental as is the case with graphical analyzers. With this apparatus it is possible to measure quite accurately component frequencies as close together as about fifteen cycles at the lower end of the range and about 200 cycles at the upper end of the range, and to detect components as close together as three to five cycles at the lower end and fifty cycles at the upper end of the range.

PRINCIPLES OF OPERATION OF THE ANALYZER

Fig. 1 is a schematic diagram of the essential elements of the analyzer circuit. The wave to be analyzed is introduced at the input terminals from which it passes to an input equalizing network and to the variable tuned circuit. The tuned circuit consists of a variable condenser of capacitance C and a coil whose inductance

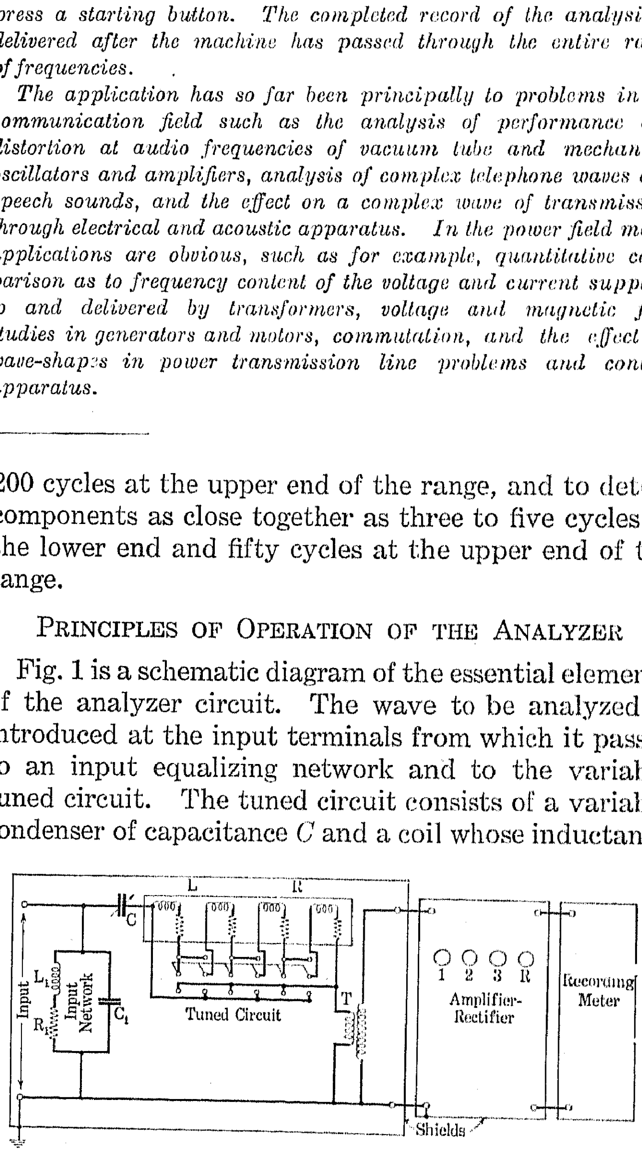

FIG. 1—SCHEMATIC ANALYZER CIRCUIT

is L and resistance R. The value of the capacitance C is varied in small steps by an automatic device to be described in the next section. The inductance L consists of four identical windings on a toroidal core which, by means of a switch, may be thrown in series or in parallel, thereby changing the value of the inductance in the ratio of 16 to 1. With the same range of capacitance values this change in inductance gives the two frequency ranges of tuning, 20 – 1250 cycles and 80 – 5000 cycles. By means of the high-ratio transformer T the response of this circuit is applied to a vacuum tube amplifier-rectifier and registered by means of the recording meter.

1. Resonance Analysis of Alternating and Polyphase Currents, TRANS. A. I. E. E., Volume XI, Page 523.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

This circuit arrangement will analyze a complex wave by virtue of the selective shunting of current by the tuned circuit from the input network. The impedance of the source of the complex wave is in practise maintained high in value at all frequencies compared to that of the input network so that the input wave-shape is independent of the small changes in impedance of the analyzer due to the varying of condenser C. The current fed into the analyzer traverses two paths, the input network and the tuned circuit. The impedances of these paths are respectively,

$$Z_1 = \frac{(R_1 + j\,\omega\,L_1)/j\,\omega\,C_1}{R_1 + j\,\omega\,L_1 + 1/j\,\omega\,C_1}$$

and $$Z = R + j\,\omega\,L + 1/j\,\omega\,C.$$

The transformer T introduces into the tuned circuit a small resistance and inductance, both of which are negligible. The input network impedance Z_1 varies gradually from 0.4 ohms for direct current to about 10 ohms at 5000 cycles. The values of the elements are: R_1 = 0.4 ohms, L_1 = 0.075 milhenries, C_1 = about 15 microfarads. Impedance Z of the tuned circuit depends on the setting of the variable condenser C.

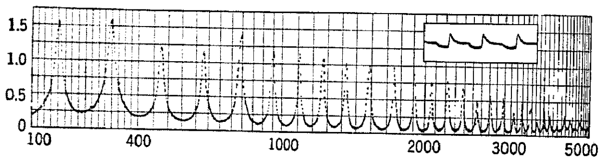

FIG. 2—RECORD OF 160 CYCLE BUZZER OUTPUT

The resistance R of the iron-core coil, varies with frequency; its values for the parallel connection are 0.7 ohms for direct current, 1.5 ohms at 2500 cycles and 4.2 ohms at 5000 cycles. The value of the inductance L for the parallel connection is 23.4 milhenries and is practically constant with change of frequency. For the series connection both R and L are sixteen times as great. The capacitance is varied from about 200 microfarads to about 0.05 microfarads. It will be seen that for each capacitance value there is a frequency, $f_r = 1/(2\,\pi\,\sqrt{L\,C})$, for which the tuned circuit impedance, Z, is R. For other frequencies Z is much greater due to the reactance. An incoming current of frequency f_r is, therefore, largely shunted through the tuned circuit while current of any other frequency passes through the input network. In this way if the capacitance C is varied gradually the tuned circuit will shunt selectively from the input network the successive components of the complex wave.

The special features of design of this analyzer circuit can be better explained by reference to a typical record made by the apparatus. Fig. 2 is the record of analysis of the current from a buzzer which vibrates with a frequency slightly under 160 per second and gives an irregularly shaped wave which is shown in the accompanying oscillogram. In taking this record the windings of the tuning inductance were in parallel so as to give the frequency range 80-5000 cycles. The vertical scale gives approximately the r. m. s. current in milliamperes at each frequency (as read on the horizontal scale) at which a peak occurs. It will be seen that a peak occurs at each multiple of the frequency of the buzzer. The r. m. s. values of input current at the corresponding frequencies as read from the peaks on the record are: 160, 1.6 milliamperes; 320, 1.6 milliamperes; 480, 1.25 milliamperes; 640, 1.2 milliamperes; 800, 1.45 milliamperes; 960, 1.25 milliamperes; 1120, 1.2 milliamperes: 1280, 1.1 milliamperes; 1440, 1.05 milliamperes; 1600, 1.0 milliamperes; 1760, 1.0 milliamperes; etc. The root square sum of all components shows that 4.7 milliamperes was the effective value of the complex current fed into the analyzer.

The fact that the 80 – 5000 cycle records read directly the current at each frequency component is due to the special design of the input network. A small correction is still necessary but can be neglected except where maximum obtainable accuracy is desired. If the input network were a pure resistance the higher frequency components would produce relatively lower peaks because of the falling off of efficiency with frequency of the amplifier-rectifier circuit and the increase in resistance of the tuning coil. The input network was designed empirically so that with constant input current the voltage drop across the input terminals increases with frequency in such a way as to compensate for these high-frequency losses. The tests to determine this were made by taking records of single frequencies of known amounts.

It will be seen that the frequency scale is gradually contracted as the upper end of the record is approached. Owing to the increase in resistance of the coil with frequency, the sharpness of tuning of the analyzing circuit decreases with frequency. Each peak on the record corresponding to a single frequency is a plot of the resonance curve of the variable tuned circuit. The sizes of the capacitance steps are so adjusted that a sufficient number of points, necessary to trace a resonance peak at all frequencies, is recorded. The length of the record and the time required for an analysis are determined by the number of points needed.

When peaks on the record are so close together as to overlap greatly, the reading on the scale is untrustworthy. If, instead of a rectifier and direct-current meter, an alternating-current meter giving deflections proportional to total r. m. s. values, were used, it would be theoretically possible to determine the component frequencies and amplitudes making up any composite peak, provided the number of frequencies could be determined. This procedure, however, would be impracticable. An examination of the theory of the rectifier shows that the problem of separation of the components of a composite peak is in general in-

determinate. The rectifier however resolves adjacent peaks somewhat better than an alternating-current meter.

The analyzer has been most used in the analysis of audio-frequency currents for which the higher frequency range, 80-5000 cycles, is more useful. For the investigation of power problems the lower range would ordinarily be more suitable. In order to simplify the change from one frequency range to the other the tuning inductance only, is changed, leaving the mechanism for varying the capacitance in steps the same for both ranges. Since the inductance change in going from the high to the low-frequency range is in the ratio 1:16 and the change in the frequency range 4:1, the abscissas on the low-frequency records have one-fourth the value of those on the high-frequency records.

Since the smallest frequency divisions at the lower end of the high-frequency records are 20 cycles, these divisions on the low-frequency records are 5 cycles. There are, therefore, four times as many steps of tuning in the same frequency interval on the low as on the high-frequency record. The low-frequency record is therefore not of minimum practicable length. Since the same input network is used with the 20-1250 range as with the 80-5000 range, the low-frequency records are not direct reading in input current, but must be used with a calibration. Our use of the low-frequency range, however, has been so limited as not to justify the preparation of additional equipment for this use of the analyzer.

The apparatus is equipped with a device which permits of making simultaneous analyses of two complex waves. The principal reason for making such double records is to reduce errors in comparing two sources which may vary with time. The device may also be used simply to save time. It operates by connecting alternately to the analyzer the two complex waves in such a way that the record for each wave is traced by points representing alternate tuning condenser settings.

Description

The mechanism of the analyzer is so designed that to take a record it is only necessary, after starting the amplifier and connecting to a 110-volt power source, to attach the leads from the source or sources to be analyzed and press a starting button. The completed record is then automatically delivered in about 5 minutes after which the apparatus returns to the starting condition ready to repeat the operation. This is accomplished by means of pneumatic apparatus operating in conjunction with a photographic recording device.

The pneumatic arrangement is a modification of a piano player mechanism in which a paper roll of standard dimensions is used. By proper perforation of the roll special pneumatic relays are operated in proper sequence to switch the condensers of the tuned circuit, flash frequency lines on the record, stop the mechanism after a record has been completed, rewind the piano roll, and perform other functions necessary to leave the analyzer in the starting condition. Electrical relays for switching the tuning condensers were not found practicable on account of the disturbances induced into the analyzer circuit.

The photographic recording apparatus consists of the camera motor for moving the sensitized record paper at a constant rate, proper arrangement of lenses and lamps for illuminating the mirror galvanometer and tracing the scale and frequency lines, and suitable baths for developing and fixing the record. The record is drawn through the mechanism by means of two motor-driven rubber rollers, which also serve to remove excess solution.

The development of the pneumatic switching apparatus was carried out with a view to making use of as many standard piano player parts as possible. However, it was found necessary to make some modi-

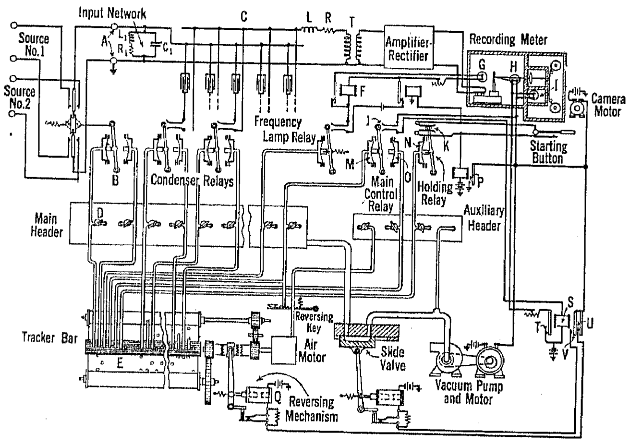

Fig. 3—Arrangement of Pneumatic and Electrical Apparatus

fications in method and apparatus; in particular a new pneumatic motor element (air relay) for switching the condensers at the requisite speed had to be developed.

Fig. 3 is a schematic drawing showing the principal features of the analyzer. In this drawing the vacuum pump is shown driven by an electric motor, and connected by means of pipes to the auxiliary and main headers and relays. This pump maintains in the headers an absolute pressure of about 4 or 5 lb. per square inch. The player piano roll *E* operates the entire mechanism by passing over the tracker bar in the usual manner. The air motor and tracker bar equipment are substantially as supplied by the manufacturers except that the reversing mechanism is arranged to be operated electrically instead of by hand.

The essential features of the air relay which was developed for this analyzer may be better understood by reference to Fig. 4. A cylindrical casting is arranged to mount two flexible diaphragms and two end plates in such a way as to form at each end of the cylinder,

compartments, one side of each of which is a diaphragm. When assembled the two diaphragms face each other and are connected together by a circular spring made of steel strip. In use the two end compartments are partially evacuated thus causing the diaphragms to pull apart, straining the spring. When distended the diaphragms lie against the inner faces of the end plates which are shaped as shown. Obviously if air be allowed to enter either of the compartments the diaphragm belonging thereto will be pulled toward the

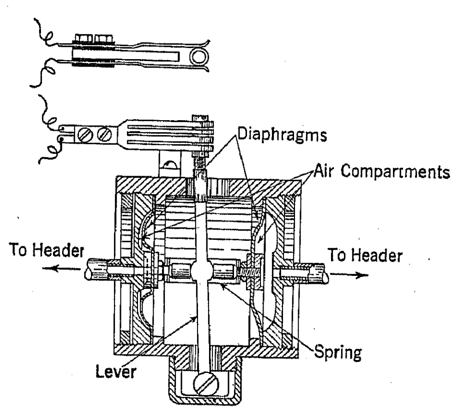

FIG. 4—PNEUMATIC RELAY

other diaphragm by the spring. Passing through the circular spring is a lever pivoted at one end and carrying on the other end an insulated metallic sleeve. This lever is not attached in any way to either diaphragm and will of itself remain in position where last placed. Switch points are mounted in such a way that the sleeve may be forced in or out between them by the action of the diaphragms. This relay has proved very satisfactory in service and is particularly fast in its operation.

Connections between the tracker bar, main header, and the pneumatic relays are made by means of rubber tubing. As shown in Fig. 3 each of these relays requires two rubber tubes leading to the main header and two from the header to the tracker bar. These tubes are connected to the header by means of stop cocks D so connected that the direct passage of air from tracker bar to relay is practically unobstructed but the passage leading from the junction to the header may be made as small as desired by turning the finger valve. As adjusted, the opening to the header is small compared to the size of the tubes so that if air be permitted to enter one of the tube lines (as at the tracker bar), the diaphragm of the relay associated therewith is immediately released. When the tube is closed again, the entrapped air is soon removed through the small opening leading to the header thus restoring the diaphragm to its original position. The relay lever, however, does not follow the diaphragm.

This arrangement possesses the advantage that small openings only are necessary in the player piano roll, and that the opening which connects a condenser into the circuit is not in line on the roll with the opening which disconnects this condenser. Also at the beginning of an analysis by suitable perforations in the roll all air relays can be set simultaneously in the off position (condensers disconnected), thus making sure of the initial conditions. The apparatus is so designed that all the openings causing condenser circuits to close are on one side of the roll and those causing them to open are on the other side.

As before mentioned the tuned circuit is made up of inductance L, having some resistance R, and a bank of condensers designated by C. The function of the "Condenser Relays" is to connect into the tuned circuit any one or any combination of the 25 fixed condensers, thus tuning the circuit in small steps over a wide range of frequencies. The input is fed into this circuit as shown at A, and the degree of resonance, that is the response of the circuit at any particular frequency of tuning, is measured by means of the small transformer T, the amplifier-rectifier and the recording meter.

In addition to operating the tuned circuit a few of the air relays are used to operate the control circuits, mark frequency lines on the chart, etc., uses which required slight modification as indicated schematically in Fig. 3.

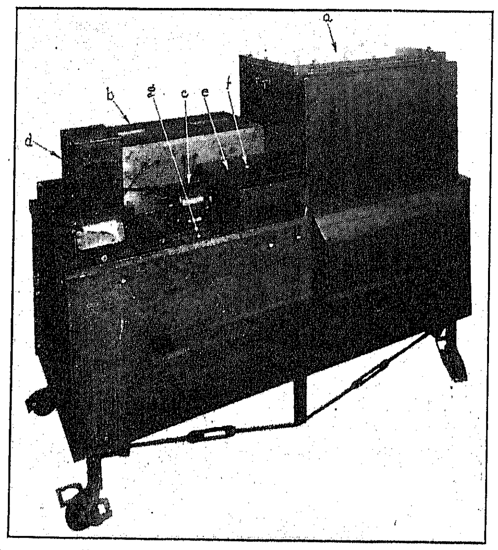

FIG. 5—VIEW OF ANALYZER READY FOR USE

a Input and tuned circuits

f Starting button
g Reversing key

In two of these control relays only one diaphragm is used, and the switch lever and diaphragm are fastened together by means of a flexible link. It has already been noted that the analyzer is equipped to trace two curves simultaneously on a single record. This is accomplished by means of air relay B which is so arranged as to connect two sources of input alternately to the analyzer. These input connections are alternated rapidly and are effected by appropriate punching of the roll.

The above covers the essential features of the analyzer but there remain a few details having to do with assembly, control, etc., that may be of interest.

Fig. 5 shows the analyzer as completed and ready to operate. The apparatus is assembled on a two-deck, structural-steel table equipped with castors for convenience in handling. Much of the equipment is inclosed for protection against moisture and dust. The recording meter, camera motor, amplifier-rectifier, control relays, and input and tuned circuits are placed

on the top. Below are mounted the batteries, the vacuum pump with its motor, and the tracker bar with paper roll mechanism. The arrangement is clearly shown in Figs. 6 and 7 taken with the protecting panels removed. In Fig. 6, *a* is a moisture-proof box containing the input and tuned circuits. The inductance coil is placed in the center of the upper half of this box together with the switch for connecting the windings in series or parallel. The smaller capacitances are of mica and are arranged around the coil and switch assembly in such a way that they may be connected with a minimum length of lead to the air relays which are located on one side of the box. The larger capacitance units are made up of paper condensers and are placed in the lower half of the box. The metal lined box *b* contains the amplifier-rectifier, and at *d* is shown the recording meter. Box *e* contains the control circuits with the necessary relays. The method of mounting the air relays, main vacuum header (attached to underside of table top), air motor, etc., is also clearly shown in this figure. Each air relay is equipped with two rubber tubes leading to adjustable cocks on the header which in turn are connected to the tracker bar. The three-control relays are also shown in Fig. 6. The vacuum pump is shown at *v* in Fig. 7. The piano roll *E* moves over the tracker bar *w* and is reversed by means of solenoid *Q*. In boxes *l* are placed the plate batteries for the amplifier-rectifier.

The control apparatus by means of which the analyzer becomes practically an automatic machine will now be described. Referring again to Fig. 3 it will be seen that there is provided an auxiliary header and an electrically operated slide valve. The functions of these devices will be discussed presently.

The machine is started by pressing the starting button which should be kept closed for a few seconds while normal vacuum is being established in the headers. The air motor then starts and the paper roll *E* begins to travel across the tracker bar. Perforations in the roll are so made that when the roll is in its initial position an opening allows air to enter chamber *N* of the holding relay. As soon as the paper starts, however this opening is closed, chamber *N* is exhausted, and contacts *K* close. This short-circuits the starting button which the operator may now release, and the machine is in full operation. It will be noted that the closing of the contacts of the starting button or contacts *K* puts into operation motors which drive the vacuum pump and the camera apparatus. Simultaneously recording meter lamp *H* and scale-line lamp *I* are lighted. The latter illuminates the record through small holes in an opaque scale strip thus marking horizontal lines due to the motion of the record.

As the roll *E* traverses the tracker bar, appropriate

perforations control the condenser relays so as to switch the proper condensers into and out of the tuned circuit. Proper perforations also control the frequency lamp relay which flashes frequency lines on the record by means of lamp *G*. Relay *F* is inserted in order to make the flash of short duration.

The tracker-bar-paper roll apparatus was received as a unit from the manufacturer and was installed after making modification in the reversing mechanism as mentioned above. This was done in the interest of

automatic control. The paper roll is kept in its proper course over the tracker bar by means of an automatic adjusting device such as used in practically all high grade player pianos.

As the paper progresses over the tracker bar a point is finally reached where the last condenser connections are made and it becomes necessary to rewind the roll and to restore the entire mechanism to its starting condition. This is accomplished by means of a perforation at the end of the record which admits air to chamber *M* of the main control relay, thus closing contacts *J*. Relay *S* then operates since its circuit to ground is completed through contacts *P*. Operation of relay *S* opens contacts *T* thus disconnecting lamps *H* and *I*, and closes contacts *U* and *V*. It will be seen that the closing of contacts *U* operates the reversing mechanism, and rewinding of the roll begins immediately. The closing of contacts *V* operates the slide valve thus releasing the vacuum on the main header, allowing the roll to be rewound with minimum mechanical drag.

It may be noted that means are also provided for rewinding the roll from any point in its forward travel by admitting air manually at the reversing key. This will cause the main control relay to operate so that rewinding will begin. Vacuum is kept on the auxiliary

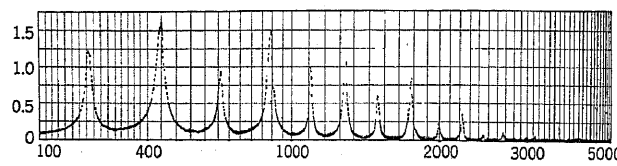

FIG. 8—OUTPUT OF CARBON BUTTON DRIVEN AT AN EXCESSIVE AMPLITUDE

header during the rewind so that control of the analyzer may be maintained to the end of the operating cycle.

When the paper has been completely rewound perforations allow air to enter simultaneously chamber *O* of the main control relay and chamber *N* of the holding relay. This action opens contacts *J* and *K*, thus bringing the entire mechanism to rest in its initial starting condition.

APPLICATIONS

To show the variety of problems in which the analyzer is a useful means of investigation, a few illustrative records have been made and will be discussed. These records were taken in each case to illustrate the use of the analyzer and are not parts of investigations to which they are related. They cannot, therefore, be taken as representative of the performance of the apparatus tested.

One of the uses of the analyzer has been in the study of the performance of microphone buttons. Fig. 8, for example, illustrates the character of the distortion in a button when driven at an excessive amplitude. The button was mounted so that its movable electrode could be driven at a single frequency by a very heavy reed at its natural frequency so that the motion was very nearly sinusoidal. The frequency of the motion was a little less than 450 cycles corresponding to the second peak on the record. The amplitude of motion was 0.001 centimeter or 0.0004 inch which is, of course, much greater than normally obtains in a transmitter. The circuit consisted simply of the button and a battery in series with the analyzer so that the record is an analysis of the current fluctuations in the button. The record shows two series of frequencies generated by the button; a primary series, having for its fundamental the driving frequency, 450 cycles, and a subsidiary series, having for its fundamental half the driving frequency or 225 cycles. The even harmonic components of the secondary series coincide, of course,

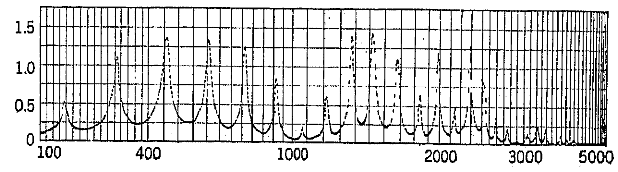

FIG. 9—NOISE IN ROOM AS PICKED UP BY CONDENSER TRANSMITTER

with the frequencies of the primary series. The primary series can be accounted for by the fact that with such large amplitudes the changes in resistance are not a linear function of the amplitude of motion. The subsidiary series is due to the non-symmetrical effect of the inertia of the carbon grains in vibration, the motion being so violent that some of the grains are thrown free from their contacts. For small amplitudes such as those ordinarily encountered in a transmitter, a record would show only 450 cycles, the other frequencies occurring in negligible amount; for intermediate amplitudes the primary series only occurs.

The analyzer has been used in connection with the

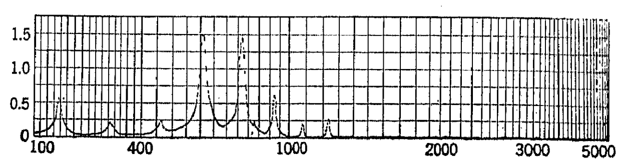

FIG. 10—NOISE IN ROOM AS PICKED UP BY TELEPHONE RECEIVER USED AS A TRANSMITTER

study of sustained sounds and of the performance of acoustical apparatus. Fig. 9 is a record of the noise in a room originating from a buzzer as picked up by a condenser transmitter.[2] The reverberation in the room probably had a large effect on the character of this record. With such a source of frequency the analyzer may be used to study the acoustics of rooms. Fig. 10 is a record of the same noise as in Fig. 9 but as picked up by a common type of telephone receiver

2. "A Condenser Transmitter as a Uniformly Sensitive Instrument for the Absolute Measurement of Sound Intensity." E. C. Wente, *Physical Review*, July 1917.

"The Sensitivity and Precision of the Electrostatic Transmitter for Measuring Sound Intensities." E. C. Wente, *Physical Review*, May 1922.

placed in the same position as the condenser transmitter. A comparison of Figs. 9 and 10 will show the inadaptability of such a receiver for use as a transmitter. The receiver, owing to the resonance of its diaphragm, is seen to be relatively sensitive in the region of 600 to 800 cycles and insensitive at most other frequencies. When this instrument is placed against the ear, as when used as a receiver, the diaphragm resonance is damped so as to give more nearly uniform response.

By means of the calibration of the condenser transmitter and its amplifier, it is possible to make an analysis of the absolute intensity of a sustained sound in the air. This method has been used to study the frequency characteristics of musical instruments. Fig. 11 shows the analyses of three low-frequency organ

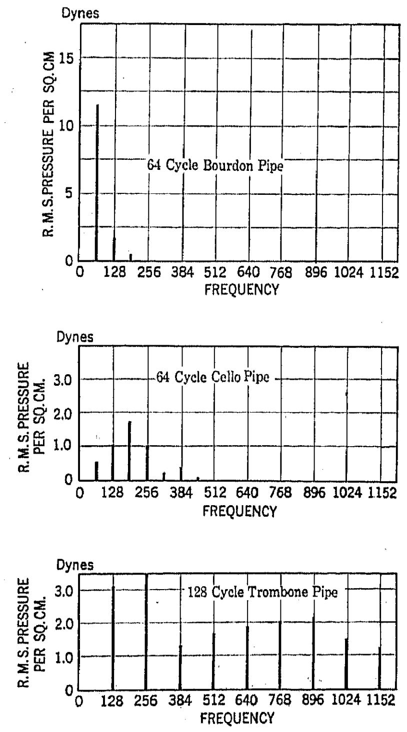

Fig. 11—Analysis of Organ Pipe Tones

pipes. These are plots of r. m. s. pressure change in the sound wave as obtained from the analyzer records. Each vertical line corresponds to a peak on the original record. The upper chart shows the almost pure tone given by a 64-cycle Bourdon pipe. In the case of the cello pipe, also having a fundamental of 64 cycles, the third harmonic is seen to be more prominent than the fundamental or second harmonic. The third chart is for a 128-cycle trombone pipe which was found to be rich in harmonics. The pressure in the single components of the cello and trombone pipes is less than in the case of the Bourdon pipe, and a larger scale of ordinates is therefore used.

To illustrate the use of the attachment which permits the making of two simultaneous analyses, a few double records will be presented. An electric wave filter which has been used in the study of telephone quality was connected to the buzzer source whose output is shown in Fig. 2. Simultaneous analyses of the current delivered to and transmitted through the filter are shown in Fig. 12. This filter is designed to pass all frequencies below 1000 cycles and to suppress all others. The input is represented by a more or less continuous series of peaks along the entire length of

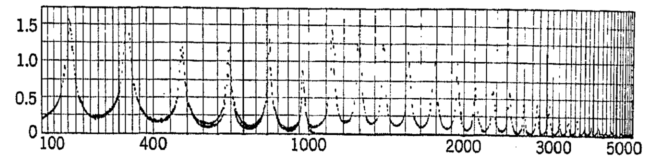

Fig. 12—Record Showing Action of Low Pass Filter

the record. The peaks corresponding to the output coincide rather closely with the input peaks for all frequencies below 1000 cycles and are not detectable for the higher frequencies.

Fig. 13 is a double record showing the analysis of the wave from a buzzer as fed into a common type of loud speaking receiver and the acoustic output as picked up by a condenser transmitter placed in front of

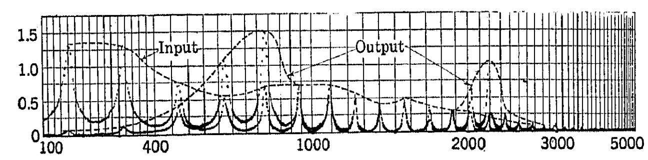

Fig. 13—Records of Electrical Input and Acoustic Output of a Common Type of Loud Speaking Receiver

it at a distance of about 15 inches. The analysis of the input current wave to the loud speaker is shown by the comparatively continuously decreasing series of peaks. The acoustic output is represented by the series having maxima in the neighborhood of 800 cycles and 2200 cycles. This record cannot be taken as an adequate analysis of this loud speaker because of probable reverberation effects in the room.

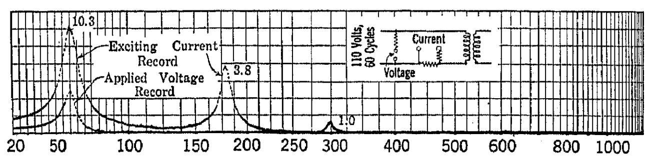

Fig. 14—Record Taken on Transformer at No Load

The analyzer has thus far not been used in the study of power problems. A few illustrative records have been taken, however, on transformers and generators and will be shown as suggestive of the use of this method of attack in such problems.

Fig. 14 is a double record showing applied voltage and exciting current of a small 110-volt, 60-cycle transformer operating at normal voltage and frequency

under the no-load condition. The presence of the well known third and fifth harmonics in the exciting current is clearly shown. Because of the rise in the calibration curve of the analyzer at the low end of the lower frequency range, a scale of ordinates is not shown on this record. Instead, the values of the analyzer current at each frequency are noted on the record. The circuit used in making this record is drawn on the figure. A computation of the components of the exciting current from the record and constants of the circuit shows that at 60 cycles the current was 175 milliamperes, at 180 cycles, 65 milliamperes and at 300 cycles, 17 milliamperes. The total r. m. s. exciting current was, therefore, 187 milliamperes.

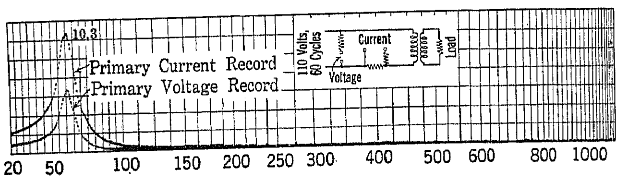

Fig. 15—Record Taken on Transformer Under Load

The operation of this transformer under full load is shown in Fig. 15, where, as before, the primary voltage and current are analyzed. The transformer load consisted of a pure resistance. It will be noted that the third and fifth harmonics have become very small compared with the fundamental. The analyzer currents at each frequency are again noted on the record. In obtaining the analysis of the current it was necessary to further shunt the analyzer. The primary current was 310 milliamperes.

Problems relating to commutation may also be conveniently studied qualitatively and quantitatively by means of the analyzer. The use of an apparatus which will indicate the source and measure the extent of

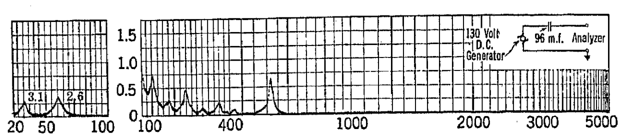

Fig. 16—Record Taken on D. C. Generator at No Load

parasitic frequencies is obvious. Information has been obtained on a small machine direct-driven by a ½-h. p., 60-cycle single-phase motor. Data of importance relating to the generator tested are as follows:

Capacity of Generator	¼ kw.
Number of Poles	2
Speed	1725-1800 r. p. m.
Voltage	125
Field	Shunt-connected
Diameter of Commutator	2.75 in.
Number of Commutator Bars	38
Number of Armature Slots	19
Size of Brush	3/8 in. square
Yoke	Ring type

Records obtained from this machine when operating under no-load and half-load conditions are shown in Figs. 16 and 17, respectively. The corresponding speeds are approximately 1800 and 1750 r. p. m. In order to show what frequencies the machine gives out over the entire range 20 to 5000 cycles each figure is made up of two parts: a portion of a 20-1250 record and a complete record over the range 80-5000 cycles. On each figure is drawn the circuit connecting the d-c. generator to the analyzer. It will be noted that a large condenser is inserted to prevent the passage of heavy direct current through the analyzer.

The consideration of these records leads to the conclusion that there are at least three independent major causes of alternating voltage operating in this d-c. machine. The fundamental frequencies due to these causes are 30, 60 and 570 cycles. It will be noted that the 30-cycle peak occurs only on the no-load record under which condition the average speed is practically 30 revolutions per second. Sixty cycles and a series of its harmonic overtones are seen to be present under both conditions of load. Under load the 60 cycles is augmented whereas its harmonics are reduced. No harmonic overtones of 30 cycles except such as might coincide with the harmonics of 60 cycles

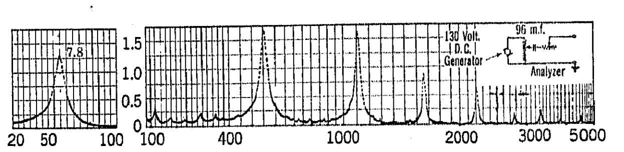

Fig. 17—Record Taken on D. C. Generator Under Load

are found in either case. This indicates the existence of independent causes of the 30 and 60 cycle frequencies, that the 30-cycle cause produces an almost sinusoidal voltage, and that the 60-cycle cause under no load produces an irregular wave which becomes smoother as the machine is loaded.

The no-load record, Fig. 16, shows 570 cycles with no harmonics while the load record, Fig. 17, shows 570 cycles with a complete series of harmonics. This indicates that at no load the cause of 570 cycles feeds a relatively smooth wave to the line while under load this cause feeds an irregular wave to the line. The fact that 1140 cycles is about as strong as the fundamental and that its harmonics are stronger than alternate ones which are overtones of 570 only, suggests the likelihood of a fourth cause having a frequency of 1140 cycles. Small irregularities at frequencies other than those already mentioned occur in the record. These are more prominent under load than at no load and indicate the presence of small, more or less irregular pulses, which increase with load. All of the above frequencies may be accounted for by a consideration of the construction and operating condition of the machine.

The generator was driven by a single-phase, 4-pole,

60-cycle motor which may give rise to torque fluctuations once per revolution, or 30 times per second. Under no load this may produce considerable corresponding fluctuations in speed while under load conditions the generator acts as a damper, eliminating these oscillations.

The 60-cycle peak may be due to any one or some combination of a number of causes, *e. g.*, eccentricity of generator armature, non-uniform winding, non-uniform thickness of mica separators in commutator, high mica between one or more pairs of segments, etc. The records show that for this particular machine in its present condition (new) at normal speed the 60-cycle voltage developed increases considerably with load indicating strongly that the cause is largely influenced by an IR drop somewhere in the machine. The most likely causes therefore appear to be commutator eccentricity, irregular spacing of the segments, or high mica.

The peak at 570 cycles may be accounted for by cyclic variation of flux entering the armature core as the teeth pass the pole faces. At no load the speed is approximately 1800 r. p. m. The number of teeth being 19, it is obvious that there will be 570 fluctuations of air-gap reluctance per second. Under no-load conditions the record shows a comparatively pure wave form for this cause. This is to be expected because of the comparatively uniform distribution of flux under the pole faces at no load. As the machine is loaded, however, the field is distorted and shifted giving rise to an irregular wave form of voltage which is responsible for at least a part of the large harmonic content shown by the load record.

The presence of 1140-cycle peak which is present only under the load condition may be due to the cyclic variation of voltage produced by the commutator bars leaving the brushes. Inasmuch as the speed is roughly about 29 revolutions per second the frequency with which bars leave brushes is about 1100 cycles. This frequency is present under the load condition only, thus indicating that it is due to an IR drop at the brush contacts or to an e. m. f. developed in the short-circuited coil with the brush off the magnetic neutral.

The very small irregularities on the record shown particularly between peaks above 550 cycles on the load record are probably due to slight chattering of the brushes.

It is of interest to note that the so-called frequency of commutation does not appear in either of the records. For this machine this frequency at no load is approximately 346 cycles per second.

From these records it is possible to determine the r. m. s. value of the alternating voltage at any frequency of interest. This is computed from a knowledge of the circuit constants and analyzer impedance. We, thus obtain for the 550 cycle peak (Fig. 17), a value of 0.8 volts and for the 60-cycle peak a value of 1.1 volts.

In general the records taken by means of the analyzer on this commutating machine, confirm quantitatively the well known fact that such machines may give rise to frequencies in the audible range. Consideration of the records indicates that these frequencies may be divided into two classes: First, those pertaining to and controlled by design, and second, those caused and controlled by the physical condition of the machine at any particular time. It is also interesting to note that the driving motor may produce an appreciable effect, particularly under the no-load condition.

Summary

In the above paper there has been given a short statement of the theory and construction of an automatic, recording, electrical frequency analyzer, together with illustrations showing its use and limitations in various fields.

This apparatus has been found very useful in the laboratory in the investigation of many different types of problems chiefly because of the speed with which records can be made and harmonic analyses obtained without computation.

In conclusion the authors wish to express their appreciation to Mr. C. E. Lane and Mr. C. E. Dean, of the Western Electric Company, Inc., for their assistance in the building of this machine and the preparation of this paper.

Discussion

H. Fletcher: I desire to emphasize the tremendous difference in the time required for obtaining analyses by means of this machine and by the method which has usually been employed in the past. After the electrical connections are made, all you have to do is to press a button and then after waiting five minutes you have a photographic record of the analysis, before you are ready for examination. This machine will do in two or three hours what previously required as much as two or three months' work for obtaining the spectrum analyses of such sounds as the output of a horn or organ pipe.

Since the development of the condenser transmitter, which has a practically uniform response with frequency, and of amplifiers, which have similar characteristics, it is now possible to use these new tools for picking up an acoustic wave and transforming it into electrical form without any appreciable distortion. When it is thus transformed it can be sent through the analyzer and in five minutes' time an analysis can be obtained which shows the frequency and magnitude of the components. You can readily see the tremendous advantage such a device will be in research work.

For example, we were trying to find the essential physical thing that caused one to judge the pitch of a musical tone. It is well-known that practically every musical tone has a large number of components, the fundamental and a series of harmonics. We were very much surprised to find that the elimination of the lower frequency range, including the fundamental and first few harmonics, did not change the pitch. For example, musical tones were observed, which had no component frequencies below 500 cycles per second, which still gave a pitch corresponding to a simple pure tone having a vibration frequency of 100 cycles per second. Naturally, when we first observed this phenomena, we were somewhat skeptical of the fact that these frequencies were actually eliminated. This

harmonic analyzer soon gave us convincing proof that they were absent.

Another example will suffice to show the usefulness of this apparatus for acoustic work. In studying the acoustics of rooms, if one took a record of a sound wave under certain conditions, and then had to wait two or three weeks before obtaining an analysis of this wave before making any changes in the room, such as, moving some of the furniture, it is evident that the progress would be very slow. With this device one can get an acoustic picture of what is taking place in the room, move a desk, or something else which you are interested in, and then take another picture, etc., so that in a few days time you can accomplish what used to required months without such a device.

L. P. Ferris: This paper describes a device which may be very useful in making investigations of wave form of power machinery such as may be carried out by large manufacturers. Because of its weight and bulk, the instrument is not suitable for making investigations in the field but for permanent installation in a large test room or laboratory, this would not be a serious drawback. Investigations are now being made of wave shape of power machinery involving the higher harmonics which are difficult to measure with the oscillograph. It is hoped, in these investigations, to obtain information looking toward the reduction of these harmonics because of their contribution to telephone interference. A device built along these lines may be of great assistance in these investigations, by disclosing quickly the magnitudes of the harmonics.

The Multiple-Radial System of Cooling Large Turbo-Generators

BY DONALD BRATT

Formerly with Power Engineering Dept., Westinghouse Electric and Mfg. Co.

Review of the Subject.—*The paper discusses the theoretical basis of a special turbo-generator ventilation system, in which the cooling air divides into several branches, and passes through the stator core radially in and out.*

An extended series of experiments on a full-size model, embodying this system, has lately been carried out by the Westinghouse Co. The tests are described in a paper by C. J. Fechheimer under the Title: "Experimental Study of Ventilation of Turbo-Alternators."

The fundamental questions in regard to the flow of air in any ventilation system are:

1. How high pressure is required to force through a certain volume of air per unit time?

2. How will the air distribute, axially and radially, in the different intake and discharge vents?

3. What will be the "balanced state" of flow, if several branches of air meet and divide in a tube, the intake and discharge taking place normal to the walls of the tube?

These questions are given a thorough analysis, under certain simplifying assumptions, and it is shown that

1. The total pressure required for a certain volume of air per unit time is expressible by means of hyperbolic and trigonometric cotangents of a certain argument, which contains the geometrical dimensions of the air-circuit.

2. The air is distributed according to a simple hyperbolic or trigonometric sine-law.

3. The "balanced state" depends on the solution of a system of simultaneous transcendental equations.

A method of solution is outlined, which is applicable for such cases where the arguments are small. In such cases the transcendental equations reduce to simple algebraic equations.

A numerical example is finally worked out in order to show the application of the derived formulas.

Description of System and Statement of Problem

FIGURE 1 illustrates the radial system of ventilation diagrammatically.

The fans $F\,F$ which are attached to the rotor R set up a static pressure in the end-bells $E\,E$. As a result the air, taken in by the fans at $a\,a$, is forced to flow through the system by way of i or g. g is the air gap, i is a duct back of the core, leading to several intake sections I in the core, in which the air travels radially

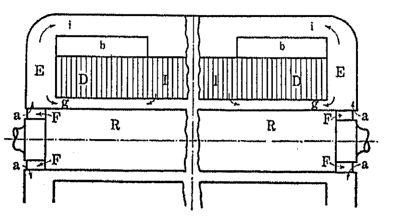

Fig. 1

inwards, dividing in the gap and discharging over the sections D, which are in communication with the external atmosphere at b.

The iron core is assembled as usual in packages, leaving equi-distant vents axially, in which the air alternatively enters and discharges. The arrows indicate the direction of flow.

It is of great importance to know how much air will pass the total system at a given static pressure in the end-bells.

Also, it is necessary to know how the velocity of the air is distributed, as this is of paramount importance relative to the temperature of the iron.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

Any attempt to answer these questions exhaustively would necessarily present very great mathematical difficulties. This is particularly evident, as the air in the gap is partly carried along by the rotation of the rotor. It will first of all be necessary, therefore, to neglect the influence of this rotation, which means the same as to assume that the static pressure in the end-bells is furnished by separate external fans. It has been conclusively proved, by actual tests on a full-scale model, that the influence of the rotation on the total volume of air passing is small, and also that the rotation tends to equalize the velocity in the different vents axially. Thus, the temperature in the iron is probably more evenly distributed under running conditions due to the effect of the rotation, so that our assumption errs on "the safe side."

The fundamental law, governing the flow of an

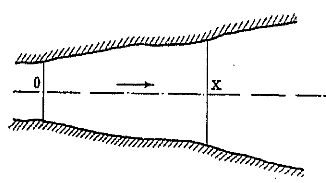

Fig. 2

incompressible fluid is the one first expressed by Bernoulli, stating, that the sum of static head, velocity head and losses, counted from some chosen origin and in the direction of the flow, remains constant. It follows from this, that for any particular circuit $o\,x$ (Fig. 2) we can put the total pressure drop from o to x proportional to the mean air velocity-square at x: the constant of proportionality depending, of course, on x.

Let P = total pressure-drop from o to x
p = static pressure at x
v = velocity at x
γ = density of fluid
g = acceleration of gravity.
then, at any point x we have

$$1. \quad p + \frac{\gamma\, v^2}{2\,g} + \sum_0^x \text{(losses)} = \text{Const.}$$

$$2. \quad P = \sum_0^x \text{losses} = k \times \frac{v^2}{2\,g}$$

The velocity v denotes the volume air per unit time divided by the cross-section at the particular point in question. Hence, no attention is paid to the fact, that the air velocity may vary across the section.

The loss in total head is neglected. Hence, the Bernoulli equation may be written:

$$p + \frac{\gamma\, v^2}{2\,g} = \text{const.}$$

This is necessary in order to obtain reasonably simple results. (Some additional remarks on this particular assumption will be found below).

It is further necessary to assume that the air behaves like an incompressible fluid, that is, that the "principle of continuity" holds.

This is comparatively justified, since the total atmospheric pressure is about 405 in. water, and the total pressure drop in a ventilation-system of this kind rarely would have to exceed 15 in. water, or 3.7 per cent of the total pressure.

The balanced state of flow in a multiple-circuit system will, for its solution, depend on the solution of the air distribution in every particular branch, each branch consisting of one intake and one discharge-length. It is, therefore, necessary to treat one such circuit for itself, assuming the intake- and discharge-lengths, etc., to be known, and then to apply the results to the multiple circuit.

This involves the assumption, that there is, between any two air streams in the tube, a closed wall across the tube, against which wall there is, however, no resultant pressure from either side, since the flow is balanced.

It is evident that such balanced points must exist in a multiple system, but it is difficult to say to what extent the conditions would change, (if they changed at all) if partition-walls were actually introduced.

It is, finally, necessary to assume a constant intake and discharge area per unit length of the gap axially, in order to apply the methods of calculus. This fictitious intake and discharge area per unit length is taken equal to the total cross-section area of one vent-circle axially, at the minimum cross-section, divided by the length of one iron package + one radial vent-width axially.

The preliminary problem has now been reduced to that illustrated by Fig. 3. A tube of, say, circular cross-section, closed at both ends, is to a certain length inserted in a pressure-chamber, while the rest of the tube protrudes into the surrounding atmosphere. The tube is perforated, giving a constant intake and discharge area per unit length of the tube.

It is required to determine the total volume of air passing the tube at a given pressure in the chamber, also to determine the law for the air distribution axially.

ASSUMPTIONS MADE TO SIMPLIFY PROBLEM

It is, perhaps, profitable to summarize the assumptions that have been discussed above.

a. The effect of the rotation is neglected.

b. The variation in air-velocity across the gap, or any other cross-section of the system, is neglected.

c. The loss of head in the gap (or tube) is neglected.

d. The air is incompressible.

e. At any such point in the air gap, where one incoming stream of air divides, or two streams meet, a closed wall is assumed to exist.

f. A uniform intake or discharge-area per unit length of gap axially is substituted for the actual, non-uniform area.

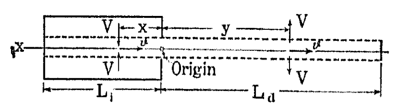

FIG. 3

LIST OF SYMBOLS (FIG. 3).

x = axial coordinate of intake-belt
y = " " " discharge-belt
p = static pressure in tube at x or y
v = axial air-velocity at x or y
V = intake or discharge air-velocity at x or y
a = uniform cross section area of tube
s = uniform intake or discharge area per unit length[1]
P = external pressure (in intake pressure-chamber)
γ = density of air
g = acceleration of gravity

c_i = intake-coefficient, defined by equation $\frac{P - p}{\gamma} = c_i \times \frac{V^2}{2\,g}$

c_d = discharge- " " " " $P/\gamma = c_d \times \frac{V^2}{2\,g}$

L_i = length of intake-belt
L_d = " " discharge-belt

1. The length-unit will henceforth be taken as one vent-pitch axially.

Note: The constants c_i and c_d deserve special attention. The definition

$$\frac{P - p}{\gamma} = c_i \times \frac{V^2}{2\,g}\,; \quad P/\gamma = c_d \times \frac{V^2}{2\,g}\,;$$

means, that the intake air-velocity V can be put proportional to the square-root of the drop in static pressure from the pressure-chamber to the air in the tube, and that the discharge air-velocity likewise can be put proportional to the square-root of the drop in static pressure from the tube to the atmosphere.

The numerical value of c_i and c_d can be determined from the dimensions of the vents in the teeth; the

method of calculation cannot, however, be discussed in this paper.

DERIVATION OF FORMULAS FOR INTAKE AND DISCHARGE

a. Intake. Consider the flow along the axis of the tube! By virtue of the assumptions, we must have the sum of the static head and the velocity head constant at all positions:

$$p/\gamma + \frac{v^2}{2g} = \text{const.} \tag{1}$$

But from definition of c_i we have

$$\frac{P - p}{\gamma} = c_i \times \frac{V^2}{2g} \tag{2}$$

So that

$$P/\gamma = P/\gamma - c_i \times \frac{V^2}{2g}$$

Substitute in equation (1), we get

$$P/\gamma - c_i \times \frac{V^2}{2g} + \frac{v^2}{2g} = \text{const.}$$

and by differentiation

$$v \frac{dv}{dx} - c_i V \frac{dV}{dx} = 0 \tag{3}$$

(observing that P/γ and $2g$ are constants.)
In addition to equation (3) we have the obvious condition that the increase in axial velocity over the infinitesimal length dx shall correspond to the air taken in over dx (principle of continuity.)

$$a\,dv = s\,V\,dx$$

or

$$V = a/s \times \frac{dv}{dx} \tag{4}$$

Hence, by differentiation of (4)

$$\frac{dV}{dx} = a/s \times \frac{d^2 v}{dx^2}$$

Substitute this expression in (3) then

$$v \frac{dv}{dx} - c_i\, a/s \frac{dv}{dx}\, a/s \frac{d^2 v}{dx^2} = 0; \text{ or, simpler}$$

$$\frac{d^2 v}{dx^2} - \frac{s^2}{a^2 c_i} \times v = 0 \tag{5}$$

This equation is linear in v and $\frac{d^2 v}{dx^2}$; it has "constant coefficients," and its solution is well-known to be:

$$v = A\, e^{\frac{Sx}{a\sqrt{c_i}}} + B\, e^{-\frac{Sx}{a\sqrt{c_i}}} \tag{6}$$

A and B are the two integration constants to be determined.

Initial conditions:

for $x = 0$ put $v = v_0$

" $x = L_i$ we have $v = 0$

Thus

$$v_0 = A + B$$

$$0 = A\, e^{\frac{SL_i}{a\sqrt{c_i}}} + B\, e^{-\frac{SL_i}{a\sqrt{c_i}}}$$

$$B = v_0 - A;\ 0 = A\, e^{\frac{SL_i}{a\sqrt{c_i}}} + (v_0 - A)\, e^{-\frac{SL_i}{a\sqrt{c_i}}}$$

$$A = -\left(v_0\, e^{-\frac{SL_i}{a\sqrt{c_i}}}\right) : \left(e^{\frac{SL_i}{a\sqrt{c_i}}} - e^{-\frac{SL_i}{a\sqrt{c_i}}}\right)$$

$$B = \left(v_0\, e^{\frac{SL_i}{a\sqrt{c_i}}}\right) : \left(e^{\frac{SL_i}{a\sqrt{c_i}}} - e^{-\frac{SL_i}{a\sqrt{c_i}}}\right)$$

Substituting in (6) thus

$$v = -v_0 \times \frac{e^{-\frac{S(L_i - x)}{a\sqrt{c_i}}}}{e^{\frac{SL_i}{a\sqrt{c_i}}} - e^{-\frac{SL_i}{a\sqrt{c_i}}}} + v_0 \times \frac{e^{\frac{S(L_i - x)}{a\sqrt{c_i}}}}{e^{\frac{SL_i}{a\sqrt{c_i}}} - e^{-\frac{SL_i}{a\sqrt{c_i}}}}$$

which can also be written

$$v = v_0 \times \frac{\sinh\left(\frac{s(L_i - x)}{a\sqrt{c_i}}\right)}{\sinh\left(\frac{sL_i}{a\sqrt{c_i}}\right)} \tag{7}$$

By aid of (4) then, after differentiation of (7)

$$V = v_0/\sqrt{c_i} \times \frac{\cosh\left(\frac{s(L_i - x)}{a\sqrt{c_i}}\right)}{\sinh\left(\frac{sL_i}{a\sqrt{c_i}}\right)} \tag{8}$$

and for the static pressure, by aid of (2)

$$p = P - \gamma \times \frac{v_0^2}{2g} \times \frac{\cosh^2\left(\frac{s(L_i - x)}{a\sqrt{c_i}}\right)}{\sinh^2\left(\frac{sL_i}{a\sqrt{c_i}}\right)} \tag{9}$$

b. Discharge. For the axis of the tube we have again:

$$p/\gamma + \frac{v^2}{2g} = \text{const. (equation 1)}$$

and by definition of c_d

$$p/\gamma = c_d \times \frac{V^2}{2g} \tag{10}$$

Substituting, then

$$c_d \times \frac{V^2}{2g} + \frac{v^2}{2g} = \text{const.}$$

By differentiation

$$c_d \cdot V \frac{dV}{dy} + v \frac{dv}{dy} = 0 \qquad (11)$$

In this case the axial velocity decreases as y increases, hence (compare 4).

$$a\,dv = -s\,V\,dy$$

or

$$V = -a/s \frac{dv}{dy} \qquad (12)$$

By differentiation of (12)

$$\frac{dV}{dy} = -a/s \frac{d^2 v}{dy^2} \qquad (13)$$

Substitute in (11) then

$$c_d\left(-a/s \frac{dv}{dy}\right)\left(-a/s \frac{d^2 v}{dy^2}\right) + v \frac{dv}{dy} = 0$$

or, simpler (compare (5)

$$\frac{d^2 v}{dy^2} + \frac{s^2}{a^2 c_d} \cdot v = 0 \qquad (14)$$

The solution of (14) is well-known to be:

$$v = A \sin\left(\frac{s\,y}{a\sqrt{c_d}}\right) + B \cos\left(\frac{s\,y}{a\sqrt{c_d}}\right) \qquad (15)$$

Initial conditions:

for $y = 0$ put $v = v_0$

" $y = L_d$ we have $v = 0$

Substitute in (15); then

$$v_0 = B;\ 0 = A \sin\left(\frac{s\,L_d}{a\sqrt{c_d}}\right) + B \cos\left(\frac{S\,L_d}{a\sqrt{c_d}}\right)$$

$$A = -v_0 \frac{\cos\left(\frac{s\,L_d}{a\sqrt{c_d}}\right)}{\sin\left(\frac{s\,L_d}{a\sqrt{c_d}}\right)};\ B = v_0$$

Then (15) becomes

$$v = v_0 \times \frac{\cos\left(\frac{s\,L_d}{a\sqrt{c_d}}\right) \times \sin\left(\frac{s\,y}{a\sqrt{c_d}}\right)}{\sin\left(\frac{s\,L_d}{a\sqrt{c_d}}\right)} + v_0 \cos\left(\frac{s\,y}{a\sqrt{c_d}}\right)$$

or, simpler

$$v = v_0 \times \frac{\sin\left(\frac{s\,(L_d - y)}{a\sqrt{c_d}}\right)}{\sin\left(\frac{s\,L_d}{a\sqrt{c_d}}\right)} \qquad (16)$$

and, by aid of (12)

$$V = v_0/\sqrt{c_d} \times \frac{\cos\left(\frac{s\,(L_d - y)}{a\sqrt{c_d}}\right)}{\sin\left(\frac{s\,L_d}{a\sqrt{c_d}}\right)} \qquad (17)$$

Finally, by aid of (10)

$$p = \gamma \times \frac{v_0^2}{2g} \times \frac{\cos^2\left(\frac{s\,(L_d - y)}{a\sqrt{c_d}}\right)}{\sin^2\left(\frac{s\,L_d}{a\sqrt{c_d}}\right)} \qquad (18)$$

If v_0 is the same both for intake and discharge and p has the same value at $x = 0$ and $y = 0$; which is, physically necessary, we may equate (9) and (18) at $x = y = 0$. thus

$$P/\gamma - \frac{v_0^2}{2g} \coth^2\left(\frac{s\,L_i}{a\sqrt{c_i}}\right) = \frac{v_0^2}{2g} \cot^2\left(\frac{s\,L_d}{a\sqrt{c_d}}\right)$$

or

$$P = \gamma \times \frac{v_0^2}{2g}\left[\coth^2\left(\frac{s\,L_i}{a\sqrt{c_i}}\right) + \cot^2\left(\frac{s\,L_d}{a\sqrt{c_d}}\right)\right] \qquad (19)$$

Equation (19) determines v_0 when P, L_i and L_d are known.

Note. The appearance of trigonometric functions in the formulas for the discharge deserves special attention.

We must have V *positive* for $y = 0$ (meaning discharge) hence it is necessary that $(s\,L_d) : (a\sqrt{c_d}) \leq \pi/2$.

The special case when $\frac{s\,L_d}{a\sqrt{c_d}} = \pi/2$ is particularly interesting. Then

$$v = v_0 \cos\left(\frac{s\,y}{a\sqrt{c_d}}\right);\ V = v_0/\sqrt{c_d} \sin\left(\frac{s\,y}{a\sqrt{c_d}}\right);$$

$$p = \gamma \frac{v_0^2}{2g} \cos^2\left(\frac{s\,y}{a\sqrt{c_d}}\right)$$

hence for $y = 0$ we have $V = 0$; $p = 0$

" $y = L_d$ " " $V = v_0/\sqrt{c_d}$; $p = \gamma \cdot \frac{v_0^2}{2g}$

If, therefore, $\frac{s\,L_d}{a\,\sqrt{c_d}} > \pi/2$ we will get $V = 0$; $p = 0$ for $y = 0$ *and* V *will remain* $= 0$ until such a y' has been reached, that

$$[s\,(L_d - y')\,] : (a\,\sqrt{c_d}) = \pi/2$$

From now on the static pressure starts to increase and the discharge begins.

It is evident, that the idea of a discharge-tube, where no air escapes except over a certain length adjacent to the closed end of the tube, must be in conflict with

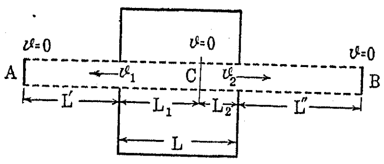

Fig. 4

reality. This is, however, a direct consequence of the assumption that there are no losses of total head in the tube. To overcome such losses a static pressure would always be necessary, resulting in a drop in static head from the tube to the atmosphere, *i. e.*, a discharge would always take place.

A good mechanical analogy is represented by a weight which is pushed over a rough table. The friction makes it necessary to apply a certain force behind the weight, which force would then correspond to the static pressure. If friction was eliminated, the pushing force would drop to zero, and the work represented by the uniform motion of the weight would just equal the work spent to establish the motion, or the work necessary to stop it.

The fundamental equation (1) would strictly have to be written:

$$p/\gamma + \frac{v^2}{2\,g} + \sum_0^x (\text{losses}) = \text{const.}$$

Assuming the losses to be proportional to the square of the axial velocity v and also, for a small length, proportional to that length, we would have

$$\sum_0^x (\text{losses}) = f \times \int_0^x \frac{v^2}{2\,g}\,d\,x$$

where f is a friction coefficient, so that

$$p/\gamma + \frac{v^2}{2\,g} + f \times \int_0^x \frac{v^2}{2\,g}\,.\,d\,x = \text{const.}$$

This equation is evidently much more complicated than (1) and it involves an assumption, which is quite arbitrary, as the law for the losses is not known. It is, therefore, necessary to neglect the losses, that is, to put

$$f \times \int_0^x \frac{v^2}{2\,g}\,d\,x = 0$$

in order to obtain simple results. To correct the error resulting from this approximation, it would be necessary to augment the values of c_i and c_d. These corrections could only be obtained from experiments.

Summary of Formulas

Intake:

$$v = v_0 \times \frac{\sinh\left(\frac{s\,(L_i - x)}{a\,\sqrt{c_i}}\right)}{\sinh\left(\frac{s\,L_i}{a\,\sqrt{c_i}}\right)}$$

$$V = v_0/\sqrt{c_i} \times \frac{\cosh\left(\frac{s\,(L_i - x)}{a\,\sqrt{c_i}}\right)}{\sinh\left(\frac{s\,L_i}{a\,\sqrt{c_i}}\right)}$$

$$p = P - \gamma \times \frac{v_0^2}{2\,g} \; \frac{\cosh^2 \frac{s\,(L_i - x)}{a\,\sqrt{c_i}}}{\sinh^2 \frac{s\,L_i}{a\,\sqrt{c_i}}}$$

Discharge:

$$v = v_0 \times \frac{\sin\left(\frac{s\,(L_d - y)}{a\,\sqrt{c_d}}\right)}{\sin\left(\frac{s\,L_d}{a\,\sqrt{c_d}}\right)}$$

$$V = v_0/\sqrt{c_d} \times \frac{\cos\left(\frac{s\,(L_d - y)}{a\,\sqrt{c_d}}\right)}{\sin\left(\frac{s\,L_d}{a\,\sqrt{c_d}}\right)}$$

$$p = \gamma \times \frac{v_0^2}{2\,g} \times \frac{\cos^2\left(\frac{s\,(L_d - y)}{a\,\sqrt{c_d}}\right)}{\sin^2\left(\frac{s\,L_d}{a\,\sqrt{c_d}}\right)}$$

$$P = \gamma\,.\,\frac{v_0^2}{2\,g}\,.\left[\coth^2\left(\frac{s\,L_i}{a\,\sqrt{c_i}}\right) + \cot^2\left(\frac{s\,L_d}{a\,\sqrt{c_d}}\right)\right]$$

Conditions for Balance in One Intake and One Discharge

If air is taken in over a total length L in a tube similar to the above (Fig. 5) and the discharge conditions at A and B are different, for instance so that the discharging ends of the tube are different in length, the question arises: How will the air subdivide between the two halves or, in other words, where is the axial air velocity = 0 in the tube?

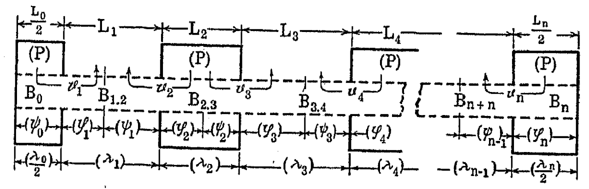

Fig. 5

Note: The quantities ψ φ and λ are here shown as lengths, but are really dimensionless quantities. This is done to show their relation to the actual lengths L_0 L_1, etc.

Notations:

P = total pressure drop
$v_1\,v_2$ = maximum axial air velocities
L = total intake-length axially
$L_1\,L_2$ = intake lengths corresponding to v_1 and v_2
$L'\,L''$ = discharge " " " " " "

Other notations as before.

Consider two separate systems, and a closed wall at $v = 0$ in the intake chamber.

The analytical expression for balance at C is the identity of V at $x = L_1$ and $x = L_2$ (counted from the left and from the right).

By use of equation (**8**) thus:

$$v_1/\sqrt{c_i} \times \frac{1}{\sinh\left(\dfrac{s\,L_1}{a\,\sqrt{c_i}}\right)} = v_2/\sqrt{c_i}$$

$$\times \frac{1}{\sinh\left(\dfrac{s\,L_2}{a\,\sqrt{c_i}}\right)};$$

which immediately gives

$$v_1 : v_2 = \frac{\sinh\left(\dfrac{s\,L_1}{a\,\sqrt{c_i}}\right)}{\sinh\left(\dfrac{s\,L_2}{a\,\sqrt{c_i}}\right)}$$

Further, from equation (**19**) applied to the left and to the right

$$P = \frac{\gamma\,v_1^2}{2\,g}\left[\coth^2\left(\frac{s\,L_1}{a\,\sqrt{c_i}}\right) + \cot^2\left(\frac{s\,L'}{a\,\sqrt{c_d}}\right)\right]$$

$$P = \frac{\gamma\,v_2^2}{2\,g}\left[\coth^2\left(\frac{s\,L_2}{a\,\sqrt{c_i}}\right) + \cot^2\left(\frac{s\,L''}{a\,\sqrt{c_d}}\right)\right]$$

Remembering $L_1 + L_2 = L$; we get for L_1 the equation

$$\frac{\coth^2\left(\dfrac{s\,(L - L_1)}{a\,\sqrt{c_i}}\right) + \cot^2\left(\dfrac{s\,l''}{a\,\sqrt{c_d}}\right)}{\coth^2\left(\dfrac{s\,L_1}{a\,\sqrt{c_i}}\right) + \cot^2\left(\dfrac{s\,L'}{a\,\sqrt{c_d}}\right)}$$

$$= \frac{\sinh^2\left(\dfrac{s\,L_1}{a\,\sqrt{c_i}}\right)}{\sinh^2\left(\dfrac{s\,(L - L_1)}{a\,\sqrt{c_i}}\right)}$$

which must be solved by some cut-and-trial method.

Discussion. For reasons of symmetry we get, when $L' = L'' : L_1 = L_2 = 1/2\,L$. Assume $L' = 0$; then

$$\cot\left(\frac{s\,L'}{a\,\sqrt{c_d}}\right) = \infty$$

and we must have

$$\sinh\left(\frac{s\,L_1}{a\,\sqrt{c_i}}\right) = 0 \text{ or } L_1 = 0$$

Similarly, when $L'' = 0$ we must have $L_2 = 0$ so that, when for instance L' decreases from $L' = L''$ to $L' = 0$, the balance point C will move from $L_1 = 1/2\,L$ towards $L_1 = 0$, and vice versa.

GENERAL MULTIPLE CIRCUIT; STATEMENT OF PROBLEM

The general problem represented by a multiple-radial system of ventilation is illustrated by Fig. 5.

This is merely an extension of the case treated above, when there are several air-branches in the tube, and hence several balance-points.

It is required to find the location of the balance-points. When these are known, the formulas for distribution of velocity are immediately applicable, and the total volume of air passing the system per unit time can be found.

It must be noted, that a solution of this problem can only be found by some cut-and-trial method, like in all cases, where transcendental functions of the unknown occur. Nevertheless, by simplifications, a sufficiently accurate solution can be obtained, as will be shown below, for certain cases.

LIST OF ADDITIONAL NECESSARY SYMBOLS

$\lambda_0/2$ is a fictitious length, corresponding to the drop in pressure, when the air enters from the End-Bell into the gap. (See Numerical Example below). $L_1\,L_2\,\ldots\,L_n$ are given lengths

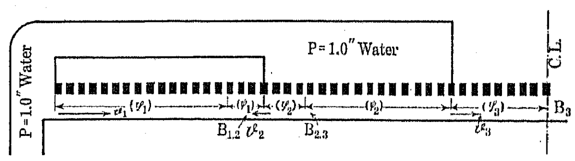

FIG. 6

Note: In regard to the quantities φ and ψ, see note, Fig. 5.

$$\lambda_0/2 = \frac{s\,L_0}{2\,a\,\sqrt{c_i}};\ \lambda_1 = \frac{s\,L_1}{a\,\sqrt{c_d}};\ \ldots\ \lambda_n/2 = \frac{s\,L_n}{2\,a\,\sqrt{c_i}}$$

are thus known, dimension-less quantities.

P = pressure in intake-chambers

$B_{i_1\,(i+1)}$ = balance-points, defined by $v = 0$

$v_1\,v_2\,\ldots\,v_n$ = maximum air velocities axially

$\psi_0\,\varphi_1\,\ldots\,\psi_{n-1}\,\varphi_n$ = unknown dimensionless quantities, determining the location of the balance-points, so that $\psi_0 = \lambda_0/2$; $\varphi_1 + \psi_1 = \lambda$, etc.

Other notations as before.

ESTABLISHMENT OF NECESSARY EQUATIONS TO SOLVE GENERAL PROBLEM

With above notations, using equations (**8**) and (**17**) as analytical expressions for balance, and equation (**19**) for the total pressure-drop to atmosphere, we get:

$$v_1/\sqrt{c_d}\cdot\frac{1}{\sin\varphi_1} \qquad P = \frac{\gamma\,v_1^2}{2\,g}\,(\coth^2\psi_0$$

$$= v_2/\sqrt{c_d}\cdot\frac{1}{\sin\psi_1} \qquad + \cot^2\varphi_1)$$

$$v_2/\sqrt{c_i}\cdot\frac{1}{\sinh\varphi_2} \qquad P = \frac{\gamma\,v_2^2}{2\,g}\,(\coth^2\varphi_2$$

$$= v_3/\sqrt{c_i}\,.\,\frac{1}{\sinh\psi_2} \qquad\qquad + \cot^2\psi_1)$$

$$\cdots\cdots\cdots \qquad\qquad \cdots\cdots\cdots$$

$$v_{n-1}/\sqrt{c_d}\,.\,\frac{1}{\sin\varphi_{n-1}} \qquad P = \frac{\gamma\, v_n^2}{2\,g}\,(\coth^2\varphi_n$$

$$= v_n/\sqrt{c_d}\,.\,\frac{1}{\sin\psi_{n-1}} \qquad\qquad + \cot^2\psi_{n-1})$$

[$= (n-1)$ equations] [$= n$ equations]

Further $\psi_0 = \lambda_0/2$, $\varphi_1 + \psi_1 = \lambda_1$, $\varphi_2 + \psi_2 = \lambda_2 \; . \; . \; .$ $\varphi_n = \lambda_n/2$ [$= (n+1)$ equations]

Unknowns are

$-\ \psi_0$	v_1
$\varphi_1\ \psi_1$	v_2
$\varphi_2\ \psi_2$	v_3
$\cdots$	
$\varphi_{n-1}\ \psi_{n-1}$	
$\varphi_n\ -\ [= 2\,n]$	$v_n\ [= n]$

There are $3\,n$ unknowns, and $(n-1) + n + (n+1) = 3\,n$ equations.

The problem is thus fully determined.

Approximate Treatment and Solution

If $\lambda_0/2\ \lambda_1\ \lambda_2\ .\ .\ .\ \lambda_n/2$ are small enough, we can put $\sin\varphi = \varphi$; $\sinh\varphi = \varphi$; also, therefore, $\cos\varphi = 1$; $\cosh\varphi = 1$ and the equations above will be considerably simplified.

$$v_1/\sqrt{c_d}\,.\,1/\varphi_1 = v_2/\sqrt{c_d}\,.\,1/\psi_1 \qquad P = \frac{\gamma\, v_1^2}{2\,g}\,.\,\frac{\psi_0^2 + \varphi_1^2}{\varphi_1^2\,\psi_0^2}$$

$$v_2/\sqrt{c_i}\,.\,1/\varphi_2 = v_3/\sqrt{c_i}\,.\,1/\psi_2 \qquad P = \frac{\gamma\, v_2^2}{2\,g}\,.\,\frac{\varphi_2^2 + \psi_1^2}{\varphi_2^2\,\psi_1^2}$$

$$\cdots\cdots\cdots \qquad\qquad \cdots\cdots\cdots$$

$$v_{n-1}/\sqrt{c_d}\,.\,1/\varphi_{n-1} = v_n/\sqrt{c_d}\,.\,1/\psi_{n-1} \qquad P = \frac{\gamma\, v_n^2}{2\,g}\,.\,\frac{\varphi_n^2 + \psi_{n-1}^2}{\varphi_n^2\,\psi_{n-1}^2}$$

$$\psi_0 = \lambda_0/2 \quad \varphi_1 + \psi_1 = \lambda_1 \quad \varphi_2 + \psi_2 = \lambda_2\ .\ .\ . \quad \varphi_n = \lambda_n/2$$

Solution:

Remove all the quantities v!

This gives, after some transformation

$$\begin{aligned} \varphi_1/\psi_0 &= \psi_1/\varphi_2 & \text{Put } \psi_0 &= \lambda_0/2 \\ \varphi_2/\psi_1 &= \psi_2/\varphi_3 & \psi_1 &= \lambda_1 - \varphi_1 \\ & & \psi_2 &= \lambda_2 - \varphi_2 \\ \cdots & & \cdots & \\ \varphi_{n-1}/\psi_{n-2} &= \psi_{n-1}/\varphi_n & \psi_{n-1} &= \lambda_{n-1} - \varphi_{n-1} \\ & & \varphi_n &= \lambda_n/2 \end{aligned}$$

then

$$\frac{2\,\varphi_1}{\lambda_0} = \frac{\lambda_1 - \varphi_1}{\varphi_2}; \quad \frac{\varphi_2}{\lambda_1 - \varphi_1} = \frac{\lambda_2 - \varphi_2}{\varphi_3};$$

$$\frac{\varphi_3}{\lambda_2 - \varphi_2} = \frac{\lambda_3 - \varphi_3}{\varphi_4};$$

$$\frac{\varphi_{n-1}}{\lambda_{n-2} - \varphi_{n-2}} = \frac{2\,(\lambda_{n-1} - \varphi_{n-1})}{\lambda_n}$$

This is a system of $(n-1)$ equations necessary and sufficient to determine the $(n-1)$ unknown quantities $\varphi_1\ \varphi_2\ .\ .\ .\ \varphi_{n-1}$

A numerical example will be treated subsequently.

Numerical Example

Fig. 6 illustrates diagrammatically the arrangement of a ventilation-system in a large turbo-generator.

$C - L$ is the center-line axially, which constitutes a line of symmetry, so that the calculation only has to be carried through for one half of the core.

E is the end-bell: G is the gap. R is the rotor surface.

The notations will be the same as used in 10. There are 84 vents axially, arranged so, that

$L_1 = 18$ vents discharge
$L_2 = 16$ " intake
$L_3 = 16$ " discharge
$L^4 = 16$ " intake
$L^5 = 18$ " discharge

Hence the calculation is performed for

$L_1 = 18$ vents discharge
$L_2 = 16$ " intake
$L_3 = 8$ " discharge

$1/2\,L_0$ is a fictitious intake-length corresponding to the drop in pressure when the air enters the gap from the end-bell.

The value of $1/2\,L_0$ will be determined below from the assumption, that the entrance-drop amounts to 20 per cent of the velocity-head in the gap. This value is found to be a good average for an ordinary-shaped entrance.

a. Value of the constants.

From the dimensions of the machine is directly calculated:

$a = 2.1$ ft.² cross-section of gap, including the sunk parts of the slots.

$s = 0.2$ ft.² per vent-circle, taken at the minimum cross-section of the tooth-vent.

$c_i = 1.30$ and $c_d = 1.07$ are values calculated from the shape of the slots and the teeth, number of teeth and shape of vent-fingers. The details of this calculation cannot be given in this paper.

It must be noted, that c_d and c_i include a correction for the loss in total head which at the present time must be considered as uncertain. This example is, therefore, of value only as far as it illustrates the application of the derived formulas.

b. Value of the arguments.

From definition we get $\lambda_1 = \dfrac{0.2 \times 18}{2.1\,\sqrt{1.07}} = 1.65$;

$$\lambda_2 = \frac{0.2 \times 16}{2.1\,\sqrt{1.30}} = 1.34; \quad \lambda_3/2 = \frac{0.2 \times 8}{2.1\,\sqrt{1.07}}$$

$= 0.73$ is obtained from equation (9) putting $x = 0$, hence

$$P - p = \frac{\gamma\, v_0^2}{2\, g} \coth^2 \left(\frac{s\, L_0}{a \sqrt{c_i}} \right) = \frac{\gamma\, v_0^2}{2\, g} \coth^2 (\lambda_0/2)$$

The pressure $(P - p)$ has partly been converted into the velocity-head $\frac{\gamma\, v_0^2}{2\, g}$ and partly been destroyed by the resistance at the gap-entrance, which is put equal to 20 per cent of $\frac{\gamma\, v_0^2}{2\, g}$ hence we can also put

$$P - p = \frac{\gamma\, v_0^2}{2\, g} + 0.2 \frac{\gamma\, v_0^2}{2\, g} = 1.2 \frac{\gamma\, .\, v_0^2}{2\, g}$$

and get for $\lambda_0/2$ the equation

$$1.2 \frac{\gamma\, v_0^2}{2\, g} = \frac{\gamma\, v_0^2}{2\, g} \coth^2 (\lambda_0/2)\ ;$$

or $\coth^2 (\lambda_0/2) = 1.2$

giving $\lambda_0/2 = 1.53$

This would correspond to a fictitious number of intake-vents L_f where

$$\frac{s\, L_f}{a \sqrt{c_i}} = 1.53 \text{ or } \frac{0.2\, L_f}{2.1 \sqrt{1.30}} = 1.53$$

so that $L_f = 18.3$ vents.

c. Equations for the balance-points.

The simplified equations determining the balance-points can now immediately be written up, *viz.*

$$\varphi_1/1.53 = \frac{1.65 - \varphi_1}{\varphi_2} \qquad \varphi_2 = \frac{1.53\,(1.65 - \varphi_1)}{\varphi_1}$$

$$\frac{\varphi_2}{1.65 - \varphi_1} = \frac{1.34 - \varphi_2}{0.735} \qquad \frac{1.53\,(1.65 - \varphi_1)}{\varphi_1\,(1.65 - \varphi_1)}$$

$$= \frac{1.34 - \frac{1.53\,(1.65 - \varphi_1)}{\varphi_1}}{0.735}$$

$$0.735 \times 1.53 = 1.34\, \varphi_1 - 1.53 \times 1.65 + 1.53\, \varphi_1$$

$$\varphi_1 = 3.65/2.87 = 1.27; \text{hence } \varphi_2 = 0.458$$

To find the number of vents axially corresponding to φ_1 and φ_2 we have

$$\varphi_1 = \frac{s\, L_d}{a \sqrt{c_d}} \text{ or } 1.27 = \frac{0.2\, L_d}{2.1 \sqrt{1.07}}\ ;$$

$$L_d = 13.8 \text{ vents}$$

$$\varphi_2 = \frac{s\, L_i}{a \sqrt{c_i}} \text{ or } 0.458 = \frac{0.2\, L_i}{2.1 \sqrt{1.30}}\ ;$$

$$L_i = 5.49 \text{ vents}$$

Note. It is immediately apparent, that the approximate method of solution is *not* applicable in this case, as for instance φ_1 comes out $\varphi_1 = 1.27$.

This is far in excess of the limit, inside which it is admissible to put $\sin \varphi = \varphi$. It will, therefore, be necessary to apply the original formulas and to find a solution by cut-and-trial.

d. Application of original formulas.

The equations determining the balanced condition are

$$\frac{v_1}{\sin \varphi_1} = \frac{v_2}{\sin \psi_1}\ ; \qquad P = \frac{\gamma}{2\, g}\ .\ v_1^2\,(\coth^2 \psi_0 + \cot^2 \varphi_1)$$

$$\frac{v_2}{\sinh \varphi_2} = \frac{v_3}{\sinh \psi_2}\ ; \qquad P = \frac{\gamma}{2\, g}\ .\ v_2^2\,(\coth^2 \varphi_2 + \cot^2 \psi_1)$$

$$P = \frac{\gamma}{2\, g}\ .\ v_3^2\,(\coth^2 \psi_2 + \cot^2 \varphi_3)$$

$$\varphi_1 + \psi_1 = \frac{0.2 \times 18}{2.1 \sqrt{1.07}} = 1.65; \qquad \coth^2 \psi_0 = \coth^2 \lambda_0/2 = 1.20 \text{ (as before)}$$

$$\varphi_2 + \psi_2 = \frac{0.2 \times 16}{2.1 \times \sqrt{1.30}} = 1.33; \qquad \varphi_3 = \frac{0.2 \times 8}{2.1 \times \sqrt{1.07}} = 0.737$$

The most straight forward method of solution is that of a successive approximation. It is, then, best to start at the $C - L$ and to make some first assumption, say that

1. φ_2 corresponds to 5 vents axially
 ψ_2 " " 11 " "

Thus $\varphi_2 = \frac{0.2 \times 5}{2.1 \sqrt{1.3}} = 0.418$

$\psi_2 = 1.33 - 0.418 - 0.922$

and $v_3 = \frac{4030}{\sqrt{\coth^2 (0.922) + \cot^2 0.737}}$

$= 2280$ ft./min. [When P is expressed in inches of water and V in feet per minute, the air taken at a density of 0.074 lb./cu. ft. $4030 \sqrt{P}$ is the value of the constant; it is further assumed here, that $P = 1.''0$ water.]

$$v_2 = v_3 \times \frac{\sinh \varphi_2}{\sinh \psi_2} = 2280 \times \frac{\sinh 0.418}{\sinh 0.922}$$

$$= 925 \text{ ft./min.}$$

$$(4030/v_2)^2 = (4030/925)^2 = \coth^2 0.418 + \cot^2 \psi_1$$

$$\psi_1 = 0.275$$

$$\varphi_1 = 1.65 - 0.275 = 1.375$$

$$v_1 = v_2 \times \frac{\sin \varphi_1}{\sin \psi_1} = 925 \frac{\sin 1.375}{\sin 0.275}$$

$$= 3340 \text{ ft./min.}$$

Finally

$$(4030/v_1)^2 = (4030/3340)^2 = \coth^2 \psi_0 + \cot^2 1.375;$$

giving the first result $\coth^2 \psi_0 = 1.41$.

If assumption 1 had been correct, the final result would have been $\coth^2 \psi_0 = 1.20$.

It is therefore necessary to put

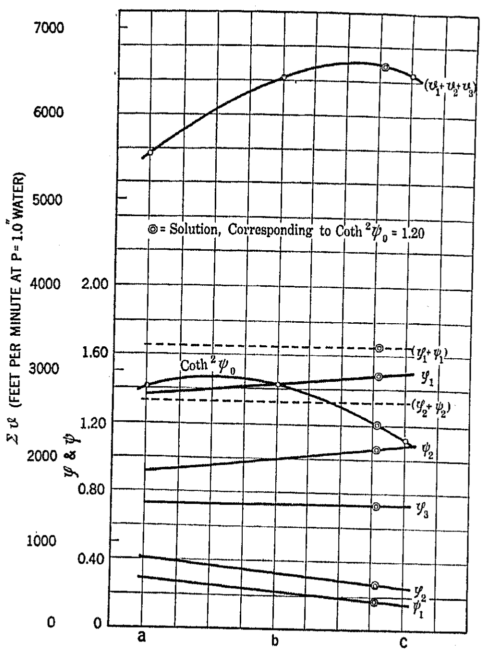

FIG. 7

Table (Fig. 7)

v_1	v_2	v_3	$\Sigma(v)$	φ_3	ψ_2	φ_2	ψ_1	φ_1	$\coth^2\psi_0$
3340	925	2280	5545	0.735	0.921	0.418	0.275	1.375	1.41
3340	751	2330	6421	0.737	0.996	0.334	0.225	1.425	1.43
3620	463	2400	6483	0.737	1.085	0.251	0.129	1.521	1.11

2. $\begin{cases} \varphi_2 \text{ corresponds to } 4 \text{ vents axially} \\ \psi_2 \quad \text{“} \quad \text{“} \quad 12 \quad \text{“} \quad \text{“} \end{cases}$

3. $\begin{cases} \varphi_2 \quad \text{“} \quad \text{“} \quad 3 \quad \text{“} \quad \text{“} \\ \psi_2 \quad \text{“} \quad \text{“} \quad 13 \quad \text{“} \quad \text{“} \end{cases}$

The calculation is exactly the same as before, and the results are given in the table below, also plotted in Fig. 7.

The solution is given on Fig. 7 and corresponds to $\coth^2 \psi_0 = 1.20$.

It is interesting to note, that $(v_1 + v_2 + v_3)$ has a maximum for the balanced condition. This means, of course, nothing else than that the balanced condition is *stable*.

Discussion

The v-values are those corresponding to $P = 1.''0$ water, and must be multiplied by $\sqrt{P}$ for any other value of P.

The φ- and ψ-values, *i. e.*, the balanced condition, is, of course, independent of P.

It has already been mentioned, that the approximate method fails, in a case like this, to give the solution with any reasonable degree of accuracy. This might have been anticipated from the low resistance at the extreme end ($\coth^2 \psi_0 = 1.20$) resulting in a high value of φ_1.

Discussion

For discussion of this paper see page 498.

An Experimental Study of Ventilation of Turbo Alternators

BY CARL J. FECHHEIMER
Fellow, A. I. E. E.
Research Engineer, Power Engineering Dept. Westinghouse Electric and Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—*When designing a large steam-turbine-driven alternator the volume of air per minute needed to cool the machine is easily calculated if the losses are known, and the allowable air temperature rise is assumed. With data hitherto available it has not been possible to estimate the pressure needed to drive the air through the various paths, nor to predict the distribution of air in the machine. The problem is too complicated to admit of an analytical solution, and even an experimental investigation becomes involved.*

In general, a complete machine is not suitable for an experimental study of air flow, as changes in the series or parallel paths, the introduction of restrictions, etc., can be made only with difficulty, delays and expense. Accordingly, two models, to imitate two radial systems of ventilation, were built. Since ventilation, as such, was to be investigated, no electrical nor magnetic losses were introduced. The stator cores were made of wood, with suitable vent fingers of steel, and with blocks of wood to imitate coils in the slots. The rotor was the same for both models, and was made of steel, ventilated as in a usual machine, but with wood in the slots to imitate coils. Its diameter was such as to give the peripheral speed adopted in the largest turbo alternators; its length was about half of the probable largest rotor of that diameter. An external blower was used chiefly because then the delivered pressure could be independent of the rotor speed. The flow of air in any circuit, such as the flow through the rotor vents, was controlled independent of the flow in any other circuit. Individual radial vents could be closed, etc. Several sizes of air gap were tried. Thus, the influence of the flow as affected by having any path open or closed, or in combination was studied.

The pressure readings were taken by means of an ordinary open-end tube placed in a region of very low velocity, so that the influence of velocity head would be negligible. The total volume was measured by means of an electric thermal meter, with thermocouples for measuring the air temperature rise, instead of the frequently used resistance exploring coils. The distribution of volumes at discharge from the vents was measured by means of a rotating vane anemometer, a special funnel being used, one end of which was inserted between adjacent vent fingers which were extended to the back of the wooden stator core.

Two systems of ventilation were studied. In both, some of the air enters the air gap directly from the end bell; in both, some of the air passes from the end bell through suitable channels at the rear of the core to selected vent ducts, then passes radially inward through those ducts to the air gap, then turns through a right angle, passing through the air gap, and finally turns another right angle and is discharged radially through other vent ducts. This air may be constrained to pass circumferentially or radially through the air gap. The mechanical construction for the two are necessarily considerably different in the arrangement of connections with inlet and outlet vent. In the first model the air moved circumferentially, and in the second it flowed axially through the air gap (Figs. 2 and 3 respectively).

The rotor diameter was 26 inches, the maximum rev. per min. 3600, corresponding to 24,500 ft. per min. In both models 54 slots were used. In Model 1 wedges were present in the vent ducts, whereas they were omitted in Model 2. In Model 1 the upper half was provided with two fingers per tooth, but in the lower, only one finger per tooth was employed. In Model 2 only one finger per tooth was used. For an understanding of the construction, Figs. 4, 5 and 9 should be referred to for Model 1 and Figs. 10, 12, 13, 14 and 15 for Model 2.

To further assist in quantitative analyses, models of tooth and vent sections were built with one, two and no fingers, with and without notches. Air was caused to flow through these small models in both directions and at various velocities, and the pressure drops were measured.

Only a few of the tests are published herewith. The study is not complete, and the paper would be entirely too long if all the tests were included. A few conclusions are:

In Model 1 (for circumferential gap flow):

1. At normal speed the circumferential distribution of volumes is substantially uniform near the end bell, but departs from uniformity as the distance from the end bell increases, the non-uniformity reaching a maximum a little before the extremity.

2. The departure from uniformity is due principally to the influence of rotation, and may cause the velocities in some vents to be quite low. Considerable differences in temperature may be due to such non-uniformity.

3. The non-uniformity causes the total volumes to be appreciably less at normal speed than at standstill, for a given pressure in the end bell.

In Model 2, (for axial gap flow), a few conclusions are:

1. The distribution circumferentially is uniform at a given position axially. The axial distribution is not uniform, being approximately sinusoidal at the discharge. By suitable selection of groups of vents, or other means, the distribution of volumes may be made nearly uniform.

2. The distribution is affected but little by rotation.

3. The proportions may be such that nearly uniform temperatures may be obtained.

4. The volumes are nearly unaffected by rotation.

A mathematical treatment is contained in a companion paper by Mr. Donald Bratt.

FOREWORD

THE purposes of this paper are twofold: To offer suggestions to others who may be struggling to find a means for solving some intricate heat problem, and to present to them in part the results of a certain investigation. It is recognized that the work is far from being complete; that only two of many types of ventilation were studied. As in any research problem, many new avenues open as work proceeds, so has it been in this case. The studies of the data obtained so far are still under way, and the experimental work for the second scheme of ventilation, being conducted in a different manner from that published herewith, is not finished. In this new work, we hope to determine loss coefficients which we cannot obtain with sufficient accuracy from the data on the turbo models.

During the investigation, the author was assisted by Mr. Donald Bratt, who is contributing a companion,

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

mathematical paper to the Institute. The author acknowledges valuable suggestions from him and from a number of co-workers in the Westinghouse Company.

When an attempt is made to analyze the data from temperature tests on electrical machinery one finds the task fraught with many difficulties. Entirely aside from the question of inconsistencies in test data, an accurate determination of the quantitative relationships of the three contributory factors is well-nigh impossible. These factors are:

(a) The generation of heat by losses;
(b) The internal flow of heat by thermal conduction;
(c) The dissipation of heat, chiefly by forced convection, and, to a more limited extent, by free convection and radiation.

In perhaps no machine is the prediction of temperatures more vital than in the large steam-turbine-driven alternator. Leaving out certain quantities which are fairly well fixed by the materials employed, as we have them at present, temperature is the principal limitation which confronts the designer.

Regarding the first factor, assume that available data on the rate of generation of heat by losses are sufficiently well known to enable the designer to predict them.

Consider, then, the second factor, the internal flow of heat. In the large turbo alternator, the stator coils are so long that the heat generated near the middle of the machine by I^2R and eddy currents in the copper can not flow longitudinally to the ends to be picked up there by moving currents of air.[1] Consequently, as regards the copper, that part of the problem is simplified, as only the transverse flow of heat by conduction through the insulation need be considered.

In most large modern steam-turbine-driven alternators, the stator slots are very deep, and the losses in the embedded copper and deep teeth are high. If all that generated heat must flow radially through—say half the depth of the teeth, the temperature drop radially is large, even when account is taken of the comparatively high thermal conductivity of the steel in the plane of the sheet. On the other hand, if the laminations are arranged in thin packages, with that generated heat flowing in a direction normal to the planes of the laminations, the average temperature of the package is only a few degrees higher than at the ends, even though the coefficient of thermal conductivity is comparatively low. Furthermore, the excellent conductivity of the embedded copper secures practically uniform copper temperature throughout that short length. Therefore, with that construction, the thermal drop in the laminations is not an important part of the temperature problem. The only important role played by thermal conductivity is concerned with the transverse flow of heat through the insulation around the coil. The drop in temperature due to that flow can readily be computed, provided the losses and coefficient of thermal conductivity are known.

This, then, brings us to the third factor, *viz.*, the dissipation of heat. In the turbo alternator, practically all the heat is carried away by forced convection, generally known as ventilation. That is the most vital and difficult factor, about which far too little is known. It, in turn, may be broken into five parts: (a) the volume of air needed for cooling: (b) the rate at which the heat is "picked up" from the heated surfaces; (c) the pressure needed to drive the needed volume through the various passages; (d) the distribution of air volumes; and (e) the pressure, delivered by the fan.

(a) The volume of air is very readily calculated from the known losses and permissible air temperature rise; (b) Various data have been published on the rate at which heat is picked up by moving air streams. These data are not always consistent; however, with the high velocities generally used in large modern turbo alternators, the drop in temperature from the iron to the air is usually not large, although it is not negligible. It is beyond the scope of this paper to treat that phase of the subject, and it is to be hoped that more consistent data will be forthcoming. A great deal of work has been done, and more is under way. (c) and (d) of this paper and a companion paper by Mr. Donald Bratt deal with the pressures required to drive a given volume of air through the vent passages, and the distribution of volumes. (e) A paper on "Centrifugal Fans for Electrical Machinery" will appear in an early issue of the A. S. M. E. *Journal.*

Bearing in mind that this paper is concerned only with the air pressures required for given volumes, and the distribution of volumes in a turbo alternator, we shall return to the consideration of the machine in which the stator core is built of thin packages of laminations. With this construction, the laminations at the ends of a package must be kept cool throughout their depth radially by moving air streams. This, in turn, implies radial flow of air.

Perhaps the simplest radial duct system of ventilation of turbo alternators is the one in which all the cooling air passes direct from the end bells into the two ends of the air gap. Then the air flows axially and passes outward through radial vent ducts, distributed in the stator core. With internal fans, either the propeller or centrifugal type may be used to generate the necessary air pressure. The system is illustrated schematically in Fig. 1. This system has been used successfully for many years and is used today for certain sizes and types of design. In some of the large turbos, particularly for 60 cycles, of proportions that are considered normal at the present time, it becomes difficult to cause enough cooling air to flow through the two paths in the air gap. The air-gap size should be based

1. The influence of the longitudinal flow of heat may be computed by formulas in paper "Longitudinal and Transverse Heat Flow in Slot-wound Armature Coils," A. I. E. E., 1921, page 589.

upon the armature ampere-turns, and then it is too small to transmit the volume of air unless the velocities (and therefore the pressures) become prohibitively high, or unless the air temperature rises in excess of that which is considered good practise. The solution then lies in providing additional paths.

If cooling air is admitted at both ends of the air gap, and additional intakes are to be provided, and the air is to pass radially throughout the depth of the vent duct, then the only feasible way for that air to enter is through selected vent ducts at the back of the core. The air then passes radially inward to the air gap, then turns through 90 degrees, then passes through the gap, and finally turns again through a right angle, flowing radially outward through other vent ducts. Although all the cooling air provided for the stator must, as before, pass through the air gap, the number of paths in parallel may be so chosen as to avoid prohibitively high air-gap velocities, and a desirable number and size of vents may also be selected. The static pressure needed may be provided by centrifugal fans at the ends of the rotor, which must generate sufficient pressure to overcome the resistance of the combined series and parallel paths in the air circuit.

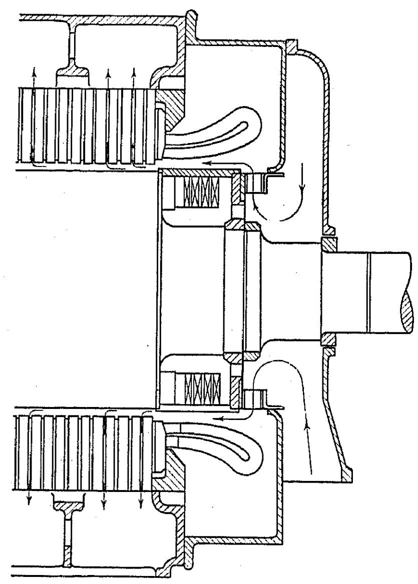

FIG. 1

The air which flows from the back of the core radially inward may be constrained to pass circumferentially or axially through the air gap. The mechanical construction is necessarily considerably different in the arrangement of connecting with the inlet and outlet vents for these two directions of flow in the gap. Diagramatically, these two types of "multiple path radial ventilation" are shown in Figs. 2 and 3. In either, the number of intake or outlet belts[2] is dependent upon (1) the ratio of the gap cross-section to the vent duct section per unit length circumferentially or axially; (2) the total volume of air, (3) the air velocities chosen by the designer; and (4) mechanical considerations.

In either of these multiple radial systems, the flow is very complicated. A solution was impossible with the knowledge of the subject possessed at the outset of the investigation. Yet, in order to design large generators intelligently, it is important to predetermine what the quantitative relations are within a reasonable percentage of error.

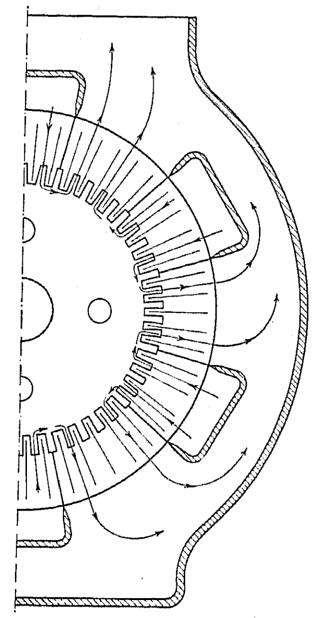

FIG. 2

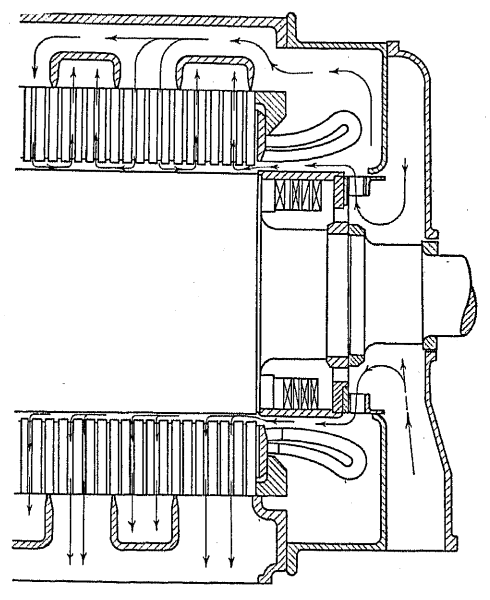

FIG. 3

Accordingly, it was decided in the early part of 1920 to build two models to imitate both systems. Since ventilation, as such, was to be investigated, no electrical nor magnetic losses were to be introduced.

2. A belt refers to a group of vents fed in parallel from the same duct.

The peripheral velocity of the rotating element should be not less than that of a large generator. The construction of the rotor was to be similar, in so far as ventilation was concerned, to that of the largest generators. The length should correspond to about half the length of the probable longest rotor in a machine having the same diameter as the rotor of the model; (half the length, because it was considered desirable to imitate only one-half the machine longitudinally, as the other half would be the duplicate in inverse order). The packages of laminations in the stator were to be imitated by rings of hard wood into which slots of standard sizes were to be cut; between adjacent wooden rings standard vent spacers were to be placed; wood could be used to imitate the coils at the vents, etc. An external blower was to be used, chiefly because the delivered air pressure would be independent of the rotational speed, but also because the static pressure could be measured in a quiet zone where the velocity head was of negligible influence. The whole was to be so made that a maximum of flexibility was to be obtained. Thus, the use of wood in the stator permitted of rapid and inexpensive alterations; steel rings placed over the entrances to the longitudinal vents in the rotor would stop the supply of air, as desired; the entrance to the air gap could be closed by means of a suitable angle ring; the entrances to the stator could be open or closed; several sizes of air gaps were to be used; various restrictions in the air circuit were to be introduced, etc. Thereby, data on the flow in any individual air circuit, such as the stator, the rotor, or the air gap, etc., or a combination, at various air pressures and at various rotational speeds, could be obtained and the results studied.

Ducts, Quantities Measured, Etc.

Before going further into the construction of the two models, and the tests made on them, auxiliary apparatus and instruments will be discussed.

1. *End Bell and Pressure Measurements.* The outer part of an existing cast iron end bell was bolted to one end of the model,[3] it was split, so that half of it could be readily removed for alterations. With the end bell parting horizontal, the upper half could be readily removed. The intake duct was easily attached. The velocities of air in parts of the end bell were so low that an ordinary open-end brass tube could be used for connecting with a manometer for measuring pressures without introducing an appreciable error due to velocity head. The tube was pushed through a sealed wooden plug fastened into one of the upper bolt holes in the end bell. Pressure readings were also taken near the parting farthest from the entrance to the end bell; there the velocities were substantially zero and the pressure readings were practically the same as in the other location.[4]

2. *Diverging Intake to End Bell.* The outlet of the blower was 18 inches square (2.25 sq. ft.), and the cross-sectional area of the end bell at its entrance was a little more than four times as great. In the second model, volumes approximating 15,000 cu. ft. per min. were admitted to the end bell, in certain cases. This corresponds to a velocity of 6660 ft. per min., at discharge from the blower, or a velocity head of 2.73 inches of water. In that case, the static pressure in the end bell was only 3.3 inches of water, and the velocity head there was only $(1/4)^2 \times 2.73 = 0.17$ inch of water. It would not have been feasible to secure that delivery from the particular blower unless a considerable percentage of the velocity head at its discharge were converted into static pressure. It is well known that to recover the maximum velocity head in a comparatively short length, the duct should be shaped like a trumpet with curved sides, and that

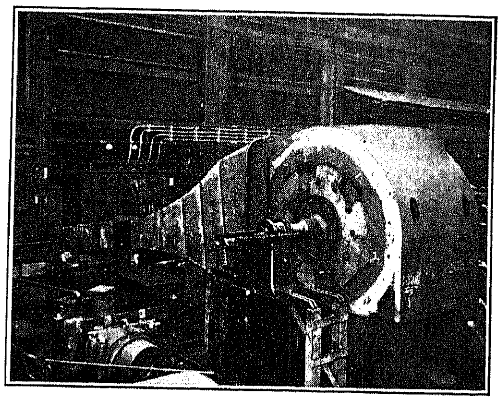

Fig. 4

was the form that was adopted; that intake is shown in Fig. 4, and several other photographs.

3. *Volume Measurement.* The volume of flow was measured by the thermal principle which Prof. Carl Thomas introduced. The air was heated by causing electric current to flow through a suitable resistor in the air stream, the power consumed being measured by familiar indicating electrical instruments. In the Thomas meter, the temperature rise of the air is

3. The lower half of the end bell attached to model 2 appears in Fig. 12.

4. The pressure readings taken on different days should be reduced to some reference standard for density. The standard chosen was 0.074 pounds per cu. ft. which is the density when the barometric pressure is 29.92 inches of mercury, and the temperature is 25 deg. cent. If departures in density, while passing through the apparatus under test, due to changes in pressure and temperature, are neglected, the correction back to the reference standard, based upon the well-known laws of Boyle and Charles, is:

$$\text{Press. corrected} = 0.1003 \left(\frac{273 + t}{P} \right) \text{Press. read.}$$

Here t is the temperature in deg. cent. P is the barometric pressure in inches of mercury.

measured by means of coils in the air stream before and after the air passes through the heater, these exploring coils being connected in a Wheatstone Bridge network. Previous experience showed that those coils were not entirely satisfactory for this kind of work, as the wires were likely to stretch, and with the large volumes, the temperature rises would be too low to obtain accuracy, unless the power consumption in the heater were prohibitive. These objections were overcome by connecting numbers of thermocouples in series; then a comparatively high reading of millivolts on a suitable potentiometer secured accuracy with the low air temperature rise of, say, 1.5 to 3.5 degrees centigrade.[5] If the specific heat of air at constant pressure is 0.2418, and the density is 0.074 pounds per cu. ft. at 29.92 inches of mercury and 25 deg. cent., the volume, as determined with this instrument may readily be shown to be:

$$Q = \frac{0.178\ n\ E\ W}{1000\ e} \quad \frac{273 + t}{P} \text{ cu. ft. per min.}$$

n = number of cold (or warm) thermocouple junctions.

E = microvolts per degree at the average temperature in the volume meter, as determined from the calibration curve.

W = Watts loss in heater.

e = millivolts read on the potentiometer,

t = temperature of the air, degrees cent.

P = barometric pressure, inches of mercury.

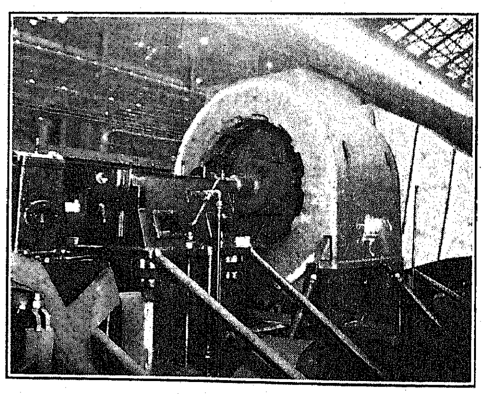

FIG. 5

Obviously, since the density of air changes with its temperature and pressure, its density changes as it passes through an electric machine, as temperature and pressure change. Consequently, the cubic feet per minute are not the same at exit as at entrance, although the weight per minute remains constant. The influences of such effects in this experimental investigation were not considered; it may be of consequence in certain turbos, as say, when the air rise is 25 deg. cent. As given in the equation, P is the barometic pressure, yet the actual pressure at entrance to the model was that plus the pressure read on the manometer, a possible maximum increase of 2.5 per cent above the barometric pressure. That increase also was ignored, and only the barometer reading was used.

While in the type of volume meter used it is not necessary for the velocities to be uniform, it is important

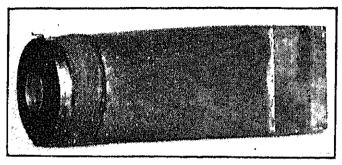

FIG. 6

that the departure from uniformity be not too great. In previous experiments, two sets of adjustable sheet steel planes were placed in a duct through which the the air passed before reaching the volume meter, and these could be adjusted in two directions so as to alter the distribution. They were applied here too, but were subsequently found unnecessary.[6]

4. *Volume Distribution.* The third important quantity to be measured was volume distribution in the model. It was desired to measure velocities or volumes in the intake and outlet vent ducts. There was no recognized way of measuring the velocities in the intake vents, except by means of hot wire anemometers. A number of those devices were made of suitable size; they were calibrated, and placed in some of the ducts on model No. 1. A considerable amount of time and effort was spent in an endeavor to get them to read with reasonable consistency and accuracy, but all attempts were unsuccessful. The hot wire anemometer, as built, is quite sensitive to direction of flow, and a calibration curve taken with the stream is materially different from one against, or normal to the stream. With air in highly turbulent state, as it is bound to be in a vent duct, the instrument readings were valueless. They were consequently abandoned.

The method used for measuring outlet duct volume-distribution was more successful. The vent duct finger spacers were made continuous to the rear, (See Figs. 7 and 8), so that a given volume of air that entered a particular space between adjacent fingers would continue to flow to the rear. The fingers were spaced uniformly at the rear. A small "funnel" which just fit between adjacent fingers was joined to an ordinary rotating vane anemometer, which was held in position

5. The volume meter will be seen in Fig. 4, where it joins the small end of the trumpet shaped diverging duct.

6. For further description see article in *Electric Journal* for May 1923, "Some Elements of Air Flow in Electric Machinery," or in A. S. M. E. Paper on "Performance of Centrifugal Fans for Electrical Machinery."

for half minute readings. (See Fig. 6). The anemometer was calibrated at the laboratory with the funnel, and from the readings, the volume of air per minute passing between adjacent fingers, could be determined by referring to the calibration curve. The sides of the part of the funnel that was inserted between fingers were tapered slightly, so that it could be pushed in tight. Putty was put around that part of the funnel to eliminate leakage, but the readings with and without the putty were substantially the same so that the putty was subsequently omitted. There were two finger spacings for the first, and one for the second, model, so three funnels were made.

In general, a rotating vane anemometer is not reliable. For example, when employed to measure velocities at a number of positions in a duct, the instrument offers obstruction to the flow, and changes the distribution of velocities. If held in the hand at, say, the efflux from a duct, one's arm and hand offer

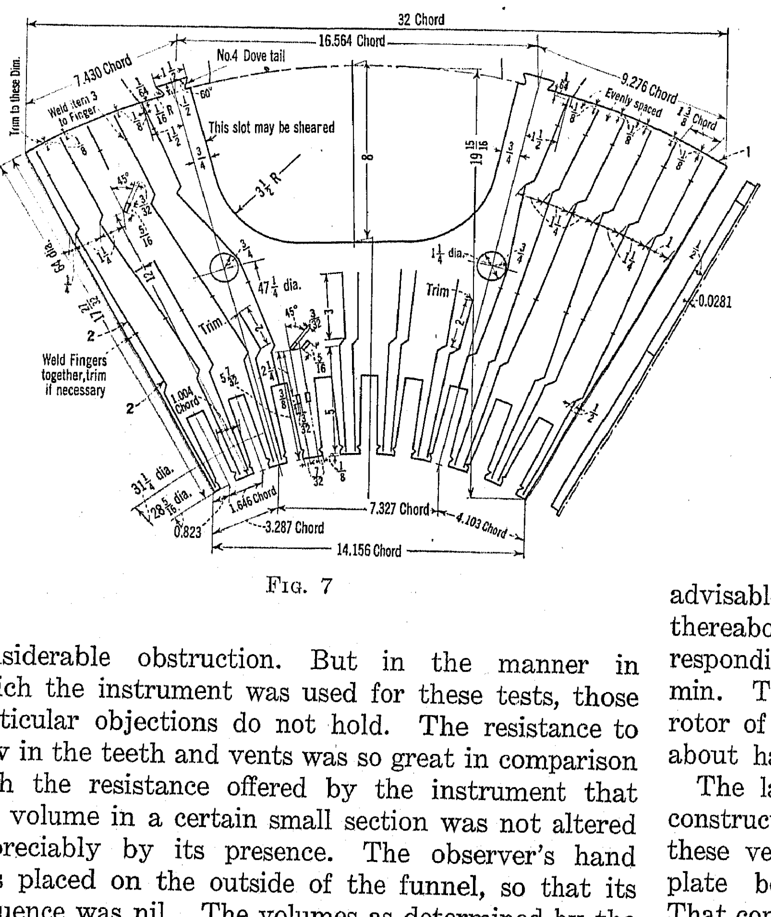

Fig. 7

considerable obstruction. But in the manner in which the instrument was used for these tests, those particular objections do not hold. The resistance to flow in the teeth and vents was so great in comparison with the resistance offered by the instrument that the volume in a certain small section was not altered appreciably by its presence. The observer's hand was placed on the outside of the funnel, so that its influence was nil. The volumes as determined by the volumemeter were compared with the summation of volumes by the anemometer, and in many cases the differences were less than ten per cent, which was considered satisfactory. The anemometer's calibration was checked a number of times during the series of tests (which extended over about ten months) and it was found to change slightly. After quite a time, it was decided that since the anemometer readings were for comparison of volume (or velocity) distribution, and not for the determination of total volumes, further attempts at checking total volumes by this method should be abandoned; the volume meter readings were relied upon for total volumes.

In the various plots of points taken by the anemometer, there are irregularities. While some of these were due to inaccuracies in readings, many were caused by slight dissimilarities between nominally duplicate vent ducts; for example, the finger was pushed more to one side than to the other, and thereby produced an appreciable change in the maximum restricted section. The vent spacers having been made by men who do that kind of work regularly, the irregularities were probably about the same as would be found in a machine, in which the same construction is employed.[7] In a number of cases, the observers were requested to repeat their readings after completing a set and usually the original observations were duplicated within a few per cent. That fact helped to place reliance in them. For the most part, the general shape of a volume distribution curve can be told quite well from a plot of observations, and usually important conclusions can be drawn.

When the tests were started, all of the principal paths for the air to flow were closed, and the volumes for various pressures were measured. These observations were for the purpose of determining the order of magnitude of leakage. When the various passages were closed, the clearances, and therefore the leakages, were about the same as when the model was operated.

Construction of the Turbo Models

1. *The Rotor.* As the peripheral velocity of the rotor was to be at least 24,000 feet per minute, and as it was not considered advisable to exceed 3600 revolutions per minute or thereabouts, the diameter was fixed at 26 inches, corresponding to 24,500 ft. per minute at 3600 rev. per min. The length of the body of the probable longest rotor of that diameter was about 120 inches, so about half that useful length was decided upon.[8]

The large Westinghouse turbo rotors are of plate construction with radial vent ducts at intervals; these vents are only around the slot portions, each plate being milled individually before assembly. That construction was adopted in the models. Fig. 10 will assist in understanding it. Air enters through slots below the main slots, the coils acting as fans. The slots were arranged in four groups to imitate four poles. As in the machines, the plates are held together

7. In the recent large turbos, a different construction has been adopted, one advantage of which is that greater uniformity is assured.

8. The rotor was made a little longer than the stator, in order that an angle iron, put in to stop the flow of air, could be placed over the extension.

by bolts between stub-end forgings. The coils are imitated by treated hard wood blocks driven into the slots, held in position by wedges of the same size as in a machine of corresponding proportions. The influence of the coils at the ends, and of the retaining rings, upon the ventilation of the stator and of the rotor body, were negligible, so those parts were not imitated in the models.

2. *Construction of Model No. 1.* The first model, Figs. 4 and 5, imitated the scheme of ventilation in which the air moved circumferentially in the air gap. The number of stator slots selected was 54, and the number of stator axial intakes or outlets was six.

as applied in model II. In this model, short fiber wedges were screwed to the small wooden blocks. The large wooden rings had previously been slotted to the depth that the wedge is sunk below the inner periphery of the stator punchings in a machine. The composite in the tooth belt simulated that portion of a generator quite accurately.

An estimate of the velocities in the vent ducts back of the teeth indicated that the pressure drops there would be very small in comparison with the drops in the teeth, around the wedges, turning through a right angle, etc. Consequently, the pressure needed for a given volume would be substantially the same if the

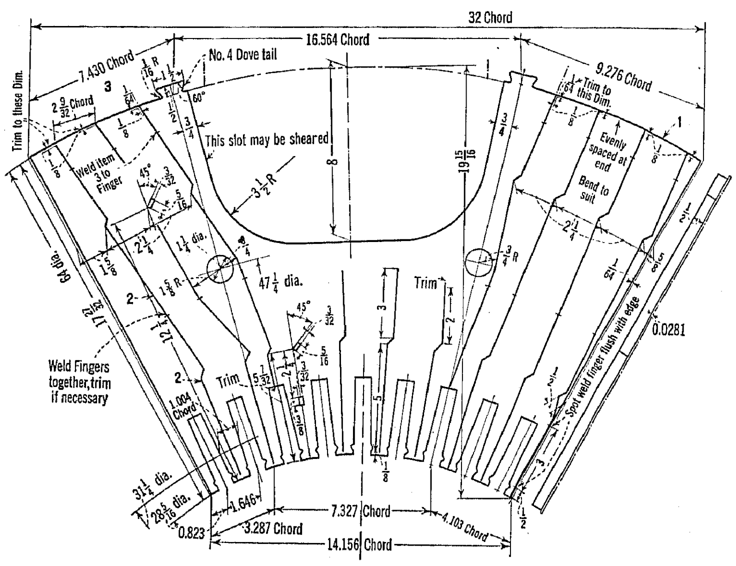

FIG. 8

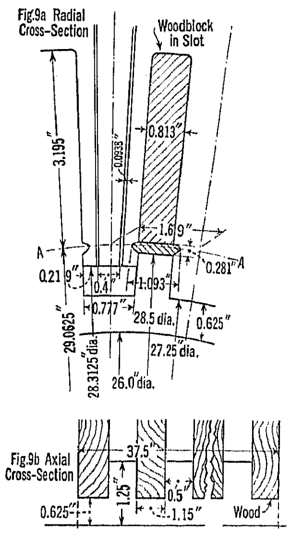

FIG. 9

Dimensions and data
54 slots, 22½" vents axially
Each intake extends over 4 toothpitches
$A - A$ Diameter of restricted area
Total cross sections at $A - A$

Intake	single spacing	0.460 sq. ft
	double spacing	0.469 sq. ft.
	total	0.929 sq. ft.
Outlet	single spacing	0.576 sq. ft.
	double spacing	0.469 sq. ft.
	r total	1.045 sq. ft.

Axial coss-section (Fig. 9B)
(single) = 0.210 sq. ft.
(total) 2 × 6 × 0210 = 2.52 sq. ft.

Then, there were (54 / 6) = 9 teeth in each combination of intake and outlet belts; as the outlet was to carry the intake air plus the air admitted direct from the end bell to the air gap, a larger number of teeth was placed in the outlets than in the inlets, five in each belt of the former, and four in the latter. Further, in order to assist in the study, the vents in the upper half were provided with two fingers per tooth, and in the lower one was used. (See Figs. 7 and 8). To simplify manufacture, a circle of existing punchings with vent fingers attached were nailed on one side of each wooden ring. Small wooden blocks, having the same width as the slot, the same depth as the slot below the wedge, and the same thickness as the vent duct width, were nailed to each wooden ring for the purpose of imitating the coils in the vent duct. They will be seen in Fig. 11

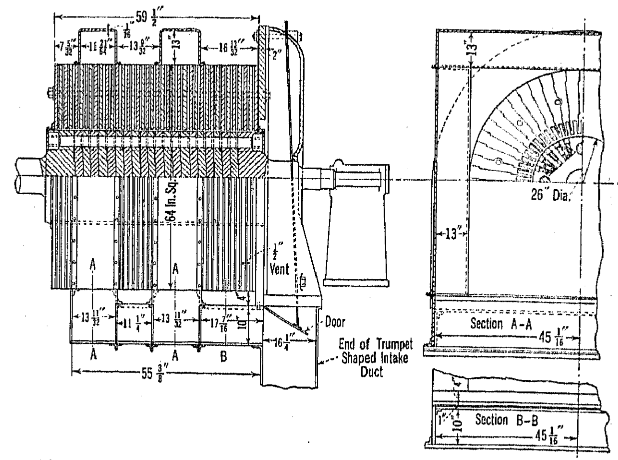

FIG. 10—MODEL FOR INVESTIGATING VENTILATION OF A TURBO-ALTERNATOR

length of the path in the vents back of the teeth were materially shortened. Recognizing this, the construction was considerably simplified by cutting out parts of the wooden rings and punchings at six equidistant places circumferentially, thereby providing ample area for the axial passage of the air from the end bell. (See Fig. 4.)[9] (If the same system of ventilation were used in a machine, these axial passages would be incorporated in the frame.)

As will be seen from Figs. 4 and 5, an existing cast iron frame was used for the first model. This frame had "chimneys" at the top and bottom, and they were so large that a man could climb into them and take anemometer observations at the outer peripheries of the wooden core. The stator of this model was shorter axially than the rotor, as will be seen from Fig. 5. This was because the blower which was used was not capable of delivering more than 10,000 cu. ft. per min. at about 10 inches of water at its maximum safe speed;

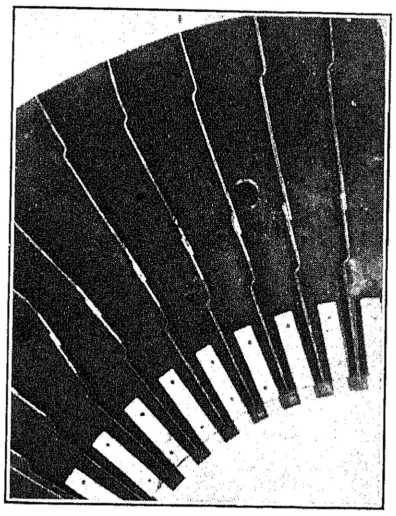

FIG. 11

and the length of the stator was made such that its resistance to the flow of air would approximately correspond to those values. These figures were based upon a preliminary rough estimate of pressure drops. Owing to the direction of flow in the gap, in the first model, it was not so important to make the length about half of the probable maximum, as in the second model. On the other hand, it was important to secure fairly high end bell pressures, in order to determine the combination of pressures and peripheral velocities. These considerations, and a preliminary inspection of an approximate curve of the blower characteristics assisted in determining the model's proportions. In order to prevent escapement of air from those radial vents in the rotor which were beyond the stator, suitable wooden stops were placed in the longitudinal ducts (those through which the air flowed to the radial vents) and those stops were removed when the rotor was used in model II.

For those who may wish to calculate velocities, and to compare results, Figs. 9A and 9B have been included. They show the sections of maximum restriction; the sketch in Fig. 9A shows two fingers, but the areas are given for both one and for two fingers.

3. *Construction of Model No. 2.* In the second model, the system of ventilation shown schematically in Fig. 3

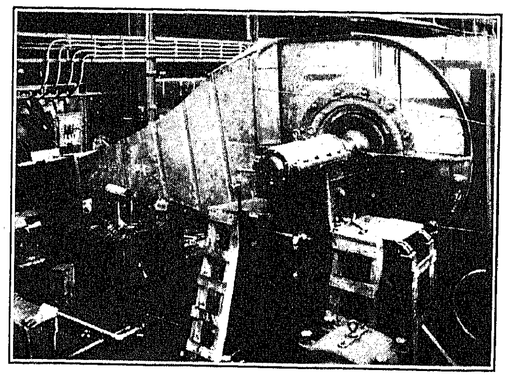

FIG. 12

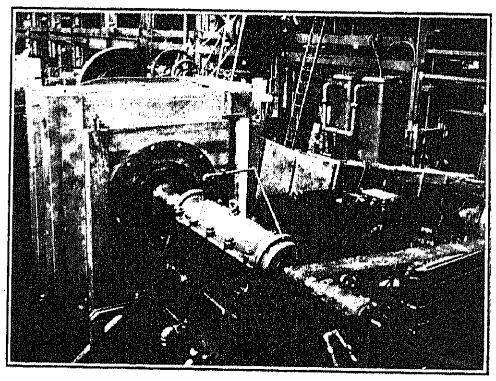

FIG. 13

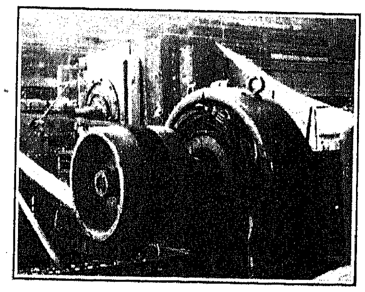

FIG. 14

(in which the air moved axially through the air gap) was simulated. The same rotor was used as for model I. The model is shown to scale in Fig. 10, and Figs. 12, 13, 14 and 15. (In the drawing, part is shown in plan, and part in horizontal section, but the bearings are shown in elevation.) The number of intake belts selected was two (equivalent to four in a machine). There were a total of 38 vents, distributed as follows:

9. In Fig. 4, some of the entrances to the intakes are closed and some are open.

10 in the first discharge belt, adjacent to the end bell; 8 in each stator intake belt; 8 in the discharge belt between the two intakes, and 4 in the final discharge belt. In the preliminary layout, it was assumed that the first six discharge vents would probably take the air which passed into the air gap direct from the end bell; the other 16 discharge vents would be fed from the 16 intake vents (after having passed through the gap). There were provisions for closing any of the vents, as might be desired, to secure other combinations.

In this model, the frame casting was abandoned. The hard wood spacers which imitated the stator

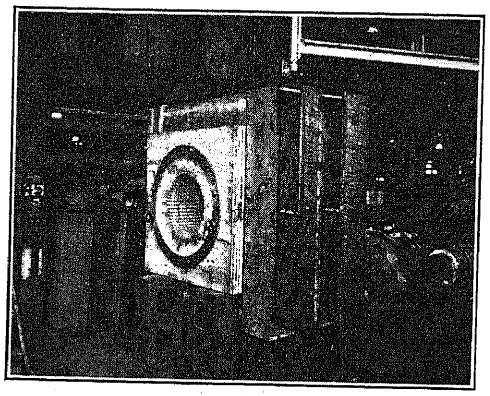

Fig. 15

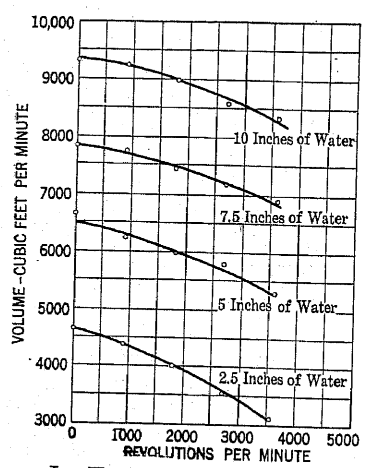

Fig. 16—Model I. Volumes for Various Rev. Per Min. and Static Pressures with Stator + Air Gap Open

punchings were square on the outside, and circular with slots, teeth, etc., inside. The dimensions of the teeth and slots were the same as in model I, shown in Fig. 9A. The vent spacers were made, like in model I, by fastening fingers to punchings, with slots spaced as for 54 per circle, the punchings being circular on the outside (see Fig. 11). Only single fingers were used; these were run to the backs of the punchings and were uniformly spaced there, to assist in volume distribution measurement.[10] Stator slot wedges were omitted in this model. The same method for imitating coils in the vent was adopted as in model I, but the small wooden blocks which imitated the coils in the vents were made of such depth as to correspond to the coil plus the wedge; the wedge notches were absent. The stator was supported on suitable steel structure, so arranged as not to interfere with the flow of the discharged air, except at short distances from the corners of the squares, where the velocities were very low; and the air which would have been discharged there was diverted without affecting the flow in the restricted sections in the teeth appreciably.

10. The anemometer readings were taken only between 3 to 5 adjacent fingers at the top and at one side, as others were not accessible.

The entrance to the air gap could readily be shut off by fastening the angle ring shown on the drawing in Fig. 18. The leakage around the ring was minimized by use of card board rings which at first fit tightly around the outside of the rotor, and subsequently the revolving rotor wore a small clearance space. Leakage around the ring at the other end was similarly reduced.

It was highly desirable to measure the volumes

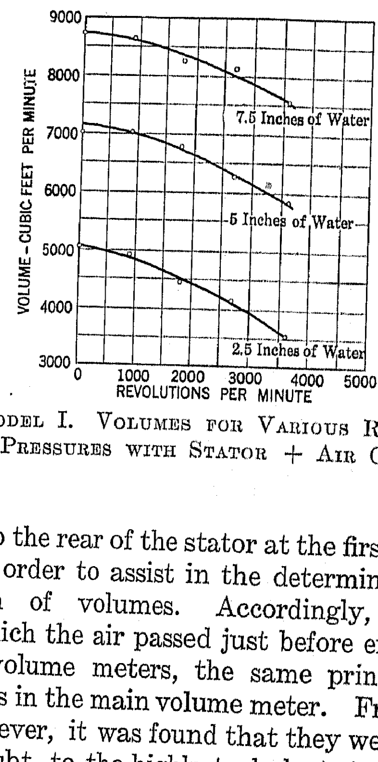

Fig. 17—Model I. Volumes for Various Rev. per Min. and Static Pressures with Stator + Air Gap + Rotor Open

passing into the rear of the stator at the first and second intakes, in order to assist in the determination of the distribution of volumes. Accordingly, the ducts through which the air passed just before entering were made as volume meters, the same principles being employed as in the main volume meter. From readings taken, however, it was found that they were valueless, due, no doubt, to the highly turbulent state, (meaning that the directions of flow were indefinite); it is well known that if the velocities through a thermal volume meter depart too far from uniformity, the readings will be considerably in error. In Fig. 15, some of the wires which were intended to be used for these volume meters will be seen.

Pressure readings were taken at various localities in addition to those in the end bell. They were taken by means of a manometer connected to open end brass tubes pushed through holes in regions of low or negligible velocities. Thus, near the regions in the sheet steel intake, enclosures around the horizontal center lines (fartherest from the entrance), the velocities

were substantially zero. The earliest readings showed an unaccountably high pressure drop from the first position in the end bell to the other positions. A piece of sheet metal was placed vertically in the end bell just beyond the end of the trumpet-shaped duct, so as to shut off the air from the end bell. The drop in pressure for the air going around the corner then assumed a value such as might have been anticipated. The subsequent tests were made with a wooden hinged door in that position, (shown in Figs. 10 and 12); it was held with horizontal steel rods which passed

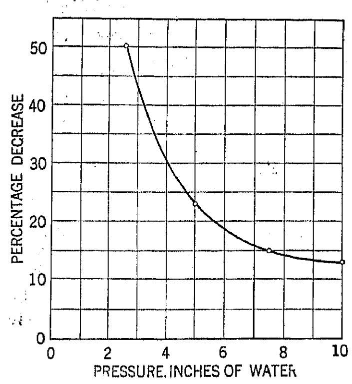

Fig. 18—Model I. Stator + Air Gap Open. Decrease in Volume from Standstill to 3600 Rev. per Min. Due to Rotation

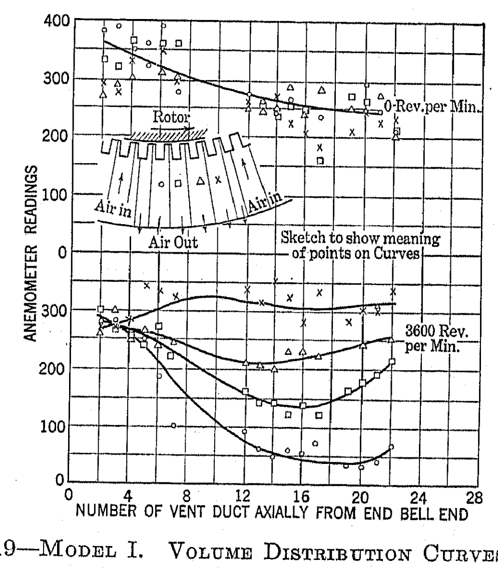

Fig. 19—Model I. Volume Distribution Curves Taken at Pressure of 7.5 in. of Water. Stator and Air Gap in Parallel

through the end bell and could be clamped in any position desired while air was flowing. It is evident that if the door were so placed as to shut off air from the end bell, the unbalanced pressure would tend to make it turn farther toward the end bell; if turned so as to close the main duct which carried air to the stator, the unbalanced pressure would keep it closed. There was one position between these two where there was practically no unbalanced pressure, and the clamps for the steel rods were secured so as to hold it in that position. The pressure drops were then of the order that one might expect.

Some later tests with the rotor removed showed what was the cause of the high pressure drop without the door. An eddy was set up, probably a spiral which whirled around the shaft, much like the familiar

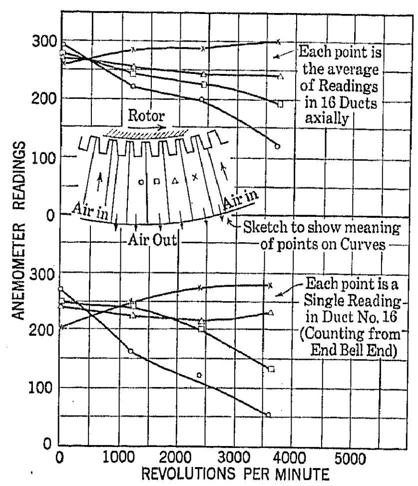

Fig. 20—Turbo Model I. Volume Distribution Curves Taken at a Pressure of 7.5 In. of Water. Stator and Air Gap in Parallel

whirling of water in a wash bowl. It is believed that the eddy was started by the unequal distribution of air discharged from the trumpet-shaped diverging entrance duct; probably caused by the departure of the duct's center line from the horizontal. The direction of

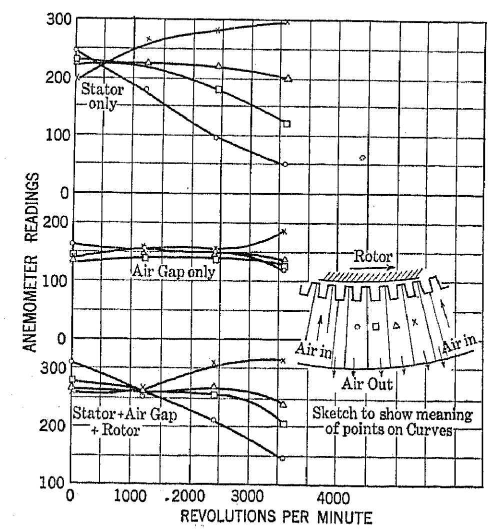

Fig. 21—Turbo Model I. Volume Distribution Curves Taken at Pressure of 7.5 In. of Water. Each Point is the Average of Readings Taken in 16 Ducts Axially

rotation of the eddy (clockwise looking axially, facing the outside of the end-bell) corresponded to the case of more than half the air entering the end-bell above the horizontal center line. In machines as built, such conditions do not obtain, except possibly in the

rare case when an external blower is used, and with a duct similarly connected to the one in the model. The experience is recorded here because the results are the kind that would not be anticipated, and may be of interest and value to others.

TEST RESULTS

Very many tests were made, far more than are included in this paper. Only a few that are representative, and that are believed to be of interest to those who have followed the development of turbo-alternator design are incorporated.

Model I. Many less tests were made on model I than on model II, but there were enough to secure that information which was needed most. A few of the results of those tests are plotted in Figs. 16 to 21 inclusive. It was believed that the deductions which were drawn were sufficient to warrant tests to be made with only one size of air gap. It was also felt that for that diameter, it would not in general be good practise to use more than six intake or outlet belts, as in a machine, the frame would be considerably complicated thereby. The average of the intake or outlet belt represents but one-twelfth of a circle. A change either in air-gap size, or in number of belts would undoubtedly have been accompanied by a change in performance; certainly the distribution of volumes would be more uniform with more intakes and outlet belts. As to the air-gap size, the circumferential distribution would probably have been improved by a larger gap, but with the number of intake and outlet belts chosen the gap velocity was then so low that at standstill only a small percentage of the pressure was consumed there. Furthermore, for electric considerations, the gap used in the model (0.625 inch on a side) is about the size that would be used with a 26-inch diameter rotor in a machine running at 3600 rev. per min.

On the various curve sheets we have designated as "stator" the condition when the air enters from the rear of the stator and travels radially toward the air gap; the condition has been styled "air gap" when the air enters the gap direct from the end bell; the path for that air which passes through the rotor vents we have called "rotor". From Figs. 16 and 17, a picture of the reduction in volume due to rotation can readily be obtained for various end bell pressures. The path is for the "stator" plus "air gap" in Fig. 16, and for the "stator" plus "air gap" plus "rotor" in Fig. 17. It will be seen that the volumes are nearly proportional to the square roots of the pressures when the rotor is stationary, but not so when the rotor is running. In every case, the influence of rotation is to reduce the volume; it is as though a counter pressure were produced by rotation, the percentage reduction in volume being greater, the lower the applied pressure. If there is a counter pressure due to rotation, its percentage is greater the lower the external pressure, and therefore the larger is the percentage decrease in volume. The "counter pressure" is due to a whirl which follows the external periphery o thereby decreases the effective cross se There is another effect of rotation in m subsequently explained.

In Fig. 18 are plotted the percenta volumes from standstill to 3600 rev. per applied pressures, as determined for stator plus the air gap from Fig. 16. seen that there is 50 per cent decrease of water and only 13 per cent with course, the percentage must approac pressure approaches infinity. The per with air supplied from the rotor in ad is nearly the same as without it. A to this system of ventilation is that siderable decrease in volume with in unless rather high pressures are used.

With the stator plus air gap plus more air is supplied than without the Thus, at 3600 rev. per min. and 7.5 i 7550 cu. ft. with air through the rotor a 6850 cu. ft. without the rotor, or ten pe The increase looks reasonable for the ad paths.

Refer now to the volume distri Only data for single finger spacing are p others were taken. In Fig. 19 th readings taken for as many vents a accessible, and for four consecutive p ferentially are plotted for standstill and min. for the one case of air feeding int air gap (at the end bell end) in paralle are various irregularities, the follow may be drawn:

(a) At standstill with low relative there are no differences circumferenti distance axially.

(b) At standstill the volume disch axially decreases with the distance fro entrance.

(c) At 3600 rev. per min. the distribution is substantially uniform ne

(d) At 3600 rev. per min. the distribution departs from uniformity from the end bell entrance increases, apparently reaching a maximum a li extremity.[11]

(e) Considering that the air in the circumferentially in the same directio surface moves, then, due to rotation are decreased materially in the first ven increased slightly in the last vent du mediate values in the intervening ducts.

(f) The distortion is undoubtedly lar for the reduction in volumes with ar

Before discussing these deductions, I

11. We call departure from uniform ci tribution "distortion."

will be examined. In both of these, volume distribution curves are plotted (for single fingers only), and the plots show the influence of change in angular velocity upon the volumes in individual vents, distributed circumferentially. From a number of curves like those for 3600 rev. per min. in Fig. 19, it was ascertained that the distortion is a maximum at about duct No. 16 axially. Consequently, the distortion for duct 16 is plotted in Fig. 20, showing approximate maximum distortion. A glance at Fig. 19 will show that the distortion is less if the average values rather than the individual points are plotted, and these averages also appear in Fig. 20.[12] In Figs. 19 and 20 the curves plotted are for air feeding into the back of the stator and into the air gap at the end bell. The average of 16 readings axially for other combinations are shown in Fig. 21. Thus, for the upper plot, air is fed into the stator only; for the middle plot, air is fed into the air gap only; and in the lowest plot, air is fed into the stator, the air gap and the rotor, all in parallel. From an inspection of Figs. 20 and 21, the following additional deductions may be drawn:

(g) The distortion due to rotation is largely dependent upon the manner in which the air is fed into the gap. If the air is fed in axially, (which we call air gap), the distortion, though present, is of little consequence. If all the air is fed in from the stator, the distortion is a maximum.

(h) The distortion which would obtain with all the air fed from the stator is decreased by feeding in parallel from the air gap. It is still further decreased by feeding in air from the rotor vents in addition.

Comments on the various deductions, in so far as they may not be self-evident, will now be given.

(b) The air entering from the stator and from the air gap, (rotor stationary) meet at right angles, and consequently, much of the velocity heads are lost. This would mean that the velocity head of the air direct from the end bell is dissipated more and more the farther from the end bell,—with a consequent reduction in volume. (The loss due to friction drop may be neglected). This meant too, that, other things being equal, the combined total volume was materially less than if the volume with the air gap alone had been added to that with the stator alone. It is well to bear deduction (b) in mind, as conditions with model II were quite different.

(c) and (d) The air which enters the gap direct from the end bell undoubtedly combines with the air from the stator which nominally travels circumferentially, so that the resultant with the high peripheral rotor speeds, is a spiral, like a corkscrew. Near the end bell the influence of the air passing direct from the bell predominates, and the distortion is of little consequence. Farther on, the velocity head of the axially moving air decreases, but the velocity head of the circumferentially moving air increases as its volume increases, thereby increasing the distortion. A possible explanation for the distortion being greatest before the end (axially) is reached, is that a portion of whatever axial component of velocity that remains is converted into pressure, and as such is useful in producing a flow in the last vent ducts; the influence of axial flow in the gap is to decrease the distortion.

(e) and (f) That the discharge velocities in some vents are decreased, and in others increased, due to rotation, is undoubtedly due to a whirl of air which travels circumferentially with the rotor.

One way of regarding the phenomenon is that the influence of this whirl is to decrease the effective gap section through which the main volume of air flows, which in turn means that the velocity there is increased. Some of the applied static pressure must be consumed in creating this velocity. Therefore, at duct m in Fig. 22 the gap velocity is high and consequently, the static pressure is low, in accordance with Bernoulli's equation. Most of the velocity in a given radial vent duct is dependent upon the difference in static pressures between the entrance and exit to the duct, and if that

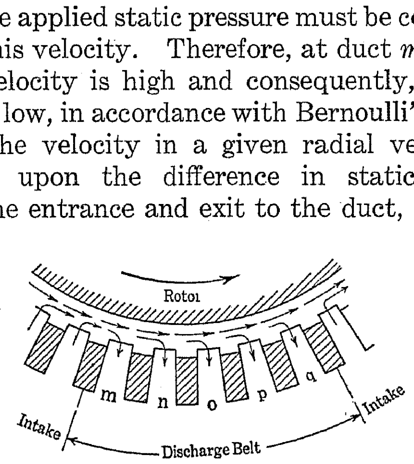

FIG. 22

pressure difference is low, the duct velocity must also be low. The velocity in the gap is lowered from m to n, due to the reduction in volume by that taken out at m. If the sum of velocity and static heads remains constant, then the static pressure at n is greater than at m, and therefore the discharge velocity at n is greater. Of course, there is a loss of head from m to n, but if only some velocity head is converted to static, the velocity in duct n is greater than in duct m. Similarly, for the other ducts; at the last duct in a belt, sufficient velocity head in the gaps may be converted into static to cause the velocity in that duct to be greater than with the rotor stationary. However, the net result is that the loss of head in the gap is sufficient to lower the average outlet velocity, with the rotor running, below that which obtained at standstill. Consequently, the total volume is lowered as a result of the distortion arising from rotation.

(g) The above explanation shows why the air that travels circumferentially through the gap is not uniformly distributed circumferentially, when running. The conditions that obtain for the air that enters the gap axially will now be given. Evidently, if all the vents were outlets, distributed uniformly, the discharge

12. It will be noted in Fig. 19, that readings were taken in 16 out of the total of 22 vents axially. That 16 should not be confused with duct number 16.

velocities would be alike at a given distance axially. The influence of rotation is to skew the air; the air which enters axially moves in a spiral, like a corkscrew and the pitch of the screw decreases as the distance from the end-bell increases. The motion may become nearly circumferential as the far end is approached. Consequently, near the far end, conditions are similar to those which obtain when the air enters through the stator intakes and moves circumferentially through the air gap; that is, distortion at the far end is to be expected. However, the gap velocities, determined from the volumes are low, since most of the air that entered axially escaped before it reached the last vents; as previously explained, if the circumferential gap velocities are low, the pressure differences over the discharge belt are small, and the outlet velocity differences are not large; but distortion is undoubtedly present. An idea of the order of magnitude of this distortion for the average of the readings axially can be obtained from an inspection of the middle set of curves in Fig. 21.

(h) Considering the rotor alone, the volume of air from the rotor vents is small, and being impelled by a high-pressure fan (the rotor coils), the outlet velocities must be nearly uniform. Consequently, the influence of that air is to reduce the distortion arising from the air that enters the stator intakes. Also, the air which travels axially from the end bells tends to reduce the distortion.

It was previously pointed out that in model I all teeth have sharp wedge notches. Laboratory tests on sections of teeth indicated that, for a given pressure, with the notches cut off the wedges, an average of about twice as much air would flow, as with the notches. In most large machines, the wedge notches are eliminated at the vent ducts. If, in model I, this had been done, the pressure drop in the vents for a given volume through them would have been considerably less, and had the gap conditions remained the same, the drop in the gap would have been a greater percentage; consequently, the distortion would have been even greater.

For the intake vent ducts, in which we were unable to secure reliable data, there must be distortion, somewhat as in the outlets. The gap velocities are maximum near the division between an intake and an outlet belt. That represents a low-pressure region, and the largest pressure difference exists between the intake (connecting with the end bell) and that low-pressure region; consequently, those vent ducts have the greatest velocities of any intake vents. That is, the high-velocity region in the intake vents is in the inverse order to the outlet vents. This will be clearer after studying results on model II.

In general, it may be said that the air flow with the type of ventilation in model I is too complicated to admit of a quantitative mathematical solution. Even at standstill, our present knowledge is too incomplete to put into equations the combined flows; and with rotation, the problem is very much more difficult. A solution of the flow with the stator alone at standstill is not very difficult, if comparatively simple assumptions are made; however, that solution is of little value unless the axial flow is combined with it, and especially, unless the influence of rotation is considered. Certain empirical relations were secured co-ordinating pressures, volumes, and rotation, use having been made of data not published in this paper, in addition to the data given. Those equations are not being published at present.

The conclusion reached is that the type of ventilation investigated with model I is undesirable, first because of the decrease in volumes with rotation, and second because of non-uniformity of discharge velocities, due

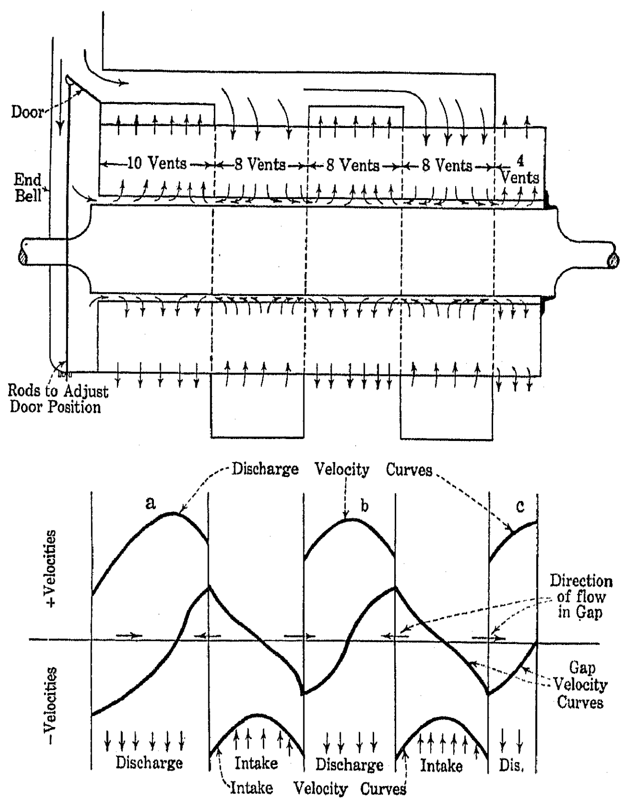

FIG. 23—TURBO MODEL NO. 2 SCHEMATIC DIAGRAM TO SHOW DIRECTIONS OF AIR FLOW AND DISTRIBUTION OF VOLUMES

to rotation. The non-uniformities, (distortion) occur for relatively long distances axially near the middle of the machine. Most of the heat generated in the tooth zones near the middle of a long machine must be carried away by moving air streams in that region; it cannot be conducted axially along the copper to the ends, as the length is too great; only a small fraction of it can be conducted circumferentially from tooth to tooth, because the length of the path is great, the cross-sectional area is small, and the thermal conductivity of the steel is rather low.[13] Consequently, those teeth

13. The thermal conductivity of low loss silicon steel is less than half the conductivity of ordinary steel; and the conductivity of ordinary steel is only about one-ninth of that of copper.

for which the air supply is small will heat considerably, and there will be high local temperatures.

A modification of model I type of ventilation consists in shunting some of the air which is admitted through the stator intakes through other paths of definite areas back of the teeth. If the same velocities are used in the teeth as with model I ventilation, and the same total volumes, then there is less air for the teeth, and the package thickness may be greater. With the same velocities in the teeth, nearly the same pressure of air must be used, and as the circumferential gap velocity is less, there probably will be a little less distortion. On the other hand, the thicker package of laminations means a greater drop in temperature axially; as that drop is proportional to the square of the thickness of the package, it may become an item of considerable magnitude. From an experimental viewpoint, the study of this type of ventilation would first mean the development of an instrument for measuring air volumes (or velocities) in the various paths. No existing instrument is adapted to this. That would have required more time than was at our disposal. Many machines have been built with this type of ventilation, and it is claimed that they are satisfactory.

Model II—*Test Results.* Very many more conditions were tried out in this model than in model I, and the test results appearing in the forms of curves in this paper are those which are believed to be most helpful and to be representative of those conducted. Only single finger vent spacers were used, and there were no wedge notches. The total number of sections of air gap for which tests were made were four. The first gap was the same as in model I, obtained with 26-inch diameter of rotor, with 0.625 inch gap, with stator slots sunk 0.625 inch below the inner periphery, giving a net gap cross-section for axial flow of 0.553 sq. ft. A second gap section of 0.364 sq. ft. was obtained by filling in the upper parts of the slots, making the inner bore of the stator smooth. The rotor was later turned down to 25.25 inches, making the gap section 0.573 sq. ft. Finally, the fillers in the slots were removed, increasing the gap section to 0.763 sq. ft. On every curve sheet for model II the gap section is recorded.

The same designations for the paths for air flow are used for model II as for model I. Thus, it is "air gap" when air is fed directly from the end bell into the air gap; it is "stator" when air is fed into the stator intake vents at the back of the core; it is "rotor" for that air which is passed through the rotor vent into the air gap. Thus, "air gap" plus "stator" means that air entered through those two paths.

A statement is given in the following of the tests conducted on model II, a few of which are published herewith; perhaps others contemplating similar work may obtain a helpful suggestion.

The 0.553 sq. ft. gap tests were made with air gap only, stator only, rotor only, air gap plus stator, air gap plus rotor, stator plus rotor, and air gap plus stator plus rotor, with all vents open, and set up as indicated in Fig. 10 and the upper part of Fig. 23. With the same gap, vents Nos. 5 and 6, and later Nos. 4 to 7, inclusive, were closed at the outside, these tests being made to determine the influence upon distribution. Later the first two vents were closed at the outside. With the 0.553 and 0.763 gaps, tests were made with various positions of the door, (Figs. 10 and 22), to determine the influence of a change in ratio of stator to end bell pressure upon total volumes and its distribution. With 0.553 and 0.573 gaps, the effectiveness of a ring in the air gap to assist to define the division of air was determined. With the 0.553 gap, and stator only, the first six vents were closed, so that the paths of the air were defined, and the pressure drops could be fairly readily determined; other combinations of numbers of ducts with the same general set-up were tried. With the same gap, all the intakes were removed, so that all 38 vents discharged air, the only intake being into the gap at the end bell end.

With 0.364 gap, the wood fillers at the tops of the slots were allowed to project into the end bell to imitate coil ends, and their influence, before and after being cut off flush, were determined. Tests were made with the stator plus air gap, and air gap only. Then a converging cone was placed at the air-gap entrance to assist the air to enter. Various combinations with certain outlet vents closed were tried.

With the 0.573 gap, in addition to tests previously cited various, rather fruitless, attempts were made to explore the velocities in the gap with a specially devised pilot tube. After that method was abandoned, the distribution was determined with the first five vents closed at the inner periphery of the stator. The influence of several kinds of guides at the entrance to the gap was determined.

Some of the tests made with a 0.763 gap were enumerated above. In addition, special restrictions were placed at the end bell entrance to the gap; and the first two wooden "packages" (imitating packages of laminations) were cut back.

Tests were also made with the rotor removed: (a) With air entering direct to the stator bore from the end bell, with the far end closed by card board; the usual entrance to the stator being closed; (b) the entrance to the stator open, the bore at the far end open, and at the end bell end closed; (c), as (b), but the bore closed at both ends.

In many of these tests total volumes, total pressures, and distribution of volumes were measured for various angular velocities. Some very valuable and some very interesting results were obtained; on the other hand, as in nearly all research work, some results have so far not been of any value. The results are so numerous that a paper several times the length of this might be written to cover the results.

A realization of the importance of being able to

estimate pressure drops suggested to us that small models be built of the full size of a tooth vent section from the inner to the outer bore, and this model was to be made so that sharp, round, and blank wedge notches could be added. Pressure drops were to be measured for various volumes, with flow in both directions, with one, two and no fingers. That in itself is quite a large and valuable research, the results of which cannot be included in this paper. The sum of the pressure drops with one finger for the two directions, are about twice as high for a given volume with sharp wedges as with none; in every case the drop is higher (for a given volume) with air flowing toward the inner bore than away from it. The test results for the blank wedges were subsequently checked for both directions of flow by applying formulas to be found in standard reference books on hydraulics. (Air is treated as an incompressible fluid; and for velocities well above the critical, viscosity has negligible influence upon the pressure drops. See author's articles in the *Electric Journal* on "Some Elements of Air Flow," beginning with August, 1922.)

Total Volume Curves

Refer now to the various figures. In Figs. 24, 25, and 26, volumes of flow are plotted against revolutions per minute for several static pressures. All volumes on these figures were those measured minus leakage. The model as shown in Fig. 10 was used, and was arranged as follows:

(a) The stator was in parallel with a 0.553-sq. ft. section air gap, results plotted in Fig. 24; (b) in Fig. 25, conditions were as for Fig. 24, plus the rotor; and (c) in Fig. 26, conditions were as for Fig. 24 with the rotor turned down to 25.25 in. diameter.

These curves for volumes are somewhat similar to those for model I. The volumes at zero speed are practically proportional to the square roots of the static pressures, and the volumes with the rotor intakes closed decrease slightly with the increase in rotor speed. It should be noted, however, that the decrease in volumes is small, at least as compared with those in model I. In Fig. 24 the percentage decrease in volumes increases as the pressures decrease, as in model I. These decreases for both models (from Figs. 18 and 24), are recorded in Table I.

TABLE I.

Pressure Inches of Water	Percent Decrease in Volume from Standstill to 3600 rev. per min.	
	Model I.	Model II.
4.95	23.5	7
3.3	38.5	8

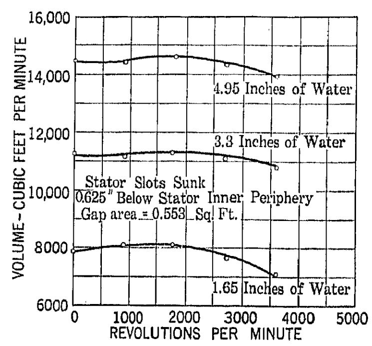

Fig. 25

Turbo Model No. 2. Volumes for various angular velocities and static pressures with stator + air gap + rotor open.

Rotor external Diameter = 26 in.

Single air gap = 0.625 in.

Had we been able to use pressures as are used in machines, of the order of 10 inches of water, the percentage decrease in volume due to rotation with model II would undoubtedly have been of the order of only a few per cent—practically negligible. With the rotor shut off, as before, but with a gap section 38 per cent larger (Fig. 26) the decrease in volume due to rotation is even less—4 per cent decrease with only 2.5

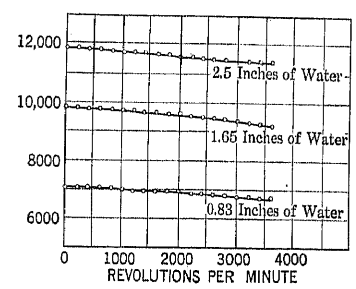

Fig. 26

Turbo Model No. 2. Volumes for various angular velocities and static pressures with stator + air gap open. Rotor external diameter = 25.25 in. Single air gap = 1 in.

Stator slots sunk 0.625 in. below stator inner periphery. Gap area = 0.763 sq. ft.

inches of water; it certainly must be negligible with pressures that are used in most turbos.

If the rotor is provided with radial vent ducts, it would seem that at moderate peripheral velocities, the pressures created by the coils that act as fans, actually increase the volumes (see Fig. 25) around 1800 rev. per min. At higher speeds there is a slight decrease in volume, so that the volume at 3600 rev. per min. is a little less than at standstill. At the low

pressure of 3.3 inches, there in only about 3.8 per cent less volume than at standstill; with the rotor shut off, the decrease was 8 per cent with the same size gap (Fig. 24 or Table I).

As was pointed out, the influence of rotation is to surround the rotor surface with a whirl which has the effect of decreasing the effective gap section, thereby increasing the velocities for the main air streams, and consequently raising the pressure drops for a given volume. As for a given diameter and angular velocity of rotor, the whirl has a certain depth, the percentage reduction in effective gap section due to it decreases as the radial depth of the gap is increased. Therefore, with the larger gap the axial gap velocities were increased less due to rotation, and the percentage pressure drop decreased. In model II, the circumferential distortion due to rotation is absent, and therefore there is no increase in pressure drop due thereto. That is why the percentage reduction in volumes due to rotation in model II, is so much less than in model I.

Relatively small volumes of air flowed through the rotor vents, and it will be seen from a comparison of Figs. 25 and 24 that the volumes at a given pressure were but little higher with the rotor open than with it closed. Separate tests, with the rotor acting alone, showed that the volumes increased materially as the speed increased, due to the fact that the rotor acted as a fan in series with the external blower. At 3600 rev. per min., the volume was nearly as high when the blower was shut down as when it was delivering a pressure of five inches of water. That would be expected, as a peripheral velocity of 24,500 feet per min. corresponds to a pressure of about 37 inches of water, part of which is realizable. At low angular speeds, the air fed into the air gap either from the end bell or from the main stator intakes is augmented by the flow through the rotor; at high speeds, however, the air thrown out of the rotor vents nearly tangentially, at high velocities, is met by air which moves nominally in an axial direction.

Much of the velocity heads in these two streams which meet is destroyed, and consequently the volume for a given pressure is not augmented at the rate that it was for lower pressures. At very high speeds there may be a decrease in volumes. This is an explanation offered for the shapes of the curves in Fig. 25. Of course, if a belt of stator vents is long enough, (axially) the influence of rotation is to cause the air to move spirally; that is, a combination of tangential and axial motions. Attempts have been made to analyze the phenomenon quantitatively, but it is too complicated for us to handle with our present knowledge. In so far as the turbo alternator is concerned, with model II type of ventilation, it is safe to predict the volume at standstill, and take that to be the volume at full speed, or to deduct a few per cent for safety.

Volume Distribution Curves

In Figs. 24, 25, and 26 for total volumes, the points plotted are those for volumes as measured minus leakage. In the distribution curves, the values of volumes as measured for the particular conditions of test, without deduction for leakage, are recorded on some of the sheets.

In Fig. 27 are shown the results of tests made on a turbo which was a duplicate of machines that were built for about 15 years. The machine receives all its air direct from the end bells, at either end, as illustrated in Fig. 1. The points were taken by pushing an open end brass tube into vent ducts at the rear, and temporarily sealing the space around the tube with putty, the other end of the tube being connected to a manometer. The readings thus obtained were taken to be the pressure that was useful in driving the air through the vent when the tube and seal were absent. The square roots of the ordinates on the pressure curve should be

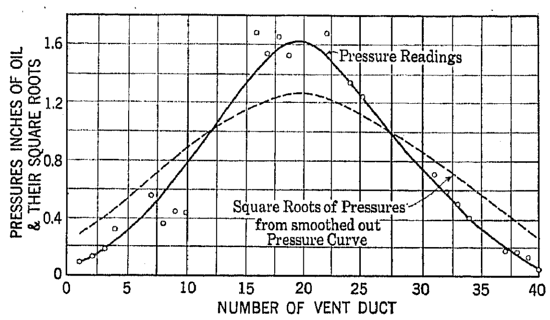

Fig. 27

Volume distribution curves in a turbo alternator with air entering only at the ends of the air gap. Each vent duct 3/8th in. wide. Ratio of summation of min. sections in teeth in 20 ducts to gap section = 2.1. Total length of stator = 65 in. Stator internal diameter = 26 in. Rotor internal diameter = 23½. Rev. per min. = 3600. Propeller type of fans at the external diameter of the rotor beyond the stator were the source of pressure. Readings taken with the use of a brass tube pushed into vent at the external diameter and the vent space around the tube was temporarily sealed. The dotted curve is an approximation of the shape of the volume distribution curve.

proportional to the velocities that obtain in normal operation. The shape of the dotted curve is that which is obtained in a machine with air fed into the air gap at both ends, and in which the ratio of cross-sections of vents to gap is the same and that has similar proportions of teeth and slots. It has long been known that with this type of ventilation the radial flow is a maximum near the center, and a minimum near the ends. It was, in fact, that that led us to anticipate similar distribution, in part at least, for model II, as the air moves axially in the air gap there, too.

Mr. Bratt, in a companion paper, has derived equations for the shapes of these curves, based upon Bernoulli's theorum, and the equation of continuity. Mr. Bratt has shown that, if losses of head in the gap are neglected, the volume distribution curve approaches that of a simple cosine. An inspection of the dotted

curve in Fig. 27 will show that its shape approaches that of a cosine. Perhaps a physical interpretation may be of assistance—to give a general idea as to why the velocities increase toward the middle of the machine.

Bernoulli's equation states that, neglecting losses, the sum of the velocity head and static pressure measured from some reference point in the direction of flow is a constant. (The velocity head is a constant times the square of the velocity). Considering the velocity head in the end bell as zero, and the pressure there a maximum, much of that pressure is converted into velocity head when the air enters the air gap, since the velocity there is high, due to the large volume passing; the static pressure is low. As the velocity in the vents is proportional to the static pressure in the gap, the outlet velocity must be low. But by whatever percentage the volume in the gap is reduced by the air that is discharged through the first vents, the velocity in the gap is decreased; the velocity head also decreases, and in accordance with Bernoulli's theorem, the static pressure rises. The latter means a higher discharge velocity at the next vent; that means a further reduction in gap velocity and velocity head; an increase in static pressure, which in turn causes the air to be discharged at a higher rate, and so on.

Evidently, the volume entering the gap must be the summation of the volumes discharged from all the vents up to the center line. Consequently, if the machine is short, the total volume is relatively small, and the maximum gap velocity must be comparatively low. Therefore, the static pressures at the regions of maximum gap velocities are higher than for the long machine, and the discharge velocities would be correspondingly higher. Thus, suppose the machine whose outlet velocities are indicated in Fig. 27 had one-half the number of vents. If the Bernoulli equation without losses is applicable, the total head in the gap at the middle of the machine is the same as in the end bells; as the gap velocity is zero at the middle, all of the head must be static, which is converted into radial velocity in the vents. If the losses of head in the gap are neglected, there must be the same vent velocity at the middle with the full length as for the half length machine for the same pressure in the end bells. For the vents next to the middle the static pressure in the gap is lower than at the middle vents by the amount represented by the velocity head corresponding to the volume that escaped through the middle vent; since that volume was the same for both lengths, the static pressure (and therefore the outlet vent velocity) is the same for either the long or the short machine, and so on. That is, the outlet velocity curve is substantially the same for the two lengths of machines, with, of course, the extremities of the curve for one-quarter length removed from the full length machine. Actually the two curves would not be exactly alike, because there are losses of head in the gap, and those losses are not the same for the two lengths. The above explanation may be of assistance in the study of some of the subsequent data in curve form.

Consider now the effect of lengthening the machine. If the length be increased to a certain critical value (defined in Bratt's paper as $\frac{S\,L}{a\,\sqrt{C\,d}} = \pi/2$) the velocities in the first vents become zero. If the length be further increased, for the ideal machine without loss in the gap, there will be no discharge in any vents until that critical point is reached. Of course, there are losses of head in any machine, and therefore, there *is* a decrease in total head. This can only take place by a small discharge all along, as then the velocity head decreases in the gap, the static pressure changing but little, until the critical point, where the approximate sine wave discharge begins.

That this is more than theory will be seen from Fig. 28. In this case all the external enclosures were removed from model II, all 38 vents being used for discharge. The only entrance was to the air gap at the end bell end. The manner in which the curves were obtained is given on the figure.[14] The ratio of vent to gap section is far greater than would correspond to the critical length.

At standstill the discharge velocities are nearly uniform until vent number 31 is reached; then the discharge rates increase to the end, along a curve that approximates a cosine. The calculated starting point of the sine curve is at about duct number 32.

14. To make clear the explanation given on Fig. 28, the calculations for a few points are given: At zero speed, the anemometer readings were as follows:

Duct. No.	Anemom. Reading	Sum	Gap Vel.
38	156	156	967
37	155		
		311	1560
36	140		
		451	2800
35	120		
		571	3540
		1518	9400
2	9		
		1527	9460
1	8	1519	9410

The maximum gap vel. = Volume/Area = 5200/0.553 = 9410 ft. per min. The proportionality constant- 9410/1519 = 6.2. The gap vel. at any event position = Sum as given above times 6.2.

To determine the vent duct velocities from the gap velocities, use the equation of continuity: If $-\Delta v$ is the decrement in gap vel. due to taking off the volume through a particular vent duct, the volume decrement $= (-\Delta v)\ a = VA$ where a = gap area, V = outlet vel., and A = vent duct area at minimum section. Then $V = -(a/A)\ \Delta v = -(0.553/0.141)\ \Delta v = -3.92\ \Delta v$.

(V is plotted as positive). If the distance is very short, and if S is the vent area per inch length axially, $S\,d\,x$ is area for short length. The volume $= V\,s\,d\,x = -a\,d\,v$; or $V = -a/s\frac{d\,v}{d\,x}$, a constant times the derivative of the gap velocity.

In the foregoing, no statement was made in regard to losses of head at entrance to the gap. When a fluid passes from a large to a smaller section, with sharp edges, it undergoes a contraction in section for a short length—called "vena contracta." The smaller section means that there is an increase in velocity, and therefore of velocity head. Some of this velocity head is lost when the air subsequently slows down; the high velocity at the vena contracta is accompanied by low static pressure there. In the turbo model, when the edges at the gap entrance were sharp, the contraction phenomenon was undoubtedly present, and therefore the velocity near the first vent was high, and the static pressure low. In fact, the static was so low, in certain cases, as to be below atmospheric pressure; the air then flowed in, instead of out through the radial vent duct. In a few tests, most of which are not being published, the flow *was inward* (negative) in the

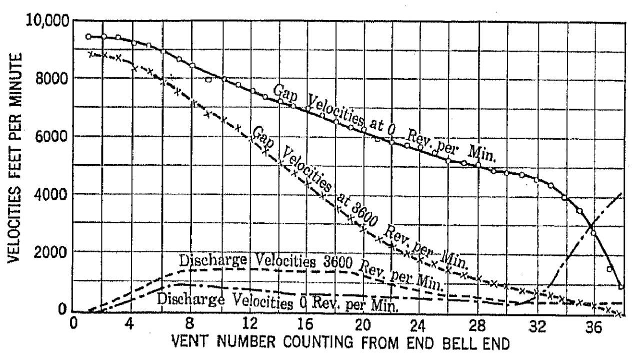

Fig. 28

Turbo Model No. 2. Velocity distribution curves. Air entering air gap only. All 38 radial vents used as discharge ducts. Rotor diameter 26 in.; radial depth of gap 5/8 in. Stator slots sunk 5 8 in. below inner periphery. Gap area = 0.553 ft. Tests made at pressure of 7.5 in. of water in end bell. Volume with rotor stationary = 5200 cu. ft. per min. Volume with rotor at 3600 rev. per min. = 4900 cu. ft. per min. Original test points not plotted, but summation of outlet readings beginning with duct No. 38 are plotted as gap velocities after determining the proportionality constant from total volumes. The derivatives of the smoothed gap velocity curves give the discharge velocity curves.

first vents. In Fig. 28, the anemometer rotated slowly in the reverse direction, indicating negative flow in the first vent, due undoubtedly to negative gap pressure which resulted from the vena contracta incident to the sharp entrance. As the air slowed down with the enlarged area following the vena contracta, the pressure rose slightly in the gap,[14] and therefore the outlet velocities became positive, and increased in value up to about duct 7. It is believed that the reason for the slight fall in discharge velocities after duct 7 is that the gap loss per unit length became less following the highly turbulent state arising from the enlargement after the vena contracta. However, the discharge velocity drops only slightly, and then becomes nearly constant. If V_1 and V_2 are the gap velocities at two points, 1 and 2, P_1 and P_2 the corresponding static pressures, and γ the density of the air, then by Bernoulli's equation:

$$\frac{V_1^2}{2\,g} + P_1/\gamma = \frac{V_2^2}{2\,g} + P_2/\gamma$$

$+$ Losses of head between positions 1 and 2.

The condition for the discharge velocities to remain constant is that $P_1 = P_2$. Then,

$$\frac{V_1^2 - V_2^2}{2\,g} = \text{Losses}$$

That is, the condition for the discharge per vent to be uniform is that the decrease of velocity head per unit length equal the loss per unit length. Actually, the problem is not so simple, since the loss is not proportional to the decrease in velocity head, but more nearly to the square of the decrease in velocities. In other words, the discharge per vent is not uniform.[15]

With rotation, conditions are different than at standstill. With conditions as in Fig. 28, the air is undoubtedly moving practically circumferentially in the air gap for a considerable part of the axial length, so that the axial component of velocity there may be neglected. Undoubtedly, starting at the end bell, the air first moves axially, then spirally, the angle that the spiral makes with an axial line becoming greater the farther from the end bell, approaching, and perhaps practically reaching 90 deg. if the length is great enough. While a crude picture of the flow is obtainable, a quantitative analysis is, at present, impossible.

The test curves will perhaps be better understood from an inspection of Fig. 23. Consider first the discharge velocity belts. There are three: (a) the belt adjacent to the end bell; (b) the discharge belt between the two intake belts; and (c) the discharge belt beyond the second intake belt. If, as before, the losses of head in the gap and influences of rotation are neglected, the discharge velocity curves are cosines. In the simplified case, illustrated in Fig. 23, the maximum velocity of the discharge in belt *b* is at the midpoint axially, and that point corresponds to zero gap velocity; equal volumes flow from the two adjacent intake belts toward the middle of the discharge belt *b*. The discharge velocity curve is proportional to the derivative of the gap velocity (as shown in the foot-note No. 14). Consequently, if the discharge velocity curves are parts of cosines, the gap velocity curves are parts of sine curves, displaced from each other by 90 degrees; the maximum of one corresponds to the minimum of the other. For belt *b* it is assumed that there is a wall at the middle. The point at which the gap velocity becomes zero, (and the discharge a maximum), we have called the "balance point." In belt *c* the conditions

14. The fact that the outlet velocities reverse and rise proves that some of the difference between the velocity heads at the vena contracta, and after filling the gap is not lost; for if all were lost, the static pressure and the outlet velocities would remain constant. This is in keeping with theoretical and experimental results published in works on hydraulics, where the loss of head for a fluid entering a duct with sharp entrance edges is given as 0.4 to 0.5 of the velocity head corresponding to the velocity when the duct is full.

15. The above is put in to give the reader a more complete and a better understanding of the statement made earlier.

are as for one-half of b; in c there is a definite mechanical stop at the far end.

In the first belt a, conditions are somewhat different. Assume that the pressures in the end bell and back of the first intake belt are equal. In general, the loss of head through the intake vents and up to the discharge belt is greater than at the gap entrance, at the end bell end, so that more total head is available for the discharge on the end bell side than at the intake side. It is almost evident, therefore, that the "balance point" in the first belt a, is usually not at the middle of the belt, but is nearer to the first intake belt, as indicated in Fig. 23. The discharge velocities are lower at the end bell side than at the intake side, as will readily be understood from previous explanations.

The intake velocities with the rotor stationary, are at minimum value at the middle and maximum at the ends of the belts. This follows from the following: Gap velocities are zero at the middle, and maximum at the ends of the belts; the static pressures in the gap are, in consequence, at maximum at the middle, and minimum at the ends of the belt; the vent velocities are dependent upon the differences between the pressures back of the core and in the gap, and those differences are minimum at the middle and maximum at the ends of the intake belt. Neglecting losses of head in the gap, those velocity curves are hyperbolic, instead of trigonometric, and are cosines for the vents, and sines for the gap, referred to the balance point.

As in most complex phenomena, the actual curves can not be so simple. There is a loss of head in the gap, and the solution of equations with allowance for that loss complicates them considerably. However, those equations have been solved, but they are not yet ready for publication. The balance point in the first discharge belt is shifted; that, in turn, shifts the balance point of the first intake away from the middle; the location of other balance points are likewise affected until, at the middle of the machine, the balance point is at the middle of the central belt. The influence of rotation also plays its part in distribution that will be subsequently discussed more at length. However, the calculations based upon the comparatively simple assumptions, giving trigonometric and hyperbolic sine and cosine distributions is extremely useful and helpful just as the use of the simple sine wave assumption in alternating-current calculations is of enormous help and usually gives results which are sufficiently accurate.

In regard to the balance point, Mr. Bratt has given methods of calculating its location. Other unpublished methods are available, all of which are more or less approximate; the final check is that the pressure drops in each of the parallel circuits are equal; and that the vent velocities at a balance point, taken from either side, are equal.

Referring now to Fig. 29, it will be seen that the shapes of the outlet velocity curves at standstill are not very different from those shown in Fig. 23. As belt the two curves are much alike, the ordinates being a little higher for the curve with two vents closed. It is substantially the same. This is indicated in Fig. 29, when the first two vents were closed, the distribution for that arrangement, as well as for all vents open, being shown. The other curve, for the first five vents closed, is for a slightly larger gap than the other two; therefore, the discharge volumes per vent should be a little larger. It is close enough to the other two curves to verify the previous reasoning. It is difficult to explain why the outlet volumes with the larger gap are apparently lower than with the smaller gap in the two other discharge belts. There was a lapse of several months between the times at

which they were taken, and the anemometer probably changed slightly in the interim. If that is correct, the volumes for the larger gap, in the first belt, should be higher.

The curves shown in Fig. 30 are also for standstill conditions. The only difference between the conditions under which the two sets of curves were taken were that in one all vents were open, and in the other two intermediate discharge vents were closed. The measured

volumes were substantially the same. In the first was previously explained, the shortening of the first discharge belt a, (effected by closing some of the vents), simply cuts off the first part of the curve, the remainder believed that whatever losses there were in the gap were less from vent 4 to vent 7, when vents 5 and 6 were closed, than when all were open; the reason therefor being that the slowing down was more gradual, like in a duct whose sides diverged more gradually. That the velocities in the first ducts adjacent to the end bell should have been so nearly alike for the two conditions, follows at once from the fact that the volumes were nearly equal.

In Fig. 31 three sets of curves are plotted: Two at

standstill, for the same conditions, but taken five months apart, and illustrate that, even though the anemometer readings were somewhat inaccurate, for the most part, the results were dependable. The volumes, too, are almost the same. The general shapes of the curves are sinusoidal. The third curve is for the same conditions except that the rotor was driven at 3600 rev. per min. The distribution is then changed, the discharge volumes are slightly more uniformly distributed than at standstill. There is an appreciable departure from a cosine wave.

In the previous curves, air entered the air gap from the stator intakes and from the end bell. In Fig. 32 air entered from the rotor also. At standstill the curves are much the same shape as previously, and at 3600 rev. per min. there is again more uniformity.

There are several ways whereby the volumes in the first vents adjacent to the end bell can be raised. One way is to shorten the belt axially, the results of which are shown in Fig. 29. Two other ways are illustrated in this paper. For the curves shown in Fig. 33, a ring was shrunk on the rotor, located between the fourth and fifth vents. This ring acted as an effective barrier,

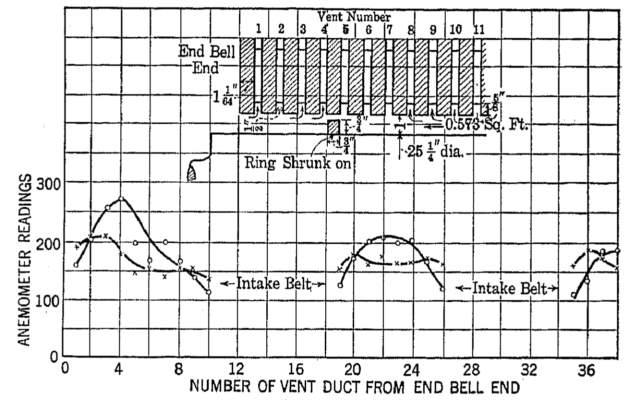

Fig. 33

Turbo Model No. 2. Volume distribution curves. Stator + air gap open, with shrunk-on rotor. Edges at entrance packages sharp. Spaces above blocks imitating coils in vents filled for entire length axially. Making inner bore of stator smooth. Gap area = 0.573 sq. ft. Tests made at a pressure of 3.3 in. of water.

⊙ = Rotor rev. per min. = 0. Total measured vol. = 13,500 cu. ft. per min.

x = Rotor rev. per min. = 3600. Total measured vol. = 11,600 cu. ft. per min.

whereby the balance point was defined. At standstill, as well as at 3600 rev. per min., the volumes in the first vents in the first belts are then a little higher than in the first vents in the middle discharge belt. In the first belt, at 3600 rev. per min. the volume distribution is not so very far from uniform. Tests were also made at standstill with a ring that could be moved to various

axial positions, and it was found that the balance point could be controlled as desired.

The other method which is shown in this paper for raising the velocities in the first vents, consists in increasing the air gap at one or more of the packages of laminations adjacent to the end bell. The sketch in Fig. 35 shows the manner of application to the turbo model: The increase in gap reduces the gap velocity at the first and second vents, thereby raising the static pressure, and consequently, the discharge velocity. The influence of high velocities due to a vena contracta are also reduced. These tests were made with a larger gap than the previous ones, and in order to show the gain, the data for the same gap, but without the first packages cut back are plotted in Fig. 34. While the volumes in the first vents in the first belt (Fig. 35) are slightly less than in the first vents in the middle belt, they are representative of velocities that are sufficiently high to

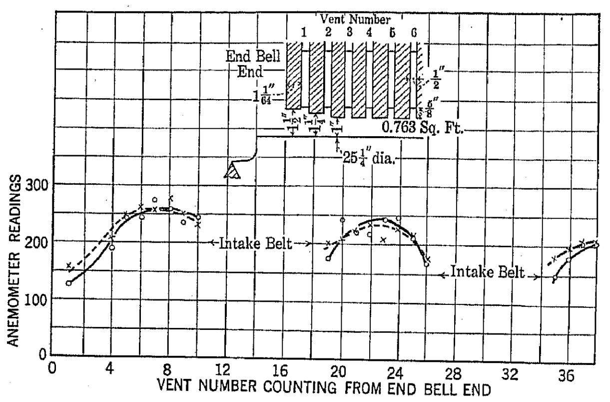

Fig. 35

Turbo Model No. 2. Volume distribution curves with first packages cut back. 0.763 sq. ft. area in gap. Taken at a pressure of 3.3 in. of water in end bell.

⊙ = Turbo rotor rev. per min. = 0
x = " " " " = 3600

" " = 14,000 cu. ft. per min. at 3600 rev. per min.
Stator + air gap.

avoid undue heating. That point will be discussed subsequently.

One interesting point, to be noted from an inspection of Figs. 34 and 35, is that the distribution of volumes at 3600 rev. per min. approaches cosine wave shape, as at standstill. There seems to be no doubt but that the formulas in Mr. Bratt's paper are of considerable assistance, even at normal speed, when the air-gap size is slightly enlarged above that originally used. The influence of the external whirl, which travels circumferentially with the rotor, becomes less the larger the gap, because more radial depth is left for the nominal axial flow in which the influence of rotation is small.

It is of interest to compare the test results on the model with those of actual machine. In Fig. 36, are curves taken in a turbo provided with internal centrifugal fans. A special device used for taking these curves is illustrated in Fig. 37. It consisted of two brass tubes, one within the other between which there was absolutely no leakage. The outer tube was connected to a pump, such as is used for inflating automobile tires, and a suitable gage showed the pressure. The inner tube connected with a U-tube manometer. A small toy balloon was fastened by cords and it could be inflated by means of the pump. The device was pushed into a vent duct from the rear, and into the space between a vent finger and a coil side, when the balloon was not inflated. The pressure was then applied by means of the pump, and the balloon swelled enough to stop any flow through that duct, the

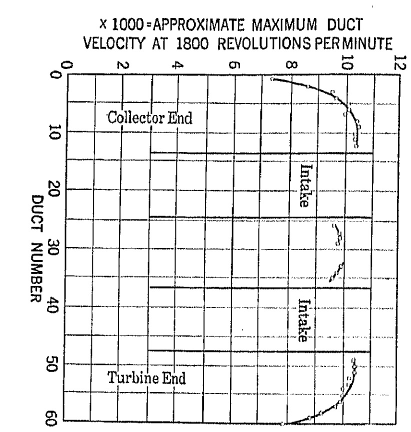

Fig. 36

Air velocities at minimum tooth sections in outlet vents in 25,000 kv-a. 1800 rev. per min., 60 cycles; turbo alternator.

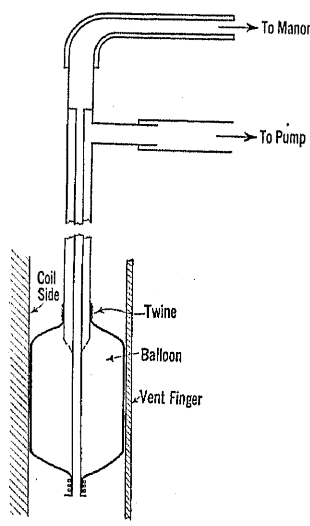

Fig. 37

gage indicating the pressure. (The value of pressure needed had been previously determined when the rotor was not in place). Then the manometer was read. As there was no flow of air, the manometer read the static pressure in the gap at that location, and the square root of that static pressure was taken to be proportional to the velocity in the vent duct when the device was absent. Observations were taken in three positions circumferentially for a given axial position, and averaged. There was usually but little difference between the three readings. The total volume was

determined from the losses and air temperature rise. From a comparison of the mean of the square roots with the mean velocity determined from the volume per vent divided by the vent area, the device was calibrated in terms of velocity.

It is, indeed, interesting to note the agreement in shapes of curves in Fig. 36 with those of the model in which the first discharge was shortened—for example, with Fig. 29. In the case of this alternator it seems that the air gap was sufficiently large to permit of minor influence due to rotation, the curves being similar in shape to those obtainable at standstill.

Other tests were made on this turbo alternator. With the field excited, and after conditions were steady, thermo-couples attached to fiber rods were pushed into vent ducts, for measuring temperatures at various depths radially and positions axially. One device was for air temperatures and the other for iron temperatures.[16] Both devices showed lower temperatures at the first vents next to the end bell, than farther on, even though the volumes through the first vents were lower. There were no stator coils in this machine while the tests were made, but instead wood occupied the same spaces which the coils ordinarily do. These wood fillers did not extend into the end bells as coils usually do; therefore, in the complete machine, the excellent thermal conductivity of the copper, taken in conjunction with the high rate at which heat is "picked up" from the surfaces of the coil ends, reduces the temperature of the machine near the ends still more.

It is believed that the lowered velocities in ducts near the ends deserves further comment. Machines like the one for which approximate volume distribution curves are shown in Fig. 27, have been built, and have been in service for about fifteen years. Those machines are 65 inches long, they have low velocities in the end vents, but they have given no trouble from heating due thereto. Undoubtedly, the longitudinal flow in the copper to the end windings has eliminated danger from that source. The ideal distribution is that which gives uniform temperatures, and is secured by velocities in the first ducts lower than in others. By proper selection of the lengths of the intake and outlet belts, with perhaps one of the several devices added by means of which the first vent volumes are increased, this condition may be approximately attained.

Some of the deductions for model II type of ventilation may be summarized. Most of these have been elaborated upon in the foregoing and require no further comment.

A. The total volumes are affected but little by the angular velocity; the decrease in any case is very much smaller than for model I type of ventilation. For air pressures of the order that are now used in large machines, without air fed through the rotor vents, the decrease is negligible.

16. These devices are described in paper by Symons and Walker. "Heat Paths in Electrical Machinery." I.E.E., 1912.

B. When air is fed through the rotor vents in addition to the air gap and stator, there may actually be a slight increase in total volume above the value at standstill.

C. With large air gaps, the decrease in volume due to rotation is practically negligible.

D. The volume of air passing through the rotor vents is generally affected more by the speed of the rotor than by external pressure. In the model, the external pressure might have been zero, with the rotor running at 3600 rev. per minute, without affecting the volume much. This is important in connection with the cooling of the rotor.

E. As ordinarily built, the volume of air which passes through the rotor has little influence upon the total volume.

F. The axial distribution of volumes in the discharge belts approach cosine curves, with minimum values at the ends of the belts. The corresponding velocities in the air gap approach sine curves, whose zero values correspond to the maximum on the cosine curves. In the intakes the curves are approximately hyperbolic; for radial flow the maximum values at the ends of the belts, and for the gap flow, the zero values correspond to the minimum values on the radial flow curves.

G. The radial velocities are proportional to the derivations of the gap velocities.

H. The discharge vent velocities decrease as the gap velocities increase; the intake vent velocities increase with the gap velocities.

I. It is possible for the flow through one or more discharge vents to be inward (negative) near the beginning of a belt of vents.

J. Other things remaining the same, the shorter the belt of discharge vents, the higher are the minimum velocities, until a critical length is reached; after which, over quite a range of belt lengths, the minimum velocities are nearly independent of the length. With low rotational speeds, or with relatively large gaps, there is then a minimum value in the vents near the entrance to the gap, which then increases to a maximum, then a dying down to a nearly uniform discharge rate until the critical point is reached, where the discharge rate increases along the approximate sine curve.

K. The position of the maximum point on the discharge velocity curve can be shifted by various mechanical means, such as a ring in the air gap, or change of entrance conditions to the belt of vents.

L. The distribution of discharge volumes (axially) is modified by the influence of rotation, the tendency being to make the volumes more uniform. The smaller the gap, the greater is that influence.

M. It is desirable to have somewhat lower volumes in the vents adjacent to the end bells than in other vents, in order that more uniform temperatures be secured longitudinally.

N. The total volume in each belt of intake vents

equals the summation of volumes in the adjacent belt of discharge vents up to the "balance points" in those discharge belts.

O. The air entering the air gap direct from the end bell is arithmetically additive to that volume entering the gap from the first intake belt, and flowing toward the same discharge belt. This is quite different than for model I.

Discussion

MULTIPLE SYSTEM OF COOLING LARGE TURBO-GENERATORS (Bratt) and AN EXPERIMENTAL STUDY OF VENTILATION OF TURBO-ALTERNATORS (Fechheimer)

Philadelphia, Pa., February 8, 1924

S. L. Henderson: The papers of Mr. Fechheimer and Mr. Bratt are of primary interest to the designer; particularly to those designers of large machines which require more than the usual air gap entrance for the admission of cooling air. To others, the papers will indicate the amount of research work which is being carried on to enable the manufacturer to build larger and better machines. To the designer the methods for calculating the air circuits may appear complicated and not easy of application. However, when the importance of the proper ventilation system is considered, the designer may well spend considerable time in laying out this part of his design. When it is realized that the construction cannot be changed once the machine is built and that the design of the machine must stand or fall on the ventilation system as laid out, too much time and care cannot be spent in its layout. In the application of the methods put forth in these papers, as in all designs, a first approximation must be made of the relative widths of the different intake and outlet belts and the pressure drops required in the different paths. When once this is done, the designer can readily see how the proportions need to be changed so that the pressures in the various paths will balance up and also so that the proper velocity distributions may be obtained.

The methods have been used in the design of a number of different machines, and Fig. 36 in Mr. Fechheimer's paper shows how the tests on one of these machines came out. The curves of velocity distribution are somewhat flatter than the calculated values; *i. e.*, the velocities in the radial ducts are more uniform than as calculated. In other words, the calculations are on the safe side.

Edgar Knowlton: A number of years ago the company with which I am associated had occasion to build a machine which was ventilated very much the same as described in Mr. Fechheimer's Type 1. We found this was unsatisfactory, and after several years' operation the machine was changed to a type of ventilation where the air entered both ends of the air gap and was discharged radially through the air ducts. This change was of considerable benefit.

When we first began the use of the system of ventilation whereby the air entered both ends of the air gap, it was very satisfactory for the quantities of air and velocities at which the air entered the gap. Later it was found necessary to chamfer the air gaps, and it was rather remarkable that in some cases the quantity of air was nearly proportional to the increase in the area of the entrance to the air gap.

I would like to ask if Mr. Fechheimer found difficulty in closing the air ducts, and if that were the reason why he used the "toy balloon" method? I consider this a very ingenious device.

I would also like to ask if any negative pressures were found in the air ducts alongside of the armature coils?

We have found some cases where zero pressure existed on salient-pole machines with low peripheral speeds, and in one case recently I had occasion to examine a machine which was somewhat unusual, in that it had − ¾-in. pressure on one side and + 1.5 in. on the other side of the armature coil.

G. E. Luke: This problem of cooling large turbo-generators is getting to be a greater one each year. The aim of the designer is not only to produce a more reliable machine but also to design one with a maximum output per pound of material. The great advances made along this line account in part for the fact that the cost of power to the consumer has not increased and in many cases has decreased in spite of the fact that other costs have materially increased.

In the cooling of an electric machine, we are practically limited to the use of air as a medium for the carrying away of the losses. The reasons for the almost universal use of air are due to its unlimited supply, its mobility or the ease with which it can be forced to flow over the ventilating surfaces, and its high insulating qualities. Other mediums such as water and oil have been used, but only in a few special cases.

The cooling of a machine with air involves three important problems: first, the conduction of heat to the ventilating surfaces; second, the transfer of heat from these surfaces to the air; and third, the proper distribution of air over the cooling surfaces. There are many systems of ventilation used and these two papers cover a detailed investigation of two of these systems experimentally and analytically. They particularly deal with the means for determining the air distribution and for evaluating the relative importance of the various factors determining this air flow. You cannot emphasize too greatly the fact that a properly designed machine necessitates a correct distribution of the air over the ventilating surfaces.

The presence of what are called "hot spots" may be due to an improper air distribution. What is attempted by the designer is to ventilate best those parts of the machine which have the greatest loss. In other words, the air velocities over the surfaces should bear an almost direct proportion to the unit watts loss dissipated from these surfaces.

Thus in Fig. 1 with the radial system of ventilation, the highest air velocities are found in the zone of maximum loss, that is, the tooth zone. The amount of heat loss which can be liberated from a given surface for a given surface temperature rise is almost proportional to the average air velocity such as shown by the solid line curve, Fig. 2.

But the limiting temperatures are the maximum copper temperatures found in the embedded copper. The copper loss must be conducted through the insulation (which is also a good heat insulator) to the iron. Here it is added to the iron loss and both losses are conducted through the iron to the ventilating surfaces. Both steps in this conduction of heat must be accompanied by a temperature difference which may be quite large, especially the gradient necessary to cause the copper losses to flow through the insulation. This temperature gradient from the "hot-spot" to the ventilating surface is always present and is proportional to the loss dissipated and cannot be decreased by an improvement in ventilation. If we plot watts loss in the machine for a given temperature rise of the copper, the curve, Fig. 2, changes from a straight line to a curve as shown in dotted line, due to this internal temperature gradient.

The experimental tests made by the authors are especially difficult. They involve the measurements of very small air pressures and velocities in very limited and inaccessible positions. An analytical treatment of the air flow, such as Mr. Bratt has given us, is valuable in that it permits of the possibility of calculating the effects of the various factors. Many difficult points are found in the air flow problem. Thus, in Fig. 1 the air must change in velocity very greatly as it is forced to flow

through the tooth zone where it is obstructed by the windings, the slot wedges and the ventilating fingers. The authors have found that the pressure required to force a given quantity of air through such a passage depends upon the direction of air flow whether radially outward or inward.

R. B. Williamson: The problem of the ventilation of turbo-generators is a complicated one involving as it does, the handling of large volumes of air in a very restricted space. In order to cool a machine of given size, a certain minimum amount of air must be passed and this air must be distributed so that all parts of the stator will be uniformly cooled, or at least the distribution must be such that the hottest parts will be well within the safe limits permissible for the class of insulation used. Furthermore, this volume of air must be circulated with moderate end-bell pressures such as can be readily developed by centrifugal fans mounted at each end of the rotor.

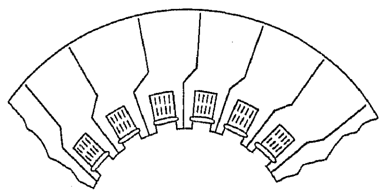

Fig. 1

In general, two methods have been used for distributing the air; these may be termed the axial method and the radial method. In the axial method the air passes axially (parallel to the shaft) from each end bell through the air gap and through longitudinal flues or ducts in the punchings back of the teeth and discharges in the center part of the stator. While this method is satisfactory for relatively short machines, it gives rise to a hot region in the central part of long stators for the reason that the air as it passes longitudinally through the stator becomes heated as it progresses towards the centre, and the air for cooling the central part is hot by the time it reaches these parts. In the radial system, as its name implies, the ducts are radial or annular, the core being sub-divided by a relatively large number of ducts as indicated in Figs. 1 and 2 of the paper. The laminations are thus sub-divided into a number of sections

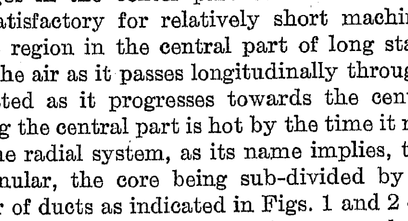

Fig. 2

of small axial width, usually not over 1½ to 2 inches as measured parallel to the shaft. The present paper describes tests of air flow in the different types of radial ventilation referred to as Method I and Method II, both of which provide a number of relatively short paths in parallel for the flow of air after it leaves the end bells. The sub-division of the flow into a number of parallel paths cuts down the distance that the air has to travel from the time it enters the machine until it leaves it, thus permitting the use of moderate air pressure. Again, if the paths are suitably arranged, and the vent spaces in the ducts properly designed, very even cooling can be obtained. As far as my personal experience is concerned, it has had to do almost entirely with Method I which has been used successfully for the past 14 years with machines ranging in size from 1500 kv-a. to 27,000 kv-a. and with stator cores up to 10 ft. in length. The original method provided only two paths at each end of the machine, but about 1910 we began constructing machines with 6 paths at each end somewhat similar to that shown in Fig. 2, except that the vent segments were arranged to by-pass part of the air back of the teeth by making the vent ribs in suitable curved form. In the more recent large machines there are 12 paths at each end of the machine, which with a 72-slot punching gives three teeth opposite each inlet and three opposite the corresponding outlet.

To my mind, the outstanding advantage of the radial system of ventilation lies not so much in the particular arrangement of the parts, but in the fact that with either Method I or II it is possible to introduce cool air directly into the central part of the machine and thus cool this part almost as effectively as the end portions. In fact, tests show that with Method I suitably applied, the air discharged from the centre ducts is no hotter than that discharged from the ends. Further, we have not yet reached any limit to the length of the machine that can be ventilated by this method so far as stator ventilation is concerned. Mechanical features may limit the length and it might also develop that external fans would be needed in some cases, but so far as getting the air through the stator is concerned, I believe, satisfactory ventilation can be secured with the largest stators and by the use of either of the methods described.

After all, the real test of any given method of ventilation is the temperature rise in the centre of the machine as indicated by temperature detectors in the slots and with a sufficient number of such detectors to give indications all around the circumference. Recent tests on large units with ventilation as per Method I, using 12 paths, show that the temperatures are uniform and that there is no difficulty in building large machines with this system of ventilation that will show a temperature rise as indicated by detectors well within 60 deg. cent. The real limitation of large units thus becomes one of rotor rather than stator heating, but the low stator temperature rise possible with the radial system is a distinct advantage, as it reduces the chances of trouble due to expansion and contraction.

An incidental advantage of Method I is that it can be worked out so as to give a very simple and compact construction of the stator yoke. However, this has no bearing on the method itself which our experience indicates gives very uniform cooling with low end-bell pressures.

C. M. Laffoon: I desire to say a few words on the general subject of ventilation for large capacity turbo-generators. At the present time one or two of the larger electrical manufacturing companies are building 12,500-kv-a., 3600-rev. per min. and 43,750-kv-a., 1800-rev. per min. turbo generators for 60-cycle operation.

There is no doubt but that the trend in generator sizes is decidedly upward, on account of the fact that central stations are rapidly increasing in size, and there is a consequent demand for greater generator output per unit of floor space.

In addition to this, the operating companies and purchasers of large capacity units are demanding machines with low temperature guarantees, in the neighborhood of 80 deg. or less, in some cases 60 deg., depending upon the type and quality of the insulation used on the electrical conductors.

It is obvious from these facts that the question of the proper choice of a ventilating system and the predetermination of the temperature rises for any chosen turbo system are of vital importance to both designing and operating engineers. As has been suggested several times this morning, the system of ventilation which should be used is the one in which a permissible amount of cooling air can carry away the generator losses with a minimum and fairly uniform temperature rise throughout the entire machine, provided, that this system of ventilation is not so complicated as to handicap the cost of the machine, and that some efficient, reliable and stable means can be obtained for delivering the air to the different parts of the generator.

Regardless of the type of ventilation that is used, it becomes necessary in large capacity turbo-generators, to resort to the multiple path system. That is, the air must be delivered to

machine at several different axial positions, in order to make a machine economical from the standpoint of cost and to assure a reasonably uniform temperature distribution. Some form of the radial systems that have been discussed here this morning is particularly applicable to machines with low temperature guarantees, because, as has been said before, large volumes of cool air or other cooling medium can be introduced into the machine in the tooth zone where the combined loss per unit volume is inherently high.

As you know, the American practise has always been, in large generators, both water-wheel and high-speed and 25-cycle turbo-generators, to use the radial system of ventilation. The radial system of ventilation is becoming quite generally used by all of the manufacturing companies in this country in order to obtain the lower temperature guarantees. With the radial ventilating system, the air can be presented to the paths at varying pressures, or can be taken into the end bell at constant pressure, if the paths are so designed and proportioned that the air will properly distribute through the machine and give fairly uniform temperatures. However, in either case the problem of actually designing the pressure-generating system for the air or the proportioning of the air paths and the number of passages that are provided, has been very difficult on account of the complexity of the problem and the lack of information available on the subject. The two papers by Messrs. Bratt and Fechheimer mark a definite advance in the published information on the subject of ventilation, and the experimental data obtained from models, as well as from turbo-generators as actually built, should greatly aid and facilitate the solution of this design problem.

It is true that machines using the radial system of ventilation have been built in the past by all of the companies in this country without the aid of this particular information. However, there is no question but that by the use of these data which have been presented here and the mathematical analysis, more comprehensive and more intelligent designs should be made with less trial. The formulas and data as given in these papers are not simplified so that they can be readily used by designing engineers. However, they can be so simplified, so arranged and modified, that they should prove a source of valuable use to engineers who are responsible for the design of large turbo-generators.

F. D. Newbury: Mr. Williamson referred to his successful use of the circumferential system of ventilation. As I was very careful to point out in presenting the paper, the system of Model I is not exactly the same as the system actually used in practise, and furthermore, I wish to emphasize that our tests have no necessary relation whatever to temperature results. We simply attacked one part of the ventilation problem, and if our results have any value, they are valuable in showing relative performances of these two systems, and what may be expected in limiting cases.

Mr. Williamson also referred to the axial system of ventilation. That is a system that was, and has been, and is being very extensively used. It has been used very successfully, but it has the limitation that Mr. Williamson pointed out: that with very long machines, the length of the path through the machine is such that the rise in air temperature may become a serious disadvantage. So, in comparing the results from the first model and the second model, we only wish to draw the conclusion that Model II, representing the multiple radial system, seems to have advantages over the circumferential system of Model I, principally in a more uniform distribution of air, circumferentially, and a substantially uniform distribution of air axially, and, in fact, a very much better distribution of air axially than in the simple radial system, which is in such extensive use.

Mr. Knowlton referred to an experience of his own in connection with a very considerable increase in total volume of air when the entrance at the air gap was increased by cutting back several of the first packages. If you will refer to Figs. 34 and 35, I believe, of Mr. Fechheimer's paper, you will notice that although the air entrance was increased from one inch in Fig. 34, to one and one-half inches in Fig. 35, the total volumes are substantially equal. That illustrates, I think, the real value of these papers—that by confining the work to a particular phase of the problem, confining it to the measurement of pressures and volumes, under various conditions, and not complicating it with temperature results or loss results, we can definitely say that such and such a thing will happen when such changes are made in the ventilating circuit.

Mr. Knowlton also referred to the device illustrated on next to the last page of the paper, which he referred to as the "toy balloon." That, I think, is a very ingenious experimental device—I can say that because I had nothing to do with it—and it was used, as Mr. Knowlton suggested, in order to completely close up the ventilation duct and thereby enable the pressure to be measured without any velocity head being present.

Mr. Henderson referred to the actual use of the results from this work in practise. I think the first impression from these papers is that the numerical calculation work is complicated. Even if that is so, the results obtained from the application of Mr. Bratt's formulas are exceedingly valuable and the work involved is well worth while. Since the results have been available within the last 12 months, the work has been applied to some million kv-a. in turbo-generators, but in that large volume only seven different sizes have been involved; so you can well afford to spend considerable time and work in properly proportioning the ventilation system of a design, when it does involve so much in the way of risk and money and is of such importance in the results to be obtained from the design.

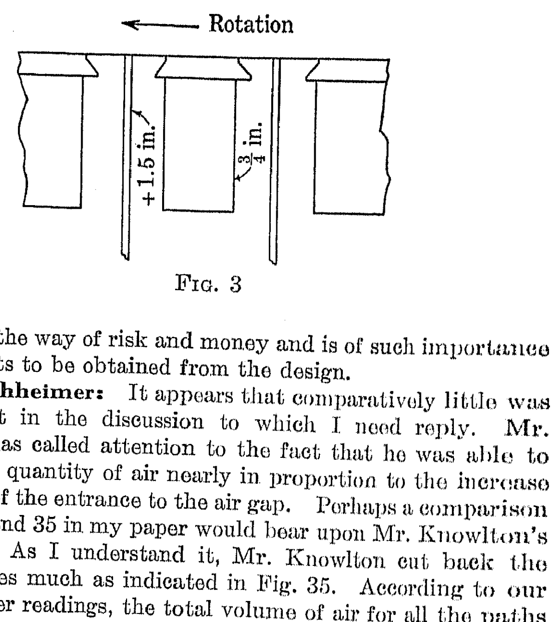

Fig. 3

C. J. Fechheimer: It appears that comparatively little was brought out in the discussion to which I need reply. Mr. Knowlton has called attention to the fact that he was able to increase the quantity of air nearly in proportion to the increase in the area of the entrance to the air gap. Perhaps a comparison of Figs. 34 and 35 in my paper would bear upon Mr. Knowlton's experience. As I understand it, Mr. Knowlton cut back the first packages much as indicated in Fig. 35. According to our volume-meter readings, the total volume of air for all the paths was not changed a great deal, but the distribution of air, particularly for the vent ducts near the end bell, was modified very materially. Undoubtedly, had we been feeding this first section only, the volume-meter would have indicated a considerable increase when the first packages were cut back. The loss at entrance to the air gap expressed as a percentage of velocity head has lowered appreciably by the gradual reduction in section of the air gap. This would be evident to any one who is familiar with a bell-mouth entrance to a duct, which this condition approaches. The fact that the volume-meter did not show more of an increase was in part due to the fact that only a fraction of the total volume of air entered the air gap direct from the end bell, and to some errors in observation. A rather cursory examination of the average values of anemometer readings for Figs. 34 and 35 would not show very great differences.

Mr. Knowlton also mentions that he measured minus $\frac{3}{4}$ in. pressure on one side of the coil and plus 1.5 in. on the other side of the armature coil in a salient pole alternator. I have

obtained from Mr. Knowlton a sketch showing positions in which the readings were taken, and this sketch I am reproducing herewith. There are undoubtedly so many things that enter into measurements of this kind that may mislead one, that it is impossible for me to offer a complete explanation. I can only suggest reasons for the difference. The air leaves the rotor at a slight angle with the periphery, and on the right-hand side of the coil it impinges on the slot wedge so as to destroy nearly all of the velocity head. What air then passes into the vent duct moves past the sharp edge of the wedge beyond which there is a "vena contracta," accompanying which there is usually a considerable reduction in pressure. If the pressure tube had been placed near this "vena contracta," it is easy to understand that the reading would be negative. On the other side of the coil, the volume of air flowing is probably more because all of the velocity head of the air as it leaves the rotor is not destroyed, and it is possible that the pressure tube was placed in such a position that the air impinged upon its opening. Consequently, the reading on the manometer would have been the static pressure plus the velocity head or a fraction thereof.

Of course, on this side, as on the other, there may have been a contraction in section beyond the edge of the wedge, but if the pressure tube were placed, say near the narrow section where the velocity head was greatest, and just before the "vena contracta," it is easy to understand why the reading was + 1.5. I might offer a number of other explanations, but this much is certain—that readings of this character are liable to be very misleading, and considerably in error. That was why we used the "toy balloon" method. The mouth of the brass tube which connected with the manometer was about 3 in. from the air gap, and we felt quite confident that disturbances due to velocity would have negligible influence. Even so, we found discrepancies when the tube was placed on the side of the coil, corresponding to the side where Mr. Knowlton obtained − ¾ in. Our final readings were taken on the other side of the coil, and apparently then we were in a region which was quiet. I believe the picture of what takes place is clarified somewhat by thinking of the moving air streams at very high velocities—as though they were water—and imagining them to splash up into the duct as a result of disturbances in the high velocity stream.

The whole subject of ventilation or air flow is an extremely complex one. It is believed that the work which has been done up to date is only a small part of what may be done, and we hope that others interested in the problem will contribute papers from time to time before technical societies, which will assist the engineering public in solving some of our difficult problems.

Donald Bratt: There is one question that Mr. Knowlton brought up. He spoke of an instance in which he had noticed, in a radial type of flow, that some of the velocities in the extreme end came out negative; that is, the air was actually traveling the other way to what was intended. That is, in fact, the result that we very often find in the flow of air and flow of water in pipes. Sometimes, where a cross-section area changes considerably from a large to a small value, there will be a contraction in section of the jet of water or air, and a very low static pressure. The same thing may actually happen in a radial ventilation system. We have observed in Model II, in many instances, that the flow actually was reversed.

I have not, of course, been able to take care of that sort of condition in my mathematical analysis. It isn't of much importance anyway.

Brush Mounting as a Factor of Satisfactory Operation

BY PHILIP CHAPIN JONES

Member, A. I. E. E.

Electrical Engineer, Goodyear Tire & Rubber Co., Akron, O.

Review of the Subject.—*That the brush is an ever present source of trouble on rotating electrical machinery is evidenced by the back numbers of our technical periodicals which are replete with innumerable articles on the subject. These articles cover practically all problems of material and application excepting that of the geometrical design. It is this phase of the subject that the following paper attempts to give.*

Undoubtedly these factors of geometrical design are known as they are readily discovered, their relations are relatively simple, but so far as I have been able to find they have not been published.

The facts brought out by the following paper are: First, that the upper angle of the brush is a function of the lower angle and the coefficient of friction between the brush and the commutator, second, that the lower angle is a function of the pressure desired against the holder, and third, that the trailing brush has little to justify its use. These three conclusions are based on a design which eliminates a resultant moment acting on the brush which would tend to make it bind in the holder.

* * * * *

IF the electrical engineer responsible for the maintenance of rotating electrical machinery is of an inquiring turn of mind he will sooner or later confront the question of brush design. The brush is one of those things which, in itself of minor importance, can so often be the seat of serious trouble. The selection of the proper brush is dependent on two groups of factors, brush quality and brush design. Relating to quality, there is quite a mass of available information, largely in the publications of the various brush manufacturers. Density, hardness, conductivity, and coefficient of friction are tabulated for all the different grades and with the help of suggestions from the manufacturers proper selection is not difficult. In regard to the design of the brush and its position relative to the holder and commutator there is very little information extant that I have been able to find. It is in an effort to relieve this situation that the following brief outline of the essentials of brush design is written.

The function of the brush is to conduct current between a stationary lead and the moving commutator. The resistance of the contact between brush and commutator is proportional to the pressure perpendicular to the plane of contact. The amount of heating at the contact and the amount of current per unit area of contact that the brush can safely carry are proportional to this resistance and therefore the foremost problem of brush design is to keep the correct pressure on the contact surface at all times.

There are, in general, four forces acting on the brush: First, the longitudinal pressure of the brush spring; second, the reaction pressure of the commutator; third, the force of friction on the commutator which tends to move the brush parallel to its plane of contact; and fourth, the resulting side pressure of the brush holder. (Although the weight of the brush itself acts in different directions depending on the relative position of the brush on the commutator, it is neglected because in general it is small in comparison to the other forces acting.) These four forces are shown diagrammatically in Fig. 1. The forces shown are the resultant forces acting on the center of the various brush faces. P is the contact force with which we are primarily concerned, and T is the inwardly acting force of the brush spring—the only force that can be varied at will. The force of the holder against the brush is shown as H. It might, of course, be on either side of the brush. F is the force of friction and is equal to the coefficient of friction (f) of the brush on the commutator, multiplied by the contact force P. $(F = f\,P)$. Since the coefficient (f) is given for various grades of brushes, the total force F can be eliminated as an unknown quantity, leaving only the other three forces, T, H and P, to be dealt with.

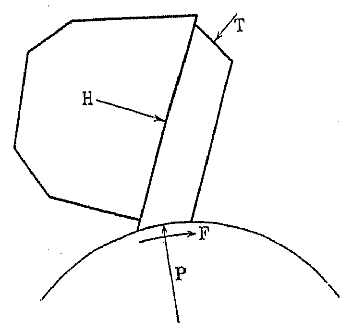

FIG. 1

Fig. 2 again shows the brush of Fig. 1 with the addition of all the critical angles marked as well as the forces. There are only three primary, independent angles — ψ, α and β. Thus, the problem of brush design is to select the values for these three angles which will most effectively keep the contact force P at the desired value under all conditions.

The main obstacle with which we have to contend is friction between the brush and the brush holder which prevents free movement of the brush and thus causes variations in the contact force P. The brush is constantly wearing along the surface of contact and in order that the contact force P may be constant, the brush must be able to move freely outward as well as inward, so that it may follow any irregularities in the

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

commutator. The forces preventing a free movement in the inward and outward direction perpendicular to the line H are friction against the brush holder, which is proportional to the side thrust H, and a possible binding of the brush in the holder when the resultant force H does not act at the center of the holder as shown, but above or below this point. This tends to cause the holder to cut into the brush at the bottom or top and thus lock it in one position.

To progress one step further, it becomes evident that

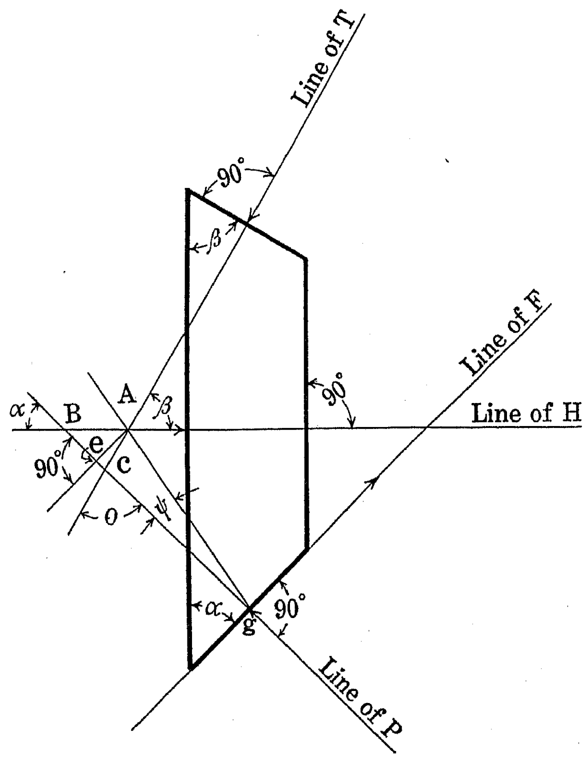

FIG. 2

correct brush design will consist in so selecting the three fundamental angles that the side thrust H not only acts at the center of the holder, to prevent binding, but is as small in absolute value as can safely be obtained with the object of minimizing the friction to radial motion.

An analysis of these forces and angles—given in the appendix—brings out the fact that there is only one independent variable, the lower brush angle α. For any value of α, the upper brush angle β, in order to prevent binding of the brush in the holder, must have a definite corresponding value represented by the expression $\beta = \alpha + \tan^{-1} f$.

Observing this requirement and keeping the contact pressure, P, constant at the desired value, the side thrust H varies as a complex function of α. The pressure of the brush spring, T, need not be changed in order to maintain the contact pressure (P) constant as α varies. (See Fig. 5)

To minimize friction of the brush against the holder it is desirable to hold the side thrust as small as possible. With a trailing brush this side thrust can never be less than ½ the contact pressure so that unless a condition exists that makes this relatively large side thrust necessary there is little excuse for the use of the trailing brush. Our natural tendency is to use the trailing position. We know, if we pushed a stick along the sidewalk ahead of us it would catch, chatter, and altogether behave unmanageably, while if we trailed it, all would be well. In the case of the brush and commutator we are dealing with as nearly perfectly smooth surfaces as can be obtained so that the cases are not at all parallel. As is quite often the case our first impression is in error. Mathematical analysis reveals the true situation and unmistakably endorses the leading brush.

The ideal condition would be to make the side thrust zero. This would require a box-type holder with the brush run in the leading position. The lower brush angle would then have to be about 75 deg. and the upper brush angle 90 deg. For reversing motors—running as much in one direction as in the other—ideal conditions can never be attained and some compromise must be accepted.

Appendix

To arrive at the correct relations between the various forces and angles connected with the brush it is best to treat it as a problem in statics and to take moments of the forces acting around the intersection of T and H. Calling the arm of the force P equal to L_p and that of F, L_f gives the following: $P \times L_p = F \times L_f$ and as $F = f P$ then, $P \times L_p = f P \times L_f$ or $f = L_p/L_f$. It is evident that $L_p/L_f = \tan \psi$ whence it follows that,

$$f = \tan \psi \tag{1}$$

The relation just indicated $f = \tan \psi$ must hold not only when the brush is new but also as it wears down to

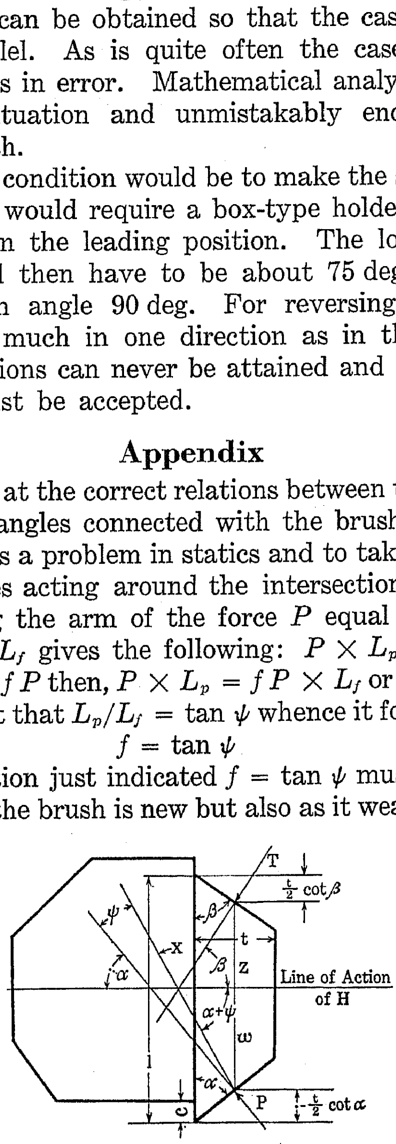

FIG. 3

its shortest length. To bring this about the intersection of the lines of action of T and H must always be on the line X which is one side of the angle ψ, and H must always be half way between the top of the brush and the bottom of the holder. With these requirements in mind it develops that, referring to Fig. 3

$$w \cot (\alpha + \psi) = z \cot \beta$$

where $w = [(1 - c)/2 + c] - (t \cot \alpha)/2 = 1/2\,(1 + c - t \cot \alpha)$

and $z = (1 - c)/2 - (t \cot \beta)/2 = 1/2\,(1 - c - t \cot \beta)$

Substituting these values of w and z in the above equation gives:

$$\cot(\alpha + \psi) = \frac{l - c - t\cot\beta}{l + c - t\cot\alpha}\cot\beta \qquad (2)$$

Now c can be made any value desired as part of the brush holder design. It should of course be quite small. If c is made of such a value that

$$\cot\beta = \cot(\alpha + \psi) \qquad (3)$$

then $1 - c - t\cot\beta = 1 + c - t\cot\alpha$

and $c = (t\cot\alpha - t\cot\beta)/2 = t/2\,(\cot\alpha - \cot\beta)$

$= t/2\,[\cot\alpha - \cot(\alpha + \psi)]$

An idea of the magnitude of c thus obtained may be had by taking $\alpha = 60$ deg. and $\psi = 15$ deg. and $t = 1/2''$ which gives $c = 1/4\,(0.577 - 0.268) = 0.077$ inch.

The great advantage of taking c of this value is that it gives the very simple relation between α, β and ψ of

$$\beta = \alpha + \psi \qquad (4)$$

This enormously simplifies the problem. The value of ψ is known as it is $\tan^{-1} f$. Thus the only angle to be determined is α whence β will follow from equation (4).

The effect of changing α is to change the relative values of H, T and P. The best method of determining the most satisfactory value of α then is to plot the relations between these quantities against α. As P is the pressure that directly affects the problem, it will be best to plot the two ratios of H/P and T/P against values of α.

To obtain these values advantage is taken of the fact that as the brush is stationary the resultant of all forces acting on it is zero. Resolving all forces into tangential and radial components and equating each group to zero gives, for radial forces (parallel to P)

$$P - H\cos\alpha - T\cos\odot = 0$$

where $\quad \odot = 180 - (\alpha + \beta) \qquad (5)$

and for tangential forces (parallel to F)

$$F = H\sin\alpha - T\sin\odot = 0 \qquad (6)$$

From (5), $\quad H = (P - T\cos\odot)/\cos\alpha$ and from (6)

$$H = (T\sin\odot - fP)/\sin\alpha$$

and equating these two values of H gives

$$(P - T\cos\odot)\tan\alpha = T\sin\odot - fP$$

whence may be deduced

$$T/P = (\tan\alpha + f)/(\sin\odot + \cos\odot\tan\alpha) \qquad (7)$$

Returning to equations (5) and (6) and solving for T and equating as was done for H gives:

$$H/P = (\tan\odot - f)/(\sin\alpha + \cos\alpha\tan\odot)$$

These values, it will be evident from a glance at Fig. 2, were obtained by considering a brush running in the leading position, *i. e.* with the direction of the commutator motion such as to tend to push the brush away from the holder. Before plotting these values, therefore, it will be well to examine the brush in the trailing position (commutator motion tending to force the brush against the holder) as shown in Fig. 4.

It will at once be evident that the same relation between f and ψ holds here as it does for leading brushes,

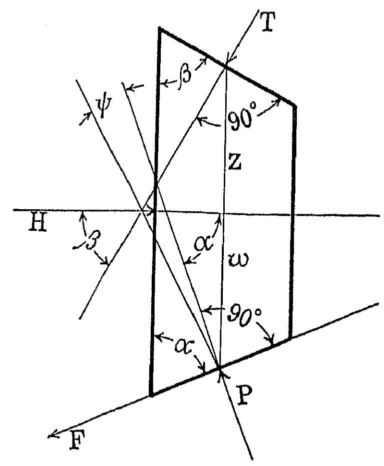

Fig. 4

i. e., $\tan\psi = f$. Here, however, ψ is on the opposite side of P. Thus ψ is always on the side of P toward the direction of F. In order, however, to use the same value for c as before we must have the relation cot

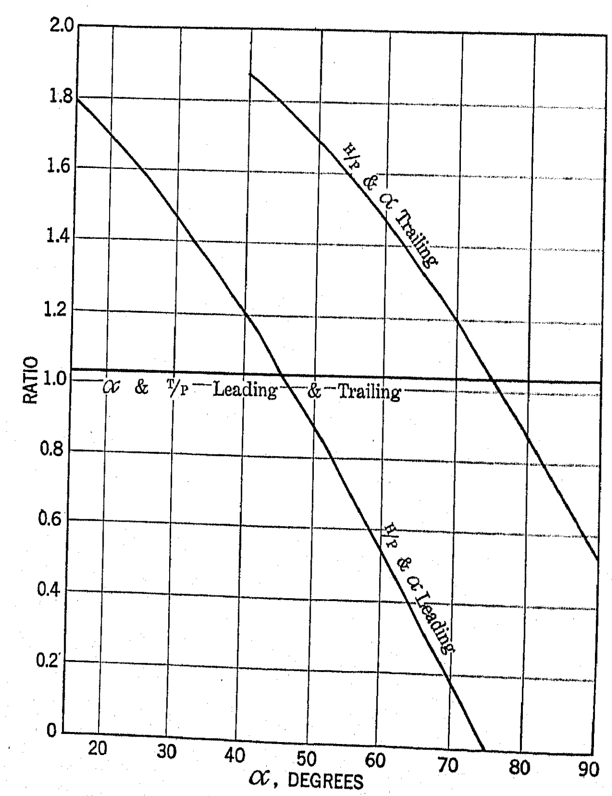

Fig. 5—Brush Data
$f = 0.268$

$(\alpha - \psi)$ equals $\cot\beta$ or $\alpha - \psi = \beta$. This is exactly the same equation as (4) with ψ taken as a negative angle. This relation will be found to hold throughout. All equations for leading brushes will hold for trailing

brushes if $-\psi$ is substituted for $+\psi$. As the tangent of a negative angle is negative f will also have to be considered as negative as $f = \tan \psi$.

This gives the two fundamental equations for trailing brushes as:

$$T/P = (\tan \alpha - f)/(\sin \odot + \cos \odot \tan \alpha) \qquad (9)$$

$$H/P = (\tan \odot + f)/(\sin \alpha + \cos \alpha \tan \odot) \qquad (10)$$

In making a plot some value of f will have to be assumed. The entire range of the coefficient of friction for different grades of brushes runs from perhaps 0.14 to possibly as high as 0.40. An average value would be in the neighborhood of 0.268 which gives 15 deg. as the value of ψ. For this value of f the curves of H/P and T/P are shown in Fig. 5. Inasmuch as no great accuracy of adjustment can be maintained in brush settings the curves shown are sufficiently accurate for all ordinary values of f.

Discussion

R. F. Franklin: I wish to discuss two points concerning Mr. Jones' paper. One is the criterion of zero box pressure; the other, the mathematical analysis of the brush forces.

The condition of zero box pressure which Mr. Jones strives to obtain, will not give satisfactory operation in practise since the slight variations of commutator friction for different points on the commutator will cause the brush to move back and forth in the box and chatter. Practical operation requires a brush angle which will insure the brush always bearing against one side of the box. However, the "box reaction" involved in this condition should not be great enough to prevent free axial movement of the brush in the box. The proper brush angle, therefore, is not the one that will give zero box pressure, but the one that will give a box pressure sufficient to hold the brush in contact with the box for all values of commutator friction and yet not so large as to prevent free axial movement of the brush.

Mr. Jones is correct in his assertion that the brush angle for reversible motors must be a compromise between that best suited for leading and trailing operation. For equal box reaction, the "lower brush angle" for the trailing brush is greater than that for the leading brush, because the tangential friction force in the former case adds to, and in the latter subtracts from, the tangential component of the axial force, $T \sin \beta$ (See Fig. 1). A compromise brush angle for reversible operation would, therefore, give increased box reaction for trailing operation and decreased box reaction for leading operation. If the friction force F becomes greater than the tangential component of $T \sin \beta$, the brush is dragged to the opposite side of the box during leading operation and will acquire what is called a "double fit," *i. e.*, one part of the brush face will be in contact with the commutator for one direction of rotation and another part of the face for opposite rotation. Definite pressure against one side of the box at the top during leading operation can be assured by beveling the top of the brush slightly so that a component of the spring pressure acts against the box.

The other point I wish to discuss is that of the author's analysis of the brush forces. The box reaction cannot be considered as acting at one point near the center of the brush since the contact surface between the brush and the box is a plane. Brushes which have been in service always show wear or polish which indicate that the box reaction is concentrated in a narrow area at the extreme bottom of the box. The method of taking moments, therefore, is incorrect. Instead, the forces acting should be resolved into components acting along and perpendicular to the axis of the brush. Thus the box reaction may be represented by two forces, as shown in the accompanying Fig. 1; force H_1 near the top of the box, due to the spring pressure, and H_2 near the bottom of the box, due to the result of commutator reaction and friction.

The analysis of the forces then becomes very simple. Thus, the expression for the forces acting along the axis of the brush for the case of a leading brush, as shown in Fig. 1, is

$$T \sin \beta = P \sin \alpha + F \cos \alpha \qquad (1)$$

The reaction at the top of the box is

$$H_1 = T \cos \beta \qquad (2)$$

and the reaction at the bottom of the box is,

$$H_2 = P \cos \alpha - F \sin \alpha \qquad (3)$$

Substituting the well-known relation $F = f P$, where f is the coefficient of the friction between brush and commutator, in (1) and (3) the following relations are obtained;

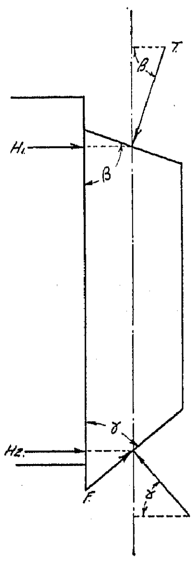

FIG. 1

$$T \sin \beta = P (\sin \alpha + f \cos \alpha) \qquad (4)$$

and

$$H_2 = P (\cos \alpha - f \sin \alpha) \qquad (5)$$

The equations for the trailing brush are obtained by reversing the sign of the friction force. Thus for the trailing brush,

$$T \sin \beta = P (\sin \alpha - f \cos \alpha) \qquad (6)$$

$$H_1 = T \cos \beta \qquad (7)$$

$$H_2 = P (\cos \alpha + f \sin \alpha) \qquad (8)$$

If a square top brush is assumed ($\beta = 90$ deg.) the force equations (2), (4), (5), (6), (7) and (8) can be written in the form,

$$\frac{T}{P} = \sin \alpha \pm f \cos \alpha$$

$$H_1 = 0$$

$$\frac{H_2}{P} = \cos \alpha \mp f \sin \alpha$$

where the upper signs are for the leading brush and the lower signs the trailing brush. These equations are plotted in Fig. 2 for the average value of $f = 0.268$ assumed by Mr. Jones. The curves in this figure should be compared with those of Fig. 5 in the paper.

P. D. Manback: Mr. Jones has presented a very interesting phase of the subject of brush application and one which probably has not been given enough consideration in the past. However, we have made this question the subject of considerable investigation and experiment for some time past. I think the mathematical deductions are very enlightening but may very easily lead one astray when making practical applications of these principles.

It may be true that the weight of the brush need not be taken

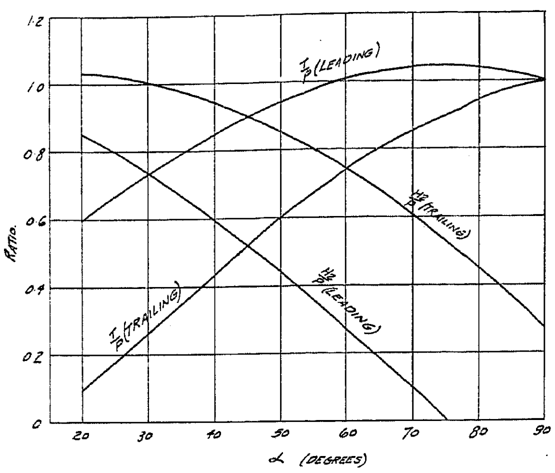

Fig. 2

into account when calculating brush pressure in the case of carbon brushes, but in dealing with metal graphite brushes the weight of the brush is quite considerable and must be taken into account when calculating brush pressure. Also it may be ideal from a theoretical standpoint to operate a brush in a leading position with a commutator bevel of 75 deg. and top angle of 90 deg., but our experience has shown this usually to be bad practise. In the case just cited, the brush is floating in the holder and the side thrust is zero. This means that the force of friction just overcomes the tangential component of the

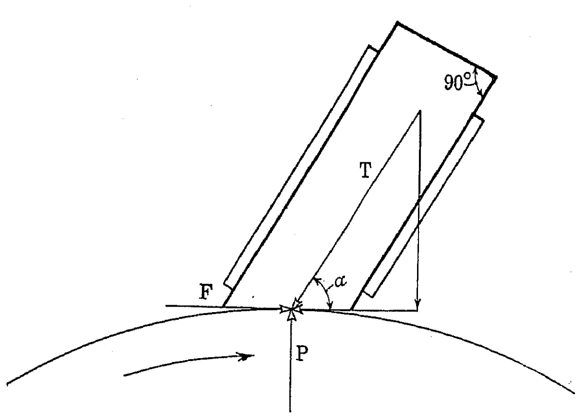

Fig. 3

spring tension. If the frictional force were absolutely constant, the practical case would approach the theoretical very closely, but this is not always true. Some parts of the commutator are not as highly polished as others, so that at one instant the friction may overcome the tangential component of the spring tension, while in the very next instant the friction may be less than the tangential component, thus giving rise to a pronounced brush chatter, harmful to commutator and brushes alike. It has been the object and aim of the brush manufacturer to keep away from this so-called critical angle so as to eliminate the undesirable element of chatter.

It has been found that a very definite relationship exists between the coefficient of friction and this critical angle. This relationship is derived as shown in Fig. 3.

If F, the force of friction, is just equal to the tangential component of the spring tension, then $F = T \cos \alpha$ where T = spring tension. $F = f P = f T \sin \alpha$ then $f T \sin \alpha = T \cos \alpha$ or

$$f = \frac{\cos \alpha}{\sin \alpha} = \cot \alpha$$

Since T, the spring tension, cancels out of the equation, it shows that the relationship holds true regardless of the magnitude of the spring tension, which agrees with practise. If we know the coefficients of friction of various brush grades, this simple relationship enables us to calculate the critical angles which should be avoided for satisfactory operation when the top angle of the brush is 90 deg. It must be taken into account, however, that the coefficient of friction will vary within certain limits, due to irregularities of commutator surfaces.

W. C. Kalb: I might mention that there is one statement in the early part of Mr. Jones' paper which I don't believe conveys quite the meaning he intended, where he says that the resistance of the contact between brush and commutator is proportional to the pressure perpendicular to the plane of contact. He is speaking, as I understand it, of the electrical resistance. Of course, that relationship is inverse.

In his presentation of this subject Mr. Jones has brought out some very interesting factors. It might be said, however, that too much emphasis has been laid on the importance of keeping the resultant force H at an extremely low value and its location central between the top of the brush and the lower edge of the holder. This suggests the approach of this problem from a slightly different point of view and its simplification by the elimination of the angle ψ.

It will be noted that the line of T in Fig. 2 of Mr. Jones' paper meets the line of F at an angle of $\alpha + \beta - 90$. If tangential and radial forces are resolved on the basis of this angle and the angle α, we have

$$P = T \sin (\alpha + \beta - 90) + H \cos \alpha \quad (1)$$

and

$$F = T \cos (\alpha + \beta - 90) - H \sin \alpha \quad (2)$$

or

$$P = H \cos \alpha - T \cos (\alpha + \beta)$$

$$F = T \sin (\alpha + \beta) - H \sin \alpha = P f$$

When

$$H = 0$$

$$f = - \tan (\alpha + \beta)$$

but this would not be a stable brush position, hence $- \tan (\alpha + \beta)$ must be greater f.

This condition must hold at the moment of starting as well as during the running period, otherwise the brushes may be rocked from their position by the high static friction encountered at that instant. The coefficient of static friction may be as high as unity on a brush with normal running friction. So $- \tan (\alpha + \beta)$ should be greater than 1 and $\alpha + \beta$ should therefore be less than 135 deg.

When the machine is running, it is not sufficient that balance of forces maintain the resultant force H slightly above zero. Freedom from chattering is only attained when the component of the force P normal to the side of the holder exceeds the like component of the force F.

That is, we should have

$$P \cos \alpha > P f \sin \alpha$$

or

$$\cot \alpha > f$$

While 0.4 is rather high as a coefficient of friction for a good grade of brush at proper tension, Mr. Jones has shown that it is a figure which may be encountered and therefore the design of the brush holder should be such as to accommodate a brush with this coefficient of friction. $\cot^{-1} 0.404 = 68$ deg., indicating that a larger angle at α is not desirable.

That the limits here suggested are reasonable is supported by the following illustrations from service conditions:

Standards that operate well,

$\alpha = 60$ deg., $\beta = 60$ deg., $\alpha + \beta = 120$ deg.

$\alpha = 60$ deg., $\beta = 50$ deg., $\alpha + \beta = 110$ deg.

$\alpha = 52\frac{1}{2}$ deg., $\beta = 75$ deg., $\alpha + \beta = 127\frac{1}{2}$ deg.

A standard that does not operate well,

$\alpha = 70$ deg., $\beta = 90$ deg., $\alpha + \beta = 160$ deg.

The foregoing discussion is confined entirely to a consideration of leading operation. We are in full accord with Mr. Jones in recommending leading in preference to trailing operation.

Philip Chapin Jones: Mr. Franklin points out that zero box pressure would not be saitsfactory in practise. In my paper I stated merely that "the *ideal* condition would be to make the side thrust zero." I had no intention of recommending it as good practise for the very reasons which Mr. Franklin mentions. As a matter of fact, I find in practise that a value of 75 deg. for β and 60 deg. for α works very satisfactorily.

The second point Mr. Franklin raises I do not believe is quite correct. In undertaking a mathematical investigation of physical phenomena it is necessary to assume certain ideal conditions and then in practise to make such allowances as will provide for a deviation from the ideal conditions. Thus, in this brush analysis I have assumed tacitly that we are dealing with plane surfaces both on the brush and in the holder. Under this assumption any force applied to the brush will react on the holder, not at a point or on a line but over the entire surface of the brush. For the purpose of taking moments, however, it is perfectly correct to consider a resultant force applied at some one point which is the center of gravity of all the differential pressures acting over the entire surface. In case there is no resultant turning moment on the brush, this point of action of the resultant pressure will be in the center of the surface. Inasmuch as I have so taken the various brush angles that there will be no resultant turning moment, the resultant force in the case I am discussing in the paper will be at the center of the surface.

Mr. Franklin's statement that "brushes which have been in service always show wear—in a narrow area at the extreme bottom of the brush" is too broad to be strictly true. This evidence of wearing at the bottom of the brush, however, is merely an indication that there is a turning moment acting on the brush.

Mr. Franklin's division of the box reaction into two forces H_1 and H_2 is arbitrary and entirely unnecessary as long as he is only dealing with components parallel and perpendicular to the axis of the brush. He would have had exactly the same resultant equations had he used only one H no matter at what point he applied it. It is impossible to compare curves drawn from his equations with my Fig. 5 as his equations correspond to only one point on my curve for leading brushes and to none on my curve for trailing brushes. Fig. 5 is plotted, as noted in the text for the condition that $\beta = \alpha + \psi$ where ψ (equal to 15 deg. in this case) is positive for leading brushes and negative for trailing brushes. Mr. Franklin starts by assuming that β is 90 deg. which at once fixes α as 75 deg. for leading brushes under my assumptions.

In my first investigation of this subject I did exactly as Mr. Franklin has but I soon found that I was not covering the subject and that my equations were indeterminate. In my final analysis, therefore, as given in this paper I use moments first to insure a radial movement only of the brush and then use force componants to get the relations between the various forces.

Mr. Manback's remarks call for no further comment from me. In replying to Mr. Franklin's first point, I pointed out that I had no intention of recommending this condition of zero box pressure as the best practical value.

My statement of contact resistance to which Mr. Kalb refers is, I believe, strictly correct but the proportionality, of course, is inverse and not direct.

As regards the second section of Mr. Kalb's comments, I have little to say. Apparently my paper has given the impression that I was recommending a zero box pressure, while, as I have pointed out previously, I was merely indicating it as an ideal limit which could never be reached in practise. The values I do recommend, of $\alpha = 60$ deg. and $\beta = 75$ deg. would, I believe, meet with Mr. Kalb's approval and they also satisfy the other requirements as pointed out in my paper.

Theory of Three-Circuit Transformers

BY A. BOYAJIAN

Member, A. I. E. E.

General Electric Co., Pittsfield, Mass.

Review of the Subject.—*The characteristics of three-circuit transformers, the literature of which is very meager, are discussed here in considerable detail. The features of the scheme of treatment are as follows:*

1. The scope and general aspects of the problems of three-circuit transformers are reviewed.

2. Some peculiar phenomena of considerable theoretical interest are cited.

3. An electrical network equivalent to the magnetically interlinked circuits of a three-circuit transformer is developed, useful in visualizing the problem and in predicting by inspection a number of its characteristics.

4. Two physical interpretations of the equivalent network are given to assist the understanding of its principle and its applications.

5. The case of auto transformers interconnecting three circuits is interpreted so that the formulas developed for three-circuit transformers become universally applicable regardless of the presence or absence of metallic interconnection among the three circuits inside the case.

6. Formulas are developed for the calculation of regulation with various loads in the different windings.

7. Formulas are developed for the division of load between two primary circuits, or two secondary circuits in parallel.

8. Formulas are developed for the equivalent effective impedance for short circuits.

9. The behaviour of a three-circuit transformer operating in parallel with a two-circuit transformer is analyzed so as to determine the flow or distribution of load kv-a. in the network.

10. The problem of unsymmetrical loads, particularly that of single-phase line-to-neutral short circuits on a polyphase system is discussed in an appendix, with a simplified method of solution, deriving formulas for some representative cases. When the transformer is interconnecting two polyphase generating systems, the division of single-phase line-to-neutral loads and short circuits between the two systems is considered and solved by the same method and formulas.

11. The theory of three-circuit transformers is extended to four circuits in another appendix illustrated by an example, and is then generalized to n-circuit transformers.

12. For convenient reference, the more important formulas and symbols are collected in another appendix.

The Problem

THREE-circuit transformers present some interesting characteristics, involve a number of new problems and cover a much wider field of application than one might suspect. As examples the following short list of the more important cases may be cited:

Transformers having two primary windings supplying one load from two separate generators or generating systems of different voltages. The systems may be single-phase or polyphase. Problems arise as to, (a) the division of load and short-circuit current between the two primaries, (b) the equivalent effective impedance of the transformer for a short circuit across the secondary lines, and (c) regulation.

Transformers having one primary winding and two separate secondary windings supplying two separate loads of different voltage ratings. One of the secondaries may be a condenser circuit for power factor correction or voltage regulation or both. The system may be single-phase or polyphase. The main problems are those of regulation and the combined load in the primary.

Transformers having one primary winding, one secondary (load) winding and one tertiary winding, the latter not connected to a load but provided for the purpose of magnetically interlacing the different phases of a polyphase bank, as for instance in the case of four-wire Y-Y distribution-transformers and grounded Y-Y banks. The problems to be solved are: Regulation for unbalanced loads (line-to-neutral), and equivalent effective impedance for line grounds, that is, for line-to-neutral short circuits.

Transformers with one primary winding, one secondary winding and one voltmeter winding. The main problem is that of regulation, and the object to be attained in design is to make the voltmeter winding indicate the true voltage of the secondary by turn ratio, or, when this condition is not a fact, to know the necessary correction.

Transformers having two primary windings interconnecting two generating systems and one tertiary winding not connected to any load but provided for the purpose of magnetically interlacing different phases of a polyphase bank. The problems are: Equivalent reactance of the bank for line-to-neutral short circuits, and the division of short-circuit current between the two primaries or generating systems.

Transformers of which the primary or the secondary (or both) consist of two or more coils in multiple. The important problem is the division of load current, on account of serious local overheating which may be caused by unbalanced current division. Ordinarily, parallel coils are balanced for normal operation, but tap connections on any winding may introduce an unbalance, or some other feature, such as many-stranded conductors may involve an unbalance that is not objectionable but requires calculation.

A three-winding transformer in multiple with a two-winding transformer. The important problem is the division of load among the various windings and generators.

Presented at the Midwinter Convention of the A. I. E. E., Philadelphia, Pa., February 4-8, 1924.

Some Peculiar Phenomena

In a two-primary one-secondary transformer, the division of load between the two primaries is not as simple a matter as the usual rule of "inversely as their impedances with respect to the secondary," as one might expect. With certain coil arrangements one primary may carry practically the entire load regardless of the reactance of the other primary with respect to the secondary. And not only that, but simple coil-arrangements are possible in which one of the primaries not only does not carry its share of the secondary load, but itself draws power from the transformer and feeds it to its generator proportional to the secondary load. That generator and prime-mover characteristics affect the load division is of course true and the division of load may be absolutely controlled thereby, as is to be discussed in due order, but the peculiar phenomenon here referred to is one which the characteristics of the transformer windings in certain combinations tend to impose, and holds particularly true if the two generators were on one shaft, or, if the two circuits were connected in multiple to the same busbars.

In certain other cases load division may be indeterminate as far as the reactances of the windings go and be entirely determined by the resistances of the windings. This happens when two primaries are thoroughly interlaced.

In case of a short circuit on the secondary of a transformer which has two independent primary circuits, the total short-circuit current is not necessarily the sum of the short-circuit currents which the two primaries would separately and independently produce.

In a one-primary two-secondary transformer, if one of the secondaries is loaded and the other is idle, the voltage regulation across the idle secondary may or may not be zero and may be positive or negative, *i. e.*, the voltage may be lowered or boosted, depending, as before, on the arrangement of the windings.

A somewhat common illustration of the difference in the regulation of two secondary windings is found in high-voltage testing transformers in which the inaccuracy of obtaining the secondary voltage by ratio from the primary is recognized and a special voltmeter coil is provided. The relative location of this voltmeter coil with respect to the primary and secondary determines the accuracy of the voltage readings taken from it.

A Function of Impedances

Although the characteristics of a three-circuit transformer are functions of the arrangement of the windings, yet, to be able to predetermine those characteristics, it is not necessary to have a drawing of the physical arrangement of the windings, or, in its absence, to dismantle the transformer to expose it to view. The arrangement and relative position of the windings are important only in their effect on the reactances of the windings for the subject under consideration, and thus, if those reactances (or, rather, impedances) are known, the performance characteristics of the transformer can be completely determined.

In dealing with alternating-current problems, it is unnecessary to go beyond the conceptions of resistance, reactance and impedance (in ohms or in percentages) into those of inductance in henries, capacitance in farads, and differential coefficients of currents and voltages. No recourse is taken to them in this paper, and the equations and formulas are developed in terms of the engineering units of resistance, reactance and impedance.

Furthermore, the reactances considered in this paper refer exclusively to those reactances which the transformer offers to the load currents (not those which apply to the magnetizing currents). They are sometimes called load-reactances and sometimes leakage-reactances. In the present paper all reactances and impedances will be understood to be those applying to the load currents, unless otherwise explicitly excepted.

Most of the characteristics of a three-circuit transformer, including the peculiar phenomena mentioned above, may be seen by the aid of an equivalent network which may, therefore, be profitably described at this point.

Equivalent Network of Three-Circuit Transformer

A single phase, three-circuit transformer is shown diagramatically in Fig. 1, as a two-line diagram in Fig. 1 A, as a single-line diagram in Fig. 1 B, with connected apparatus *A*, *B*, *C*, which may be generators, motors, lighting load, or any other kind of electrical apparatus. All that the transformer does between the circuits of *A*, *B* and *C* is to link them with a transformation in voltage and current. This transformation is accomplished at the expense of a magnetizing current taken by the transformer, core and copper losses in the transformer, and an impedance or impedances introduced between the various circuits. In considering such characteristics as regulation, division of load, short-circuit currents, etc., magetizing current may be ignored, and, since the ratio of transformation has no effect on these characteristics, it may be assumed as one-to-one for convenience. If the transformer and load constants are given in ohms, amperes, volts, etc., turn ratios must, of course, be considered in transferring or converting them from one winding to another.[1] However, if all such quantities be expressed as percentages of rated values of corresponding circuits (based on an assumed standard kv-a. load) turn ratios drop out of consideration completely. Since transformer constants are as a rule given in

1. Currents and voltages are reduced from the basis of one circuit to that of another by the inverse of the turn ratios. Resistances and reactances in ohms are reduced directly by the square of the turn ratios.

percentages, and most answers to problems are required in percentage form, and since also it is very desirable not to encumber equations and calculations by factors involving turn ratios, therefore, in all equations throughout this paper turn ratios are entirely ignored and the various constants are understood to be either per cent or converted values. As a rule, there is less chance of error in calculations if percentages are used rather than the converted values of ohms, volts and amperes.

With this understanding, the magnetically interlinked circuits of a three-circuit transformer may be completely represented by the electrically interlinked

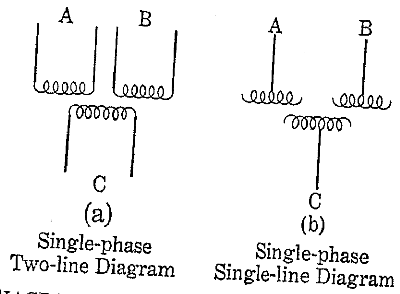

FIG. 1—DIAGRAMMATIC SKETCH OF THREE-CIRCUIT TRANSFORMER

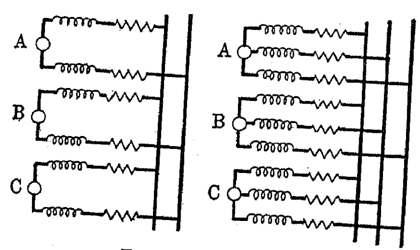
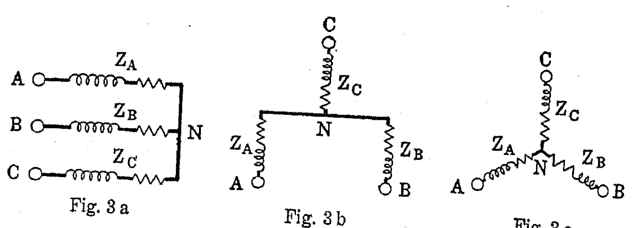


FIGS. 2A AND 2B



FIGS. 3A, 3B AND 3C

circuits of Fig. 2; Fig. 2A representing a single-phase unit (or bank) of three-circuit transformers, and Fig. 2B a three-phase unit (or bank) of three-circuit transformers. Both Figs. 2A and 2B are considerably simplified by the use of a single line diagram as in Fig. 3A. Fig. 3A, therefore, applies to all single-phase and symmetrical polyphase transformers interconnecting three circuits per phase. Fig. 3B is essentially the same as Fig. 3A, but may sometimes be preferred so as to segregate the primary and secondary circuits from each other. Fig. 3C is a perfectly symmetrical diagram and may be preferred by some. It should be carefully noted that Fig. 3C is a connection diagram like the others (not a vector diagram) and that, therefore, its appearance like a three-phase Y must not lead one to think that the circuits A, B and C are 120 deg. away from each other. These three circuits or systems (*i. e.*, A, B and C) are in phase with each other except for what little phase-shift may be produced by impedance drops due to load currents.

It will be noted that the equivalent network amounts to the connection of the three circuits or systems A, B and C to the same busbars through impedances Z_a, Z_b and Z_c, equivalent to the impedance effect of the interconnecting transformer (or auto transformer). The physical significance of this equivalence will be discussed below.

IMPEDANCES OF THE EQUIVALENT NETWORK

The impedances Z_a, Z_b, Z_c of the equivalent network (Fig. 3) are not as a rule equal to each other, and, although they originate in the commonly recognized leakage impedances between pairs of windings of the transformer, they are not numerically equal to them but are determined by them as follows:

It is well-known that power or kilovolt-amperes flowing between a pair of circuits, say A and B, interconnected by a transformer must overcome the leakage impedance Z_{ab} introduced by the transformer. Looking at the equivalent network of such a transformer (Fig. 3C), it will be seen that the impedance to the flow of kilovolt-amperes between A and B is $(Z_a + Z_b)$. Hence, if the equivalent network is to represent the performance of the transformer correctly, it must satisfy the condition that,

$$Z_a + Z_b = Z_{ab} \tag{1}$$

Similarly, it must satisfy the conditions that,

$$Z_a + Z_c = Z_{ac} \tag{2}$$

$$Z_b + Z_c = Z_{bc} \tag{3}$$

Solving these equations for Z_a, Z_b and Z_c, which are the impedances of the equivalent network, in terms of Z_{ab}, Z_{ac} and Z_{bc} (which are standard data of a transformer) we obtain

$$Z_a = \frac{Z_{ab} + Z_{ac} - Z_{bc}}{2} \tag{4}$$

$$Z_b = \frac{Z_{ab} + Z_{ac} - Z_{ac}}{2} \tag{5}$$

$$Z_c = \frac{Z_{ac} + Z_{bc} - Z_{ab}}{2} \tag{6}$$

These equations are naturally vectorial. The resistance and reactance components of the equivalent impedances are, therefore,

$$X_a = \frac{X_{ab} + X_{ac} - X_{bc}}{2} \tag{7}$$

$$X_b = \frac{X_{ac} + X_{bc} - X_{ac}}{2} \tag{8}$$

$$X_c = \frac{X_{ac} + X_{bc} - X_{ab}}{2} \quad (9)$$

$$R_a = \frac{R_{ab} + R_{ac} - R_{bc}}{2} \quad (10)$$

$$R_b = \frac{R_{ab} + R_{bc} - R_{ac}}{2} \quad (11)$$

$$R_c = \frac{R_{ac} + R_{bc} - R_{ab}}{2} \quad (12)$$

In a transformer with three independent windings, $?_a$ is identically the same as the effective $A\ C$ resist-.nce of winding A; R_b the same as that of winding B; nd R_c the same as that of winding C. Equations 10), (11) and (12), however, have not been put in nerely for their symmetrical looks in comparison with he reactances, but in apparatuses, having considerable tray a-c. impedance-losses the effective a-c. resistance f each winding may be difficult to predetermine while he effective resistance of pairs of windings may be asier to predetermine and still easier to test. In ther words, exact values of the equivalent resistances re obtained more accurately from the impedance-vatts measurements per pair of windings with the aid f formulas (10), (11) and (12). Furthermore, in auto ransformers the windings of the various circuits not eing independent of each other, the simplification which applies to straight transformers would not apply ɔ them, while equations (10), (11) and (12) apply niversally. Since in any transformer or auto trans-ɔrmer the copper or impedance loss (watts) for any air of circuits (one acting as primary the other as econdary) is a requisite datum, the convenience and mplicity of these equations may be appreciated.

It may not be amiss to emphasize two considerations t this point:

(a) All impedances used in these equations (whether ı ohms or in percentages) must be those effective at ıe external circuit terminals. In straight transformers ıere is not much chance of error in this matter (especi-ly if the impedances are expressed as percentages) ıt in the case of auto transformers there is a possibility f confusing the impedances between series and common indings of the unit as a transformer and the values ; auto transformer, in which case the auto transformer alues must be used because they are the values fective at the circuit terminals. It is for this reason ıat throughout this paper the word "circuit" is very equently used instead of "winding."

(b) If the various impedances are expressed as ercentages, they must all be based on a common andard kv-a. output which standard output may be ssumed arbitrarily regardless of the capacity of the rcuits. The actual kv-a. loads in the various circuits ay then be given as certain fractions or multiples this assumed standard kv-a. output.

Physical Significance of the Equivalent Impedances

The physical significance of the impedances of the equivalent network may be viewed in two different ways:

Equivalent Impedances considered as the Effective Impedances of the Individual Windings (or Circuits). If the total impedance between the windings of two circuits, say A and B, is Z_{ab}, we may conceive that a portion Z_a of this total impedance Z_{ab} belongs to the winding of circuit A, and the rest of it, which we may call Z_b, belongs to the winding of circuit B, and then of course, as in equation (1),

$$Z_a + Z_b = Z_{ab}$$

We have already seen that in a simple case, such as a transformer with three independent windings, the resistance components of the equivalent impedances are identical with the resistances of the corresponding individual windings, and it is therefore most natural to conceive of the reactance components of the equivalent impedances as the reactances of the corresponding individual windings.

This is an extremely simple point of view and therefore very convenient and useful in practical problems.

In a two-circuit transformer the resolution of its total reactance into primary and secondary reactances is indeterminate[2] and unnecessary: unnecessary for the simple reason that the usual operating characteristics of a two-winding transformer depend on the total impedance and not on its division between primary and secondary. In a three-circuit transformer such a resolution becomes necessary and the problem is rendered determinate by the condition that the resolutions of the three total leakage impedances Z_{ab}, Z_{ac} and Z_{bc} between corresponding circuits be consistent as formulated by the simultaneous equations (1), (2) and (3), and solved by equations (4), (5) and (6).

The equivalent network, then, instead of dealing directly with the total leakage-impedances between pairs of windings or circuits, deals with the leakage-impedances of the individual windings or circuits.

This point of view is quite simple, and very helpful in attacking problems of regulation, division of load, short-circuit currents, and allied problems, and is valid within the scope of all such problems. It is recommended, therefore, to all who are interested in practical applications and do not wish to be encumbered by refinements of more rigorous theory. The scope and limitations of this point of view are critically discussed in Appendix A, after which the second interpretation of the equivalent impedances is given considering them as "mutual impedances" effective for load currents. This second point of view is ab-

2. Unless the complete design of the transformers were available.

solutely rigorous and universal but somewhat more difficult to grasp than the first.

Explanation of the Peculiar Phenomena

A number of the peculiar phenomena mentioned in the foregoing may be explained by an inspection of the equivalent network.

It is possible for one of the reactances in the equivalent network to be negative (See Fig. 4). Equations (7-9) do not contradict this possibility, and experience

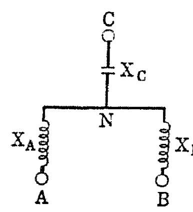


FIG. 4

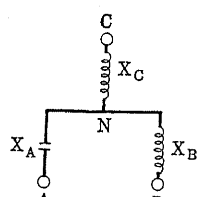

FIG. 5

with concrete transformer designs confirms it. It can be reasoned out, however, that not more than one branch can have a negative reactance, because the net impedance between every pair of windings of the transformer must be positive or inductive and can not be negative or condensive. It also follows from this consideration that the negative reactance must be smaller than either one of the positive reactances in the other branches. As a matter of fact, if a negative reactance occurs, it is very small compared with the other reactances. How a negative or condensive reactance effect can occur in the leakage reactance of the inductive windings of a transformer involves a rather elaborate analysis of leakage flux linkages described in Appendix C. It is this equivalent negative reactance that is responsible for most of the peculiar phenomena mentioned above.

(a) *Explanation of Regulation Peculiarities.* Considering Fig. 4, assume that C is a generator, A is an inductive load, and B an idle secondary. Evidently, the voltage of A will drop under its assumed lagging-power-factor load, because the net impedance from C to A is inductive. However, the voltage of B must rise under the lagging-power-factor load of A because the drop in the condensive reactance X_c by a lagging current will boost the voltage at the point N, and as there is no current and no drop in X_b, the voltage of B will be same as at N and therefore boosted above that of C. To state it in a more general way: With a lagging load in either A or B or both, the voltage of the neutral point N will be higher than the impressed voltage at C. Thus, it may be seen how a given load at a given point may lower the voltage of some part of the network and raise that of another.

(b) *Explanation of Short-Circuit Current Peculiarity.* Let A and B in Fig. 3B be two primary circuits, and C the secondary. If the impedance Z_c were zero, the short-circuit current in C furnished jointly by A and B would be the vector sum of the short-circuit currents which A and B would independently produce. However, if Z_c is the dominant impedance of the network, and Z_a and Z_b comparatively negligible, the short-circuit current in C will be practically the same whether A alone or B alone or both are excited.

(c) *Explanation of Peculiarities in Load Division.* Let A and B in Fig. 5 be two primary circuits, A with a condensive reactance, B with an inductive reactance. If the secondary C is loaded, evidently A and B will divide the load inversely as the impedances of their respective branches. But thè impedances of these two branches have opposite signs, and therefore the currents and kilovolt-amperes in those two circuits will have opposite signs. Thus, if the secondary load is of unity power factor, one of the primary circuits, *viz.*, A, will act as generator, the other, B, as motor, A furnishing power to both C and B. The vector diagram of this is shown in Fig. 6. If the load in C is a zero power factor lagging load, A will furnish a lagging load, B a leading load, the latter being neutralized by the excess lagging load in A.

The foregoing peculiarity in load division is rather of theoretical interest only and does not imply a possible source of difficulty in practise, because division of load between two primary circuits can not in practise be left to the peculiarity of the apparatus but is controlled externally: the division of the kw. component of the load is controlled by the setting of the governors of the prime-movers, the division of the reactive component of the load being controlled by the setting of the voltage regulators of the generators or primary circuits, as will be further discussed below. The peculiarity mentioned above could take place only under two different conditions, *viz.*, (a), if the two primary windings A and B were actually connected in multiple, or (b), if the

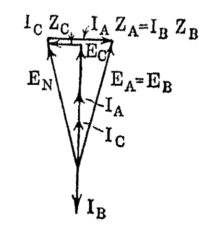

FIG. 6

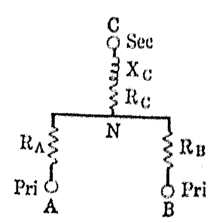

FIG. 7

generators of A and B were mounted on one shaft and their angular position fixed so as to make their voltages in phase in accordance with the vector diagram in Fig. 6 where E_a and E_b, the terminal voltages of A and B, are shown as identical. This condition, of course, does not arise ordinarily in practise except in complicated tie-in networks and can even in those cases be controlled completely by means of regulators.

The second peculiarity in load-division, the case in which load-division is independent of the reactances

of A and B with respect to C, but is determined by their resistances only, is when the reactances of the branches of A and B is zero, the reactance between the two primaries being zero and that from either primary to the secondary being X_c. (Fig. 7.)

With the aid of the foregoing general physical concept of the network of a three-circuit transformer, we are in a position to proceed to the derivation of formulas for the calculation of regulation, load division and short-circuit currents.

Calculation of Regulation

Regulation may be formulated in a number of ways, some absolute, some approximate. We may first review the regulation formulas for a two-circuit transformer and then indicate how they apply to three-circuit problems.

Two-Circuit Transformers. (a) Absolute Formulas.

$$\text{Per Cent Regulation} = \left\{ \frac{E \text{ total}}{E \text{ load}} - 1 \right\} 100 \qquad \textbf{(13a)}$$

$$= \left\{ \frac{Z \text{ total}}{Z \text{ load}} - 1 \right\} 100 \qquad \textbf{(14a)}$$

$$= \left\{ \frac{\text{kv-a. input}}{\text{kv-a. output}} - 1 \right\} 100 \qquad \textbf{(15a)}$$

$$= \left[\sqrt{ \left\{ 1 + m \frac{(\% I R)}{100} + n \frac{(\% I X)}{100} \right\}^2 + \left\{ m \frac{(\% I X)}{100} - n \frac{(\% I R)}{100} \right\}^2 } - 1 \right] \times 100 \qquad \textbf{(13b)}$$

$$= \left\{ \sqrt{ \frac{(R_{load} + R_{trans})^2 + (X_{load} + X_{trans})^2}{R_{load}^2 + X_{load}^2} } - 1 \right\} 100 \qquad \textbf{(14b)}$$

$$= \left\{ \sqrt{ \left(m + \frac{\% I R}{100}\right)^2 + \left(n + \frac{\% I X}{100}\right)^2 } - 1 \right\} 100 \qquad \textbf{(14c)}$$

$$= \left\{ \sqrt{ \frac{(\text{kw.}_{output} + \text{kw.}_{imp.})^2 + (\text{kv-a}_{react.\,output} + \text{kv-a}_{react.\,imp})^2}{\text{kw.}^2_{output} + \text{kv-a.}^2_{react.\,output}} } - 1 \right\} 100 \qquad \textbf{(15b)}$$

Notes on Absolute Formulas. In equation **(13a)** the total voltage is the no-load secondary voltage which also, of course, corresponds to the no-load primary voltage reduced to the same basis of turns. The total voltage might also be called the input voltage, and the load voltage might be called the output voltage.

Formulas **(14a)** and **(15a)**, if not self-evident, can be derived from **(13a)**; **(14a)** is derived by *dividing* the numerator and the denominator of the fraction in **(13a)** by the load-current: **(15a)** is derived by *multiplying* the numerator and denominator of the fraction in **(13a)** by the load-current. In **(15a)** the kv-a. input is exclusive of the magnetizing current and the core loss. These are ignored because they do not change from no-load to full-load and do not produce a change in voltage with varying load. Even ignoring the excitation kilovolt-amperes of the transformer, the input kilovolt-amperes is different from the output kilovolt-amperes on account of the kilovolt-amperes consumed in the impedance of the transformer.

Formulas **(13a)**, **(14a)** and **(15a)** are basic, and although they are not in terms of commonly given data for direct substitution, they can be expressed in terms of such data as shown in formulas **(13b)** deduced from **(13a)**; **(14b)** and **(14c)** deduced from **(14a)**; and **(15b)** deduced from **(15a)**. In **(14b)** the resistances and reactances are in ohms. In **(15b)** the subscript "imp." designates the kw. or reactive kv-a. consumed in the impedance of the transformer.

Of all these formulas, the simplest, most direct and as a rule, the most convenient one is **(14c)** m is the power-factor of the load and n its reactive factor. All percentages and other variable data must, of course, correspond to the actual load, otherwise a conversion or correction factor must be included.

The absolute formulas give the regulation as the difference of two numbers which are very nearly equal, and, therefore, to get this difference, *i. e.*, the final answer, correct to two or three significant figures, the value of the square root term must be computed correct to four or five places. Hence, the absolute formulas as such do not yield much accuracy with a ten-inch slide rule, but they are useful for reference, and they also form the basis of all approximate formulas.

Regulation may be positive or negative. Positive regulation corresponds to drop in secondary voltage at full load, or, rise in secondary voltage at no-load as the A. I. E. E. definition puts it. Negative regulation is then rise in voltage at full-load, or drop in voltage at no-load. The A. I. E. E. wording is preferable, one of the many reasons pertinent to the following discussion being that the rise or drop of voltage from full-load to no-load is also the rise or drop of voltage from (loaded) secondary to primary, from output voltage to input voltage. Corresponding to negative regulation, primary or input voltage (per cent or converted value) will be less than secondary or output voltage; the primary or input kilovolt-amperes (exclusive of excitation kilovolt-amperes) will be less than the load or output kilovolt-amperes and the total impedance (*i. e.*, impedance of load plus vectorially the impedance of the transformer) will be less than the load impedance alone.

Approximate A. I. E. E. Formula. An approxima-

tion based on formula (**13b**) and standardized by the A. I. E. E. is as follows:[3]

$$\text{Per cent Reg.} = m\,(\text{per cent } I\,R) + n\,(\text{per cent } I\,X) + \frac{[m\,(\text{per cent } I\,X) - n\,(\text{per cent } I\,R)]^2}{200} \quad \textbf{(16)}$$

Regulation of Three-Circuit Transformers

Since the load of a three-circuit transformer is not likely to be the same in any two of its circuits, the two-circuit regulation formula cannot be applied directly but must be applied in two steps as is to be described below.

Just as in a three-circuit transformer with two secondary circuits the regulation in the two secondaries need not be alike, so, in a transformer with two primary circuits, if the share of each primary from the total load is to be externally controlled, then, the two primary circuits will have to have different voltages at full load than on no load. Therefore, in a three-circuit transformer there are three regulations to be considered corresponding to the three pairs of windings or circuits.

Referring to Fig. 3B, the regulation between A and C may be calculated in two steps: From A to N (the neutral), and from N to C. Then, designating the first Reg_{an} and the latter by Reg_{nc}, the regulation, Reg_{ac}, between A and C is,

$$\text{Per Cent Reg}_{ac} = \text{Per Cent Reg}_{an} + \text{Per Cent Reg}_{nc} \quad \textbf{(16a)}$$

$$= \text{Per Cent Reg}_{an} - \text{Per Cent Reg}_{cn} \quad \textbf{(16b)}$$

The correctness of this procedure will be recognized considering the fact that regulation is not a vector concept but an algebraic one. It can only be positive or negative; one representing drop in voltage, the other rise in voltage. Regulation between two points (or circuits) can, therefore, be calculated as the algebraic sum of two steps; one from the first point to an intermediate point, and the second, from that intermediate point to the final point, these points and the direction being indicated by the subscripts. Accordingly, if per cent Reg._{an} is positive, per cent Reg._{na} must be considered negative, since, if the voltage rises from A to N, it must drop from N to A. That is the basis of the difference between (**16b**) and (**16a**) which differ in the order of the subscripts of the second term, the two forms being given to emphasize the algebraic character of the formula. However, it is believed that no error is likely to be made in practise due to confusion of signs if the physical facts are clearly kept in sight. As a convenient rule, we can say that if two circuits are dissimilar in duty, that is, one is primary, the other secondary, the regulation between them is the algebraic sum of the regulation from the secondary to the neutral and the regulation from the neutral to the primary (eq. **16a**); but, if both are primary or both secondary, then, the regulation between them is the algebraic difference of their regulations with respect to the neutral point (eq. **16b**).[4]

Example. A three-phase bank of three 5000-kv-a. transformers interconnects a 66,000-volt generating system, a 114,000-volt transmission system and a 13,860-volt synchronous condenser load. The 66,000 volts are stepped up to 114,000 volts through a single winding, that is, through an auto transformer, but that does not in any way influence the calculation of regulation once the impedances effective at the external circuit terminals are known.

Data. The following data are by test, and all the percentages are based on an output of 5000 kv-a. per phase.

Per Cent $I\,R_{PS} = 0.55$; Per Cent $I\,R_{PT} = 0.60$;
Per Cent $I\,R_{ST} = 0.50$

Per Cent $I\,X_{PS} = 8.65$; Per Cent $I\,X_{PT} = 10.6$;
Per Cent $I\,X_{ST} = 8.3$

From these data the impedances of the individual circuits are calculated to be,

Per cent $I\,R_P$

$$= \frac{\text{per cent } I\,R_{PS} + \text{per cent } I\,R_{PT} - \text{per cent } I\,R_{ST}}{2} = 0.325$$

Per cent $I\,R_S$

$$= \frac{\text{per cent } I\,R_{PS} + \text{per cent } I\,R_{TS} - \text{per cent } I\,R_{PT}}{2} = 0.225$$

Per cent $I\,R_T$

$$= \frac{\text{per cent } I\,R_{PT} + \text{per cent } I\,R_{ST} - \text{per cent } I\,R_{PS}}{2} = 0.275$$

Per cent $I\,X_P$

$$= \frac{\text{per cent } I\,X_{PS} + \text{per cent } I\,X_{PT} - \text{per cent } I\,X_{ST}}{2} = 5.475$$

Per cent $I\,X_S$

$$= \frac{\text{per cent } I\,X_{PS} + \text{per cent } I\,X_{TS} - \text{per cent } I\,X_{PT}}{2} = 3.175$$

Per cent $I\,X_T$

$$= \frac{\text{per cent } I\,X_{PT} + \text{per cent } I\,X_{ST} - \text{per cent } I\,X_{PS}}{2} = 5.125$$

The equivalent network of this transformer together with the numerical values of its constants are shown in Fig. 8, which should be kept in view in the following calculations.

3. A. I. E. E. standardization Rule No. 6391-b. We have written out above as per cent $I\,R$ the meaning of "q_r," and as per cent $I\,X$ the meaning of "q_x" used in the A. I. E. E. formula.

4. Regulation of a three-circuit transformer may be calculated correctly by at least three different methods. The scheme of referring all regulations to the meutral point was suggested by Mr. K. K. Palueff. Another method is given in Appendix F.

To calculate the various regulations for the following conditions of load:

Circuit S delivering 5000 kv-a. at 80 per cent lagging power factor

Circuit T delivering 2900 kv-a. at 0 per cent leading power factor.

The regulation from the secondary to the point N by the A. I. E. E. formula (equation (**16**) is

$$\text{Per cent Reg}_{SN} = 0.80 \times 0.225 + 0.60 \times 3.175 + \frac{(0.80 \times 3.175 - 0.60 \times .225)^2}{200} = +\,2.11$$

In calculating the regulation from the terminals of the tertiary circuit T to the point N, we must note that the actual load (2900 kv-a.) is less than the standard load (5000 kv-a.) on which the percentage values of the impedances of its branch are based. The latter should, therefore, be reduced by the ratio (2900/5000 = 0.58) in the calculation of regulation which will be

$$\text{Per Cent Reg}_{TN} = 0 \times 0.58 \times 0.275 - 1 \times 0.58 \times 5.125 + \frac{(0 + 1 \times 0.58 \times 0.275)^2}{200} = -\,2.97$$

In calculating the regulation from the point N to

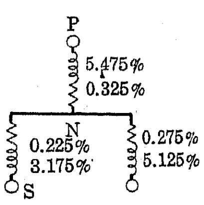

FIG. 8

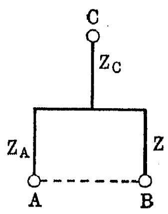

FIG. 9

the terminals of primary P, we must first calculate the actual load in that branch.

Evidently, the output of the branch P is the vector sum of the following four items, *viz.*, (a) kv-a. in the external load of circuit C, (b), kv-a. in the external load of circuit T, (c) kv-a. consumed in the impedance of branch S, (d), kv-a. consumed in the impedance of branch T. Making this calculation in tabular form, we have,

Output of Circuit P per Phase

	Kw.	Kv-a. Reactive
Output of S........	0.80×5000	+0.60×5000
Output of T........	0	− 2900
Impedance kv-a. of S	0.00225×5000	+0.03175×5000
Impedance kv-a. of T	0.00275×.58×2900	+0.05125×0.58×2900
Total...........	4016 kw.	+345 kv-a. lagging

4030.79 kv-a. at 99.63 per cent power factor
8.56 per cent reactive factor

The percentage values of the impedances of branch P are based on an output of 5000 kv-a. per phase, but since the actual output is 4030.79 kv-a. the actual percentages will be (4030.79/5000 = 0.807) times the values given in Fig. 8.

The input of circuit P (exclusive of excitation kv-a.) will be the vector sum of its output and the kv-a. consumed in the impedance of branch P. Thus,

Input of Circuit P

	Kw.	Kv-a. Reactive
Output....	+4016	+345
Impedance.	+0.00325×0.807×4030.8	0.05475×0.807×4030.8
Total......	4026.55	+523 lagging

4060.37 kv-a. at
99.17 per cent power factor
12.88 reactive factor

Since we know the input and output of branch P, we could calculate the regulation from N to P by formula (**15a**) as an illustration:

$$\text{Per cent Reg}_{NP} = \left\{ \frac{4060.37}{4030.79} - 1 \right\} \times 100 = \left\{ \frac{4060.37 - 4030.79}{4030.79} \right\} \times 100 = 0.734$$

The regulations between pairs of circuits then follow as

$$\text{Per cent Reg}_{SP} = \text{Per cent Reg}_{SN} + \text{Per cent Reg}_{NP} = 2.11 + 0.734 = +\,2.84$$

$$\text{Per cent Reg}_{TP} = \text{Per cent Reg}_{TN} + \text{Per cent Reg}_{NP} = -\,2.97 + 0.734 = -\,2.24$$

$$\text{Per cent Reg}_{ST} = \text{Per cent Reg}_{SP} - \text{Per cent Reg}_{TP} = +\,2.84 - (-\,2.24) = +\,5.08$$

or

$$= \text{Per cent Reg}_{SN} - \text{Per cent Reg}_{TN} = +\,2.11 - (-2.97) = +\,5.08$$

DIVISION OF KV-A. LOAD

In a double-secondary transformer of which both secondary windings have the same voltage rating and are actually connected in parallel, also in a double-primary transformer in which the division of the kv-a. load between the two primary circuits is not externally controlled, the division of load will obviously be inversely as the impedances of the respective circuits. Thus, if A and B are those two circuits, (Fig. 3B).

$$\frac{(\text{kv-a.})_A}{(\text{kv-a.})_B} = Z_B / Z_A \qquad (\mathbf{18})$$

Since the load in the third circuit C must be the vector sum of those in A and B, therefore,

$$\frac{(\text{kv-a.})_A}{(\text{kv-a.})_C} = \frac{(\text{kv-a.})_A}{(\text{kv-a.})_A + (\text{kv-a.})_B} = \frac{Z_B}{Z_A + Z_B} = Z_B / Z_{AB} \qquad (\mathbf{19})$$

$$\frac{(\text{kv-a.})_B}{(\text{kv-a.})_C} = \frac{(\text{kv-a.})_B}{(\text{kv-a.})_A + (\text{kv-a.})_B}$$

$$= \frac{Z_A}{Z_A + Z_B} = Z_B/Z_{AB} \quad (20)$$

The two simplified equations, *viz.*:

$$\frac{(\text{kv-a.})_A}{(\text{kv-a.})\ \text{total}} = Z_B/Z_{AB} \quad (21)$$

$$\frac{(\text{kv-a.})_B}{(\text{kv-a.})\ \text{total}} = Z_A/Z_{AB} \quad (22)$$

hold numerically as well as vectorially and are, therefore, very convenient.[5]

It may appear as though, since in a double-primary transformer load division must be externally controlled, and in a double-secondary transformer the two circuits are usually connected to independent external loads, that these load division formulas have no practical application. We may, therefore, indicate here some practical applications for them.

(a) In a double primary transformer in case of a short circuit on the secondary side, the division of short-circuit kv-a. between the two primary circuits follows the foregoing formulas at least initially, because control apparatus can not come into play instantly, and, even after they have come into play, they can not function half as effectively under short circuit as at normal loads.

(b) In some complicated interconnections of systems and apparatus, external control, though possible, is not resorted to on account of increased complication, in which case division of load takes place along the lines indicated above. An illustration of this is afforded in the case of a three-circuit transformer operating in parallel with a two-circuit transformer to be discussed at a later point.

(c) Transformers with only two external circuits will sometimes have two or more circuits in parallel internally. In such cases the parallel circuits are as a rule designed with as perfect symmetry as possible but exceptional cases of dissymmetry may arise in which these formulas will be needed to determine the load taken by each circuit. Eddy current or circulating current problems in some circuits subject to large losses due to such causes incapable of a simple exact theoretical calculation may be approximated by the foregoing formulas.

5. The term (kv-a.) total here means the total output of the two circuits or the input of the third circuit. The input of each primary circuit is its share of this total kv-a. plus (vectorially) the kv-a. consumed in its branch. This qualification is mentioned here to make the principle clear but in many practical cases such refinements of calculation may be unnecessary and the kv-a. consumed inside the transformer may be ignored except in high impedance transformers.

Short Circuit Impedance

In a one-primary two-secondary transformer, the impedance of the unit for a short circuit across either secondary (one at a time) is, of course, the same as that of a two-circuit transformer, since one of the secondaries is assumed not to take part in the short circuit. However, in a two-primary transformer, both circuits being excited, also in a two-secondary transformer having a simultaneous short-circuit across both circuits, the effective impedance of the unit in limiting the short circuit is calculated as follows: Designating the two circuits similar in function as A and B (See Fig. 9), and considering them as though they were connected in parallel as shown by the dotted line in the figure, the effective impedance from combined (A B) to C is evidently

$$Z_{short} = \frac{1}{1/Z_A + 1/Z_B} + Z_C \quad (23a)$$

$$= \frac{Z_{AC}\, Z_{BC} - Z_C^2}{Z_{AB}} \quad (23b)$$

Since in short-circuit problems the resistance of the circuits may in practise be ignored, we may write for the short-circuit reactance of the unit,

$$X_{short} = \frac{X_{AC}\, X_{BC} - X_C^2}{X_{AB}} \quad (24)$$

The share of each one of the two similar circuits of the short-circuit current (or rather kv-a.) follows in accordance with the division of load formulas (equations **21** and **22**).

Example. In the example given for regulation, assume that the secondary and tertiary circuits were simultaneously short-circuited. What would be the short-circuit loads in the primary, secondary and tertiary? Calling the secondary A, the tertiary B, and the primary C, we have the constants,

$X_{AC} = 8.65$ per cent; $X_{BC} = 10.6$ per cent; $X_{AB} = 8.3$ per cent

$X_A = 3.175$ per cent; $X_B = 5.125$ per cent; $X_C = 5.475$ per cent

Substituting these in equation (**24**),

$$X_{short} = \frac{8.65 \times 10.6 - 5.475^2}{8.3} = 7.43 \text{ per cent}$$

(approx.)

The short-circuit current and kv-a. will, therefore, be (100/7.43) that is, 13.5 times normal.

The share of the secondary A and tertiary B of this short circuit will be, by formulas (**21**) and (**22**),

A's share $= Z_P/Z_{AB} \times 13.5 \times$ normal
$= 8.35 \times$ normal (approx.)

B's share $= Z_A/Z_{AB} \times 13.5 \times$ normal
$= 5.15 \times$ normal (approx.)

Since the normal, that is, the kv-a. base, is 5000

kv-a., the short-circuit kv-a. in the different circuits will be,

C (primary), 13.5 × 5000 = 67,500 kv-a. per phase
A (secondary), 8.35 × 5000 = 41,700 " " "
B (tertiary), 5.15 × 5000 = 25,800 " " "

The short-circuit currents are calculated similar to the short-circuit kv-a., with this difference, however, that the normal or basic current is not the same for all three circuits on account of their different voltage ratings. The short-circuit currents may also be derived from the short-circuit kv-a.

Three-Circuit Transformer in Parallel with a Two-Circuit Transformer

Fig. 10 shows a three-circuit transformer with primary C, and secondary circuits A and B, in parallel with a two-circuit transformer with primary M and secondary N, the parallel connection being between primaries C and M, and between secondaries B and N.

Considering the load on the bus $B\,N$, it is evident that this will be furnished over two paths in parallel (shown by solid arrows), one path with the impedance $(Z_c + Z_b)$, the other with the impedance Z_{mn}; the load dividing between these two paths inversely as their impedances.

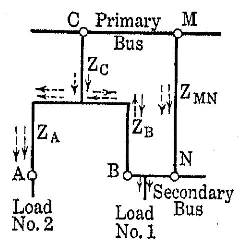

Fig. 10

Considering the load in A, it is evident that this also will be furnished over two paths in parallel (shown by dotted arrows), one path with the impedance Z_c, the other with the impedance $(Z_{mn} + Z_b)$; the load dividing between these two paths inversely as their impedances.

In branches C, M and N, the two component loads add vectorially as shown by the relative directions of the solid and dotted arrows. In branch B, link Z_b, they subtract vectorially. As a consequence of this, we have the seemingly absurd condition that, assuming the load 1 and 2 to have the same kind of power factor (*i. e.*, both lagging or both leading), the removal of one of the loads increases the load in B. The reason for this is, of course, the fact that B acts like a secondary for load 1, but as a primary for load 2.

An interesting feature to observe in this connection is that for a load in A the circuits of C and B acting like two primaries in parallel, the division of load between them is completely determined by the impedances of the network as indicated above, independent of generator and prime mover control apparatus. It desired, it would be possible of course to control this by suitable regulators between B and N, or, between C and bus $C\,M$, or between M and bus $C\,M$.

The foregoing considerations show that the planning design and operation of three-circuit transformers in parallel with two-circuit transformers is a much more involved problem than the parallel operation of two-circuit transformers.

Example. Let the three-circuit transformer be the same as that used in the previous illustrations. (See also Fig. 8.). Let the reactance Z_{mn} of the two-circuit transformer be 6 per cent. Ignoring the resistances to a first approximation, we have for the constants of the network shown in Fig. 10,

$$X_a = 3.175 \text{ per cent}$$
$$X_b = 5.125 \text{ per cent}$$
$$X_c = 5.475 \text{ per cent}$$
$$X_{mn} = 6 \text{ per cent}$$

Let the load on bus $B - N$ be designated $(\text{kv-a.})_1$ and that on A, $(\text{kv-a.})_2$.

$$B\text{'s share of } (\text{kv-a.})_1 = + \frac{Z_{mn}}{Z_{bc} + Z_{mn}} (\text{kv-a.})_1$$
$$= +0.36\,(\text{kv-a.})_1$$

$$\text{" " " } (\text{kv-a.})_2 = - \frac{Z_c}{Z_c + Z_b + Z_{mn}}$$
$$= -0.33\,(\text{kv-a.})_2$$

$$\text{" total load} = 0.36\,(\text{kv-a.})_1 - 0.33\,(\text{kv-a.})_2 \text{ (vectorially)}$$

$$C\text{'s share of } (\text{kv-a.})_1 = B\text{'s share of } (\text{kv-a.})_1 = 0.36\,(\text{kv-a.})_1$$

$$\text{" " " } (\text{kv-a.})_2 = \frac{Z_b + Z_{mn}}{Z_c + Z_b + Z_{mn}} (\text{kv-a.})_2$$
$$= 0.67\,(\text{kv-a.})_2$$

$$\text{" total net load} = 0.36\,(\text{kv-a.})_1 + 0.67\,(\text{kv-a.})_2 \text{ (vectorially)}$$

$$M\,N\text{'s share of } (\text{kv-a.})_1 = (\text{kv-a.})_1 - B\text{'s share} = 0.64\,(\text{kv-a.})_1$$

$$\text{" " " } (\text{kv-a.})_2 = \text{same as } B\text{'s share but positive} = 0.33\,(\text{kv-a.})_2$$

$$\text{" total net load} = 0.64\,(\text{kv-a.})_1 + 0.33\,(\text{kv-a.})_2 \text{ (vectorially)}$$

$$A\text{'s total net load} = (\text{kv-a.})_2$$

When very precise results are desired, especially if the reactances are low and the resistances are appreciable, the actual impedances should be used in such calculations (instead of merely reactances), and their manipulation will be vectorial.

When the three-circuit transformer operating in parallel with a two-circuit transformer has two primary circuits instead of two secondary circuits, the general

scheme of analysis is very similar to the foregoing and will be evident in the light of it. Loads 1 and 2 will correspond to generators 1 and 2, respectively, and in most practical cases the load taken up by the two generators will be governed by external control, in which case the problem is much simpler than the case discussed in the foregoing in which $(\text{kv-a.})_1$ and $(\text{kv-a.})_2$ were not assumed to have any constant relationship to each other.

Influence of Generator and Prime-Mover Characteristics

A generator may influence the operation of a three-circuit transformer to which it is connected, by virtue of its impedance and by the action of its voltage regulator.

If the generator is equipped with an automatic voltage regulator, the generator impedance will not influence either regulation or load-division, but it will influence the short-circuit currents and should therefore be included in the impedance of the circuit to which it is connected. That is, in the calculation of the effective short-circuit impedance, also in the division of short-circuit current,

Z_a is to include also the impedance of the generator connected to A;

Z_b is to include also the impedance of the generator connected to B, etc.

Of course, if the generators are not equipped with any voltage regulators, the modified values of Z_a, Z_b and Z_c as defined in the preceding paragraph apply in the calculation of regulation, and also in that of division of load if it is not otherwise externally controlled.

If the induced voltages of two alternators connected in parallel have the same phase-angle but different magnitudes (a condition which may be brought about by the manipulation of the voltage control of the alternators) their difference, the unbalanced voltage, produces a circulating quadrature current through the impedance of the alternators which is practically all reactive. This circulating current is lagging in one and leading in the other unit. If the two induced voltages are equal in magnitude but out of phase from each other (a condition which may be brought about by the manipulation of the governors of the prime-movers) their difference, the unbalance voltage, is in quadrature with their mean value, and produces a circulating current parallel to the mean voltage. This current acts like a generator or load current in one and as motor or power current in the other. Now, if the two alternators are furnishing kv-a. to an external load, it will be evident that the circulating kv-a. load will add (vectorially) to the share of one unit in the external load, and will subtract (vectorially) from the share of the other unit in the external load. The foregoing statements hold whether the alternators are paralleled directly or through transformers. Three conclusions follow from these considerations:

(a) The total net reactive load in one of the two alternators or primary circuits can be increased or decreased at the expense of the other by producing a circulating reactive kv-a. by the manipulation of their induced voltages.

(b) The total net kw. load in one of the two alternators or primary circuits can be increased or decreased at the expense of the other by producing a circulating power by the manipulation of the governors of the prime-movers.

(c) The share of each alternator or primary circuit in the external load is completely determined by the inverse of the impedances of their respective circuits and this is not really altered by either alternator-voltage or prime-mover governor control. These controls merely superpose a circulating kv-a. so as to bring about a desired resultant load in each unit. This superposed circulating kv-a. becomes apparent when the external load is removed; therefore, the resolution of the total load in either circuit into two components as circulating kv-a. and as its share of the external load is not a mathematical fiction but a statement of actual fact.

Appendix A

Critical Analysis of the Interpretation of the Equivalent Impedances as the Impedances of the Corresponding Individual Windings

Although the resolution of the total leakage impedances Z_{ab}, Z_{ac} and Z_{bc} of a three-circuit transformer into equivalent components Z_a, Z_b and Z_c is absolutely correct and valid yet the interpretation of these latter as the leakage impedances of the respective windings is only a very convenient and useful fiction, not an absolutely, universally and uniquely valid interpretation. It is desirable to point out the limitations of this interpretation before proceeding to the absolute interpretation.

(a) If the interpretation of the equivalent impedances as the leakage impedances of the respective windings were absolute, it would appear as though here we had a simple scheme of settling an old controversy relative to the question as to how much of the reactance of a transformer belongs to the primary and how much to the secondary, a subject on which no two transformer engineers may be expected to agree.

(b) The very scheme of resolution shows that the resolution of, say, the total impedance Z_{ab} into Z_a and Z_b is made dependent on and with respect to the winding (or circuit) C, and that this resolution changes when the impedance of C *with respect to* A and B is altered. The physical meaning of such a resolution *with respect to* a third winding is better grasped from the second point of view (to be described below).

(c) It has been seen that one of the equivalent reactances (which we are identifying with the leakage

reactances of the corresponding individual windings) may be negative, that is, condensive. Obviously, a resolution that leads to a condensive leakage reactance in an inductive winding can not be absolute and inherent but must be relative. This fact also is better understood from the second point of view.

(d) The equivalent network of a transformer with more than three circuits, discussed in another appendix, clearly shows that such a resolution is relative, and valid only for particular classes of problems.

Appendix B

Equivalent Impedances Considered as "Mutual" Impedances

The basic problem in the theory and calculation of the characteristics of three-circuit transformers is to know what effect a load in one circuit has on the other circuit.

To see how the equivalent network and its impedances give us the effect of two circuits upon each other, consider Fig. 3c. Let us assume that C is a primary circuit and A and B are two secondary circuits. If A draws a current from C, there will be an impedance drop between C and A through the impedances ($Z_a + Z_b$). There will also be an impedance drop between C and B due to the current taken by A through the impedance Z_c. If the current was taken by B instead of by A, the drop through Z_c would now be effective for A.

Evidently, Z_c is that portion of the leakage or load reactance of $C A$ which also belongs to B, and that portion of the leakage or load reactance of $C B$ which also belongs to A. To put it a little differently, Z_c is the reactance common to loads in A and B. An inductance common to two circuits is known as mutual inductance, and we may therefore call the reactance common to the loads in A and B load-mutual-reactance between A and B, writing it as M_{ab}. If one prefers to think of mutual-inductance not as inductance "common" to two circuits, but as the coefficient which gives the voltage in one circuit induced by a unit current in the other, that point of view also applies to the present case, because Z_c is the coefficient which gives the voltage induced in A by a unit load-current in B, and vice versa. It will be observed, similarly, (see Fig. 3c) that Z_a is the mutual-reactance between B and C effective for their load currents, and that Z_b is the mutual-reactance between A and C effective for their load currents. The qualification of this mutual-reactance as load-mutual-reactance, or, as mutual-reactance effective for load-currents should be clearly recognized as follows:

In classical literature inductance, reactance, mutual-inductance, mutual-reactance are applied to quantities which relate to currents considered as magnetizing currents. In usual technical literature, especially in transformer literature, reactance has come to be used for the quantity which applies to the load currents of the transformer. When it is desired to be rigorous and explicit, distinction is made by qualifying the reactance as magnetizing-reactance for one and load or leakage-reactance for the other. Following the same analogy, there is no reason why we could not speak of magnetizing-mutual-reactance and load-mutual-reactance. The magnetizing-mutual-reactance between two windings of a transformer is usually of the order of from 1000 per cent to 2000 per cent, while the load-mutual-reactance is of the order of from a fraction of 1 per cent to 10 per cent or more. The reason why such a distinction has not been recognized before is simply because occasions calling for it have been rare. Load-mutual-reactance in a transformer requires at least three circuits, and three-circuit transformers have come into importance only within the last few years.

If the interpretation of the equivalent reactances as "common" or "mutual" reactances is grasped once, its absolute character as compared with the first interpretation will be evident. To make the discussion and proof of this interpretation more rigorous, we shall derive the mutual-reactances effective for load currents independently of the equivalent network and thereby show the identity of the two.

Equivalent Impedances Derived Analytically as Mutual Impedances

Required to find the mutual impedance between A and B effective for their load currents.

The following classical equation for leakage-reactance between two circuits A and B will be recognized

$$X_{ab} = X_a + X_b - 2\,M_{ab} \tag{25}$$

In this equation X_a and X_b are commonly interpreted as self- or magnetizing-reactances and M_{ab} is interpreted as magnetizing-mutual-reactance. Equation (**25**) holds true and can be verified by test regardless of the presence or absence of other windings, and regardless of the condition in which those other windings may be. We may therefore assume a short-circuited winding C on the same core with A and B. Now, one who is ignorant of the existence of this short-circuited winding, C, would call the measured value of X_a the self-inductive reactance of winding A, but one who is aware of the fact, would call this measured value that of X_{ac}, and the measured value of X_b that of X_{bc}. The current with which the measurements are made will be considered by the latter a load-current (not a magnetizing current) and the mutual-reactance M_{ab} will apply only to the load currents. Recognizing the existence of a short-circuited winding C explicitly, he will write:

$$X_{ab} = X_{ac} + X_{bc} - 2\,M_{ab}$$

and solving for M_{ab},

$$M_{ab} = \frac{X_{ac} + X_{bc} - X_{ab}}{2}$$

Comparing this with equation (**6**), the identity of

the equivalent reactance X_c (see Fig. 3c) with the load-mutual reactance of the circuits of A and B becomes evident.

Appendix C

Physical Explanation of Negative (Condensive) Equivalent Impedance

It has already been pointed out that one of the equivalent impedances may be negative. This would be unintelligible if considered as the straight reactance of a winding, and although not immediately self-evident when considered as a mutual-reactance, it yet becomes amenable to explanation.

A negative equivalent reactance considered as a mutual reactance raises the question: Can a circuit carrying a lagging load induce a voltage in another

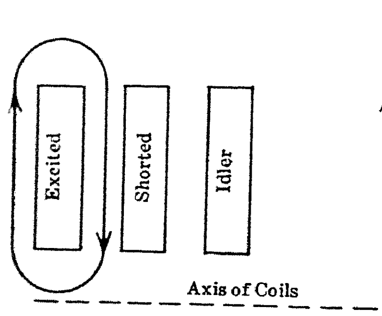

Fig. 11

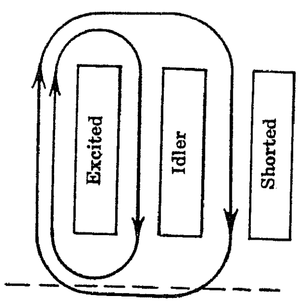

Fig. 12

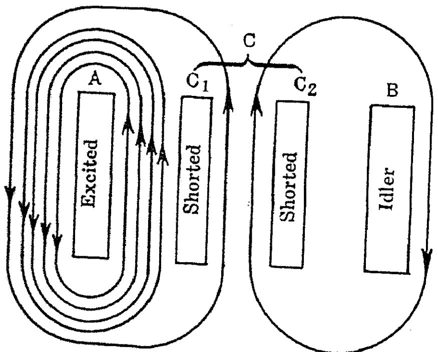

Fig. 13—Total Flux Linkages of A = + 5
Total Flux Linkages of B = − 1

circuit opposite to the voltage induced by the magnetizing current? Or, putting the question another way, can one secondary carrying a lagging load and lowering its own voltage, boost the voltage of the other secondary? Reversing the direction of the windings cannot influence this matter in the least, for, if we assume that the polarity of the idle winding in which the induced voltages are being observed is reversed, then, both the voltage induced by the magnetizing current and that induced by the load current will be reversed and thus the relative phase of the two voltages will remain unchanged. To understand the physical nature and basis of this phenomenon properly, it is necessary to examine the distribution of load- or leakage-flux in some representative cases.

Distribution of Load- or Leakage-Flux

Case I. Load-Mutual-Reactance Zero. Fig. 11 shows the distribution of load flux in a simple case: C is short-circuited, A is excited. The flux linkage being a measure of reactance, it is evident that no load or leakage-flux links B when A is carrying a current. And hence the load-mutual-reactance M_{ab} is zero. In this and the following diagrams the influence of the thickness of the conductor on reactance is ignored to simplify the discussion of the principles.

Case II. Load-Mutual-Reactance Positive. Assume as another case that the arrangement of the windings is as in Fig. 12. The flux linkages and corresponding reactances will be as follows: Assuming the distance between A and B, and that between B and C, equal,

Total net flux linkage of $A = 2 = X_{ac}$
" " " " " $B = 1 = M_{ab}$ (Positive)

In this instance, the load-mutual-reactance between A and B is one half the leakage reactance between A and C, and has the same sign.

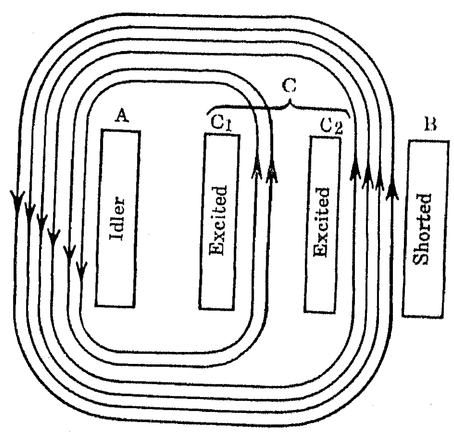

Fig. 14—Total Flux Linkages of C = 5
Total Flux Linkages of A = 6

Case III. Load-Mutual-Reactance Negative. Assume now that C consists of two coils, C_1 and C_2 in series, spaced similar to A and B, (Fig. 13). With C short-circuited and A excited, the distribution of flux and corresponding flux-linkages will be as shown in the diagram.

Assuming the spacings between coils equal:

Total net flux linkages of $A = +5 = X_{ac}$
" " " " " $B = -1 = M_{ab}$ (Negative)

Thus, it is evident that the windings may be so arranged as to produce a load-mutual-reactance which is positive, zero, or negative.

A practical aspect of the last case considered is that if the circuit of A carry zero power factor full load and its voltage *drops* 5 per cent, the voltage of B will be *boosted* 1 per cent.

Case IV. Load-Mutual-Reactance Greater than Total Leakage Reactance. A feature of load-mutual-reactance that is as interesting and important as the possibility of the load-mutual-reactance being negative, is the

possibility of it being larger than the reactance of the coil itself. That is, M_{ab} may be greater than the load or leakage reactance of A or B with respect to the primary. That mutual reactance from one coil to another (of equal turns) can be greater than its own self reactance does sound queer but its truth may easily be established.

Considering Fig. 14, where B is short-circuited and C excited, the flux linkages and corresponding reactances are as follows:

Total net flux linkages of $C = 5 = X_{cb}$

" " " " " $A = 6 = M_{ca}$

That it is possible for the mutual reactance of two coils to be larger than the self reactance of one, is true for the no-load condition as well as for the load condition. Thus, referring back to equation (**25**), if we solve for M_{12}, and ignore X_{12}, as negligibly small, we get

$$M_{12} = \frac{X_1 + X_2}{2}$$

That is, the mutual reactance is practically the mean[6] of the two self reactances and therefore larger than the lesser of the two.

The possible per cent divergence between self and mutual reactances for load currents is far greater than that for magnetizing currents.

Appendix D

Direct Testing of the Equivalent Impedances

The consideration of the equivalent impedances as mutual impedances leads readily to a convenient way of testing them directly without having to use equations (**4-6**) while the first point of view would not help so well, if at all, in this matter. For instance, considering Z_c (see Fig. 3c) as load-mutual-impedance between A and B, it follows that it ought to be possible to test it directly by putting a load current in A and measuring the voltage in B, or putting a load current in B and measuring the voltage in A.

In order that the current may be a *load* current and not a magnetizing current, it is necessary to short-circuit the third circuit C, because the distinction between a magnetizing-current and a load-current in a transformer is that a current in a winding not neutralized by an equivalent opposite current in another winding is a magnetizing current, while a current which is neutralized by an equal and opposite ampere-turns in another winding is a load current. In the present case the short-circuited winding carries the equal and opposite ampere-turns.

In obtaining the equivalent impedances directly by test, in order that their resistance and reactance components may be determined, in addition to the voltmeter reading in the idle winding and ammeter reading in the excited winding, a wattmeter reading should also be taken connecting its current coil in series with either the excited or short-circuited winding and its potential coil across the idle winding. Knowing thus the volts, watts and amperes of the load-mutual-impedance, its resistance and reactance components are calculated in the usual manner.

In as much as ordinarily the three leakage-impedances have to be tested as a matter of course as standard data, the equivalent impedances are preferably calculated from them rather than doubling the work of testing. The discussion of the method of testing them directly has been given here primarily for the sake of the light which it throws on their physical nature and interpretation.

6. This is sometimes given as geometric mean instead of arithmetic mean.

Appendix E

Single-Phase Loads and Short-Circuits on Polyphase Banks

Single-phase loads and short circuits may be divided into two classes, *viz.*, (a) those between lines, and (b) those between a line and the neutral. A review of the former is helpful in formulating the latter, and, furthermore, it may be desirable to review the phenomena of two-winding transformers before proceeding to the more complicated case of three-winding transformers.

In a polyphase network consisting of two or more different banks of apparatus, it is highly desirable to express the constants, that is, the per cent impedance of each bank, based on one assumed standard symmetrical polyphase load, and then to express the effective impedance to various single-phase or unsymmetrical loads in terms of these impedances.

A consideration which the writer finds very convenient and safe in analyzing the impedance of a polyphase network to single-phase loads and single-phase short circuits is to add up the impedance (kv-a.) of every branch of the network for the particular distribution of the assumed load-current and express this sum as a percentage of the assumed load or reference kv-a., which then is also the percentage impedance drop; instead of considering either the per cent impedance volts or the ohms in each branch, because in these latter cases there is always the troublesome question whether certain branches should be considered in series or in multiple, as ohms or voltage drops combine differently in series than in multiple, whereas the kilovolt-amperes consumed reactively can and should always be added just as the kilowatts consumed by the resistances are added up. This procedure is identical with the principle of basing the per cent resistance of a transformer on the per cent impedance watts. In using the reactive kv-a. method for the calculation of reactance drops, it is necessary to note that reactive kv-a. loss (like resistance kw. loss) varies as the square of the load.

The following theorems underly the analysis of

single-phase loads and short circuits on symmetrical polyphase systems.

Theorem I. A *single-phase* load on the lines (not through the neutral) of a symmetrical three-phase system, equal to one third of the rated (or assumed standard) polyphase kv-a. of the system, encounters a per cent impedance drop equal to two-thirds of the per cent impedance of the system for the rated (or assumed standard) kv-a. of the system.

This law holds true whether the load is limited to two line wires (Fig. 15), or to all three line wires, two lines acting as return to the remaining line (Fig. 16). This law also holds true regardless of the kind of apparatus; regardless of the type of connection of apparatus, as long as it is a symmetrical three-phase

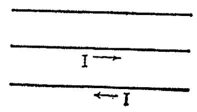

Fig. 15

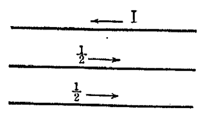

Fig. 16

connection; and, regardless of how composite the system may be. Due to structural peculiarities, generators may slightly vary from the above law, but this variation need not be considered except in very refined work. Transformers may be considered practically free from any such variation.

It will be noted that in the case of Fig. 16, the load voltage is the altitude of the triangle of the line voltages, that is, 86.6 per cent of the line voltages.

Theorem II. The per cent impedance of a three-phase apparatus, as for instance a transformer bank, to a single-phase load from one line to its neutral must be worked out specially for each particular connection. However, on the primary side, this single-phase load is transferred to the lines and therefore the impedance

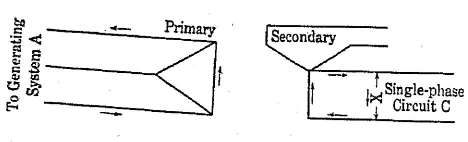

Fig. 17

of the system connected to the primary lines follows the law of Theorem I.

If the neutrals of a number of apparatuses are connected together, as for instance by grounding a system at a number of points, these apparatuses must be considered in parallel for a line-to-neutral load or short circuit.

Theorem III. A line-to-neutral single-phase load distributes itself in such a way as to encounter the minimum impedance drop. When it is possible for the load to distribute itself without magnetizing the transformer core, it does so distribute itself.

Theorem IV. Two interconnected polyphase systems divide any kind of a load, including single-phase loads and short circuits in accordance with the general formulas developed in the foregoing for double-primary three-circuit transformers, as will be illustrated in due course.

The more important connections for line-to-neutral loads and short circuits are the *Y*-delta or delta-*Y* connection, and the interconnected *Y* or Zig-Zag connection, in two-circuit transformers; and, *Y*-*Y*-delta tertiary connection in three-circuit transformers.

Two-Circuit Transformers interconnecting Two Generating Systems, when Loaded Line-to-Neutral, become a Three-Circuit-Transformer Problem. All voltages, currents and impedances in the following discussions are in percentages unless otherwise specified. The per cent marks (%) are omitted for simplicity.

(I) Delta-Primary, Y-Secondary Connection

Assume a single-phase line-to-neutral load (Fig. 17) equal to the kv-a. rating of one leg, or, one-third of the polyphase kv-a. rating of the bank. It is evident that there will be current in only one leg, and will be equal to the rated current of that leg. Designating the per cent impedance of the transformer for rated symmetrical polyphase load, Z_T; and, that of the system A, to which the primary lines are connected,

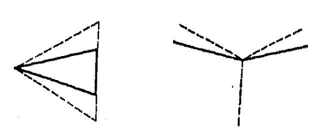

Fig. 18

Z_A; the per cent impedance drop for this single-phase power flowing from system A to the load circuit C equal to the kv-a. rating of one leg, will be,

$$Z_{AC} = Z_T + 2/3\, Z_A \tag{25}$$

Hence, for a line-to-neutral single-phase short-circuit,

$$\text{Short Circuit kv-a.} = E/Z_{AC} \times \text{Rated kv-a.} \tag{26}$$

Current in short circuit

$$= E/Z_{AC} \times \text{Rated line current on } Y \text{ side} \tag{27}$$

The per cent regulation on primary side across the loaded lines follows at once as

$$\text{Regulation} = (2/3)\ (Z_A/Z_{AC})\ E \tag{28}$$

Example. A 15,000 kv-a. bank of step-down delta-*Y* transformers having 8 per cent impedance at rated polyphase load is connected to a 25,000 kv-a. generating system having 20 per cent impedance at its rated load. The latter includes the impedances of the generators, step-up transformers, lines and any other apparatus in series with the system.

Since the kv-a. rating of transformer bank and system are different, it is desirable to reduce the impedances to a common kv-a. basis.

Let the kv-a. basis be 15,000 kv-a. Then, the transformer impedance will be the same as before.

Z_T = 8 per cent

The system impedance will be less in the ratio of 15,000/25,000, making

Z_A = 15,000/25,000 × 20 per cent = 12 per cent

The effective impedance for a 5000-kv-a. single-phase load on circuit C will be:

Z_{AC} = 8 per cent + 2/3 × 12 per cent = 16 per cent

Assuming 100 per cent voltage on the system,

Short-Circuit kv-a. = 100/16 × 5000 = 31,200 kv-a.

Current in the Short Circuit = 100/16 × Rated line current (Y side) for 5000 kv-a. per leg.

Regulation across loaded lines on delta side = 2/3 × 12/16 × 100 = 50 per cent.

The short-circuit voltage diagram for this case is shown in Fig. 18 in heavy lines. Dotted lines show the normal voltages on no-load.

(II) Y-Primary, Delta-Secondary Connection

Referring to Fig. 19 it will be seen that with a single-phase load in circuit C equal to the kv-a. rating of one leg, the load in each leg is only one-third its rated load. The reactive kv-a. consumed in each leg is one-ninth of that at full rated load and the reactive

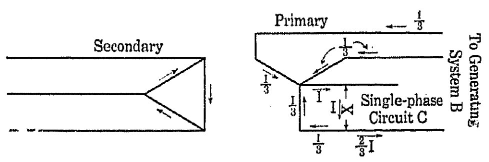

Fig. 19

kv-a. consumed in the three legs is three times this, that is, one-third of the normal reactive kv-a. in one leg at its rated load. The per cent reactance of one leg at rated load is Z_T, and, therefore, the per cent impedance of this bank for a single-phase line-to-neutral load equal to the kv-a. rating of one leg is $Z_T/3$. The impedance of system B to which the primary Y is connected has an impedance 2/3 Z_B for this single-phase load.

Therefore,

$$Z_{BC} = 1/3\, Z_T + 2/3\, Z_B \tag{29}$$

Short-Circuit kv-a. = E/Z_{BC} × Rated kv-a. of one leg (30)

Current in short circuit = E/Z_{BC} × Rated line current (31)

The per cent regulation on the delta side across the short-circuited phase is

$$\text{Regulation} = 2/3\, Z_B/Z_{BC}\, E \tag{32}$$

Example: Assume the same transformers as before.

Let system B be rated 50,000 kv-a. 25 per cent impedance at rated load. On a 15,000 kv-a. base, its impedance will be (15,000/50,000) 25 per cent, or 7.5 per cent.

Then,

$$Z_{BC} = 8/3 + 2/3 \times 7.5 = 7.667 \tag{33}$$

Total short-circuit kv-a. = 100/7.667 × 5000 = 65,200 (34)

The kv-a. in each leg is one-third of this.

The regulation on the delta side across the short-circuited phase is,

Regulation = 2/3 × 7.5/7.667 × 100 = 65.2 per cent (35)

The short-circuit voltage diagram is shown in Fig. 20.

It follows from the regulation formula that if the impedance of the generating system were negligible compared with that of the short-circuited transformer,

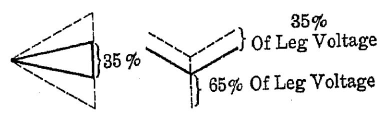

Fig. 20

the line-to-neutral short-circuit on the Y side would not in the least affect the voltages across the delta secondary. This is an interesting feature and has an application in the following case.

(III) Delta-Y Transformer Interconnecting Two Generating Systems, Fig. 21

It was seen in the discussion of Case II that if the generating system on the Y side (System B) had negligible impedance compared with the transformer, the voltages on the delta side would be unchanged from no-load to a line-to-neutral short circuit. It follows, therefore, that in such a case, whether the delta side is connected to a generating system or not would make no

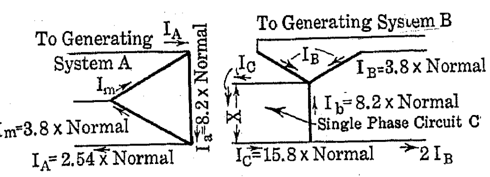

Fig. 21

difference to line-to-neutral loads and short circuits, and all such loads and short circuits will be furnished entirely by the system on the Y side. However, it is not very often that the system impedance can be ignored as compared with the transformer impedance, and it is therefore desirable to take it into consideration, and the problem may be tackled very conveniently as follows:

With the load circuit C, and interconnected generating systems A and B (Fig. 21), it is to be noted that we have a veritable case of a three-circuit transformer, consisting of two primary circuits and one secondary circuit, and, therefore, we may confidently apply the three-circuit transformer formulas to the present case.

As has already been seen, the impedance of the load circuit in conjunction with either generating system is

$$Z_{AC} = Z_T + 2/3\, Z_A \tag{36}$$

$$Z_{BC} = 1/3\, Z_T + 2/3\, Z_B \tag{37}$$

Also $$Z_{AB} = 2/3\, Z_A + 2/3\, Z_T + 2/3\, Z_B \tag{38}$$

The last equation is in accordance with Theorem I, and refers to single-phase kv-a. flowing from one system into the other equal to one-third of the assumed standard three-phase kv-a.

Example: Assume the various constants used in the examples of cases (1) and (2).

$$Z_{AC} = 16 \text{ per cent} \tag{39a}$$

$$Z_{BC} = 7.667 \text{ per cent} \tag{39b}$$

$$Z_{AB} = 2/3\,(12 + 8 + 7.5) = 18.3 \text{ per cent} \tag{39c}$$

The various impedances of the equivalent circuit (Fig. 3c) are by formulas 4, 5, 6,

$$Z_A = \frac{Z_{AB} + Z_{AC} - Z_{BC}}{2} = 13.32 \text{ per cent} \tag{40a}$$

$$Z_B = \frac{Z_{AB} + Z_{BC} - Z_{AC}}{2} = 5 \text{ per cent} \tag{40b}$$

$$Z_C = \frac{Z_{AC} + Z_{BC} - Z_{AB}}{2} = 2.68 \text{ per cent} \tag{40c}$$

The impedance of the whole combination, effective at the short circuit, is, by formula 24,

$$Z_{short} = \frac{Z_{AC}\, Z_{BC} - Z_C^2}{Z_{AB}} = 6.32 \text{ per cent} \tag{41}$$

Assuming 100 per cent line voltage, the short-circuit kv-a. is 100/6.32, that is, 15.8 times 5000 kv-a., which equals 79,000 kv-a. Of this the share of each generating system is,

$$(\text{kv-a.})_A = Z_B/Z_{AB} \times 79{,}000 = 21{,}500 \text{ kv-a.} \tag{42a}$$

$$(\text{kv-a.})_B = Z_A/Z_{AB} \times 79{,}000 = 57{,}500 \text{ kv-a.} \tag{42b}$$

(IV) Interconnected *Y* or Zig-Zag Connection

Referring to Fig. 22, let Z_t be the per cent impedance between the two coils on one leg of the apparatus acting as a single-phase transformer. When the two coils are connected in series as a zig-zag auto transformer, the impedance in per cent of the load voltage (line-to-neutral voltage) becomes $Z_t/1.73$. With normal rated line current in the single-phase line-to-neutral circuit *C*, making the load kv-a. equal to the rated kv-a. per leg, the current in each leg is only one-third normal, the impedance kv-a. in each leg one-ninth normal in the three legs one-third normal. Hence, the effective impedance of the apparatus for circuit *C* is one-third normal, that is $Z_t/(1.73 \times 3) = Z_t/5.2$. If we designate the impedance of the generating system for the rated symmetrical load of the apparatus by Z_A, its effective impedance for a single-phase load equal to the rated kv-a. per leg will be two-thirds of this, that is, $2\, Z_A/3$. The net effective impedance for the circuit *C* is thus,

$$Z_{AC} = 2/3\, Z_A + 1/5.2\, Z_t \tag{43}$$

$$\text{Short circuit } I = \frac{E}{2/3\, Z_A + 1/5.2\, Z_t} \times \text{Rated } I \tag{44}$$

The current in the coils is one-third of this as indicated in Fig. 22.

(V) *Y*-*Y*-Delta Connection

(1) *Y-Primary, Y-Secondary, Delta Secondary.*

(a) Line-to-neutral single-phase load (or short circuit) on the primary *Y*. (Fig. 23).

Since the secondary *Y* circuit takes no part in the

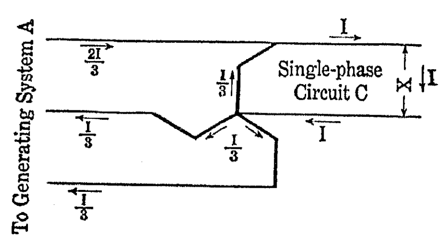

Fig. 22

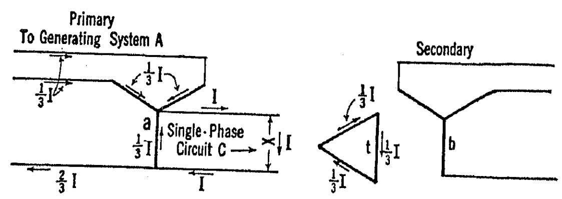

Fig. 23

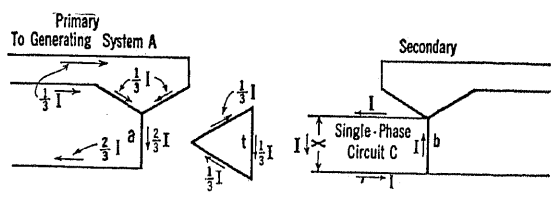

Fig. 24

phenomena under consideration, it will be seen, especially on comparing Fig. 23 with Fig. 10, that this is the same as the case of two-winding *Y*-primary delta-secondary transformer.

Representing the impedance between *Y*-primary and delta tertiary by Z_{at} based on the rated symmetrical polyphase kv-a. of the *Y*, the effective impedance between system *A* and circuit *C* for a single-phase load equal to one-third of the rated polyphase load will be, similar to the case referred to,

$$Z_{AC} = 1/3\, Z_{at} + 2/3\, Z_A \tag{45}$$

where Z_A is the impedance of the generating circuit *A*.

(b) Line-to-neutral single-phase load (or short circuit) on the secondary *Y*. (Fig. 24).

Designating the symmetrical three-phase impedance

between secondary and tertiary by Z_{bt}, the impedance between system A and circuit C, for a load equal to one-third of the polyphase rating, will be

$$Z_{AC} = 2/3\, Z_{ab} + 1/3\, Z_{bt} + 2/3\, Z_A \tag{46}$$

Short circuit kv-a. $= E/Z_{AC} \times$ Rated kv-a. per leg (47)

Current in short circuit $= E/Z_{AC} \times$ Rated line current (48)

The current in the different windings and lines may be readily calculated from the current in the short circuit with the aid of the diagram (Fig. 24). Note

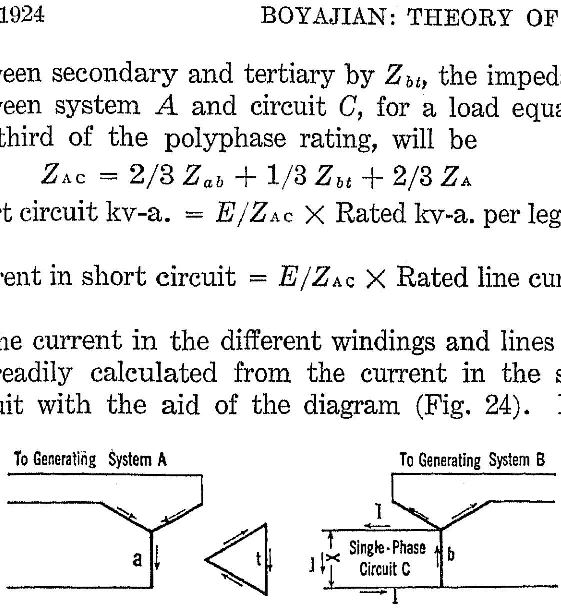

FIG. 25

that the diagram assumes one-to-one ratio on each leg.

(2) *Both (Y)s Connected to Generating Systems, Delta Secondary.* (*Fig.* 25).

Single-Phase Load, Line-to-Neutral, on Either Y

Let the side to which the single-phase load is connected be designated system B; the other side, system A (Fig. 25).

The impedance of either primary system with respect to the circuit C, by itself, would be

$$Z_{AC} = 2/3\, Z_A + 2/3\, Z_{ab} + 1/3\, Z_{bt} \tag{49}$$

$$Z_{BC} = 2/3\, Z_B + 1/3\, Z_{bt} \tag{50}$$

Also $$Z_{AB} = 2/3\,(Z_A + Z_B + Z_{ab}) \tag{51}$$

The equivalent impedances of each circuit will be,

$$Z_A' = \frac{Z_{AB} + Z_{AC} - Z_{BC}}{2} \tag{52a}$$

$$Z_B' = \frac{Z_{AB} + Z_{BC} - Z_{AC}}{2} \tag{52b}$$

$$Z_C' = \frac{Z_{AC} + Z_{BC} - Z_{AB}}{2} \tag{52c}$$

the values of the three impedances on the right to be taken from the preceding equations:

The net effective impedance of the combination of the two generating systems and transformer for the load (or short circuit) in circuit C is, by formula (**24**),

$$Z_{short} = \frac{Z_{AB}\, Z_{BC} - Z_C'^2}{Z_{AB}}$$

The kv-a. drawn by a line-to-neutral short circuit is:

Short circuit kv-a. $= E/Z_{short} \times$ Rated kv-a. per leg.

Of this kv-a. the part furnished by each generating system is (by formulas **21** and **22**).

(Short circuit kv-a.)$_A$ $= Z_B'/Z_{AB}$ $\times$ Total short circuit kv-a.

(Short circuit kv-a.)$_B$ $= Z_A'/Z_{AB}$ $\times$ Total short circuit kv-a.

Knowing the (single-phase) short-circuit kv-a. in each generating system, the line currents follow. It should be remembered that for a single-phase load (or short circuit) as in Fig. 16, the corresponding voltage is 86.6 per cent of the line voltage.

The current in the short circuit is

$I_s = E/Z_{short} \times$ Rated line current

Of this current the part furnished by each generating system is, by formulas (**21**) and (**22**),

$(I_s)_A = Z_B'/Z_{AB} \times I_s$

$(I_s)_B = Z_A'/Z_{AB} \times I_s$

Knowing the currents $(I_s)_A$ and $(I_s)_B$, the corresponding currents in the various parts of the network may be calculated, although the method of calculation by kv-a. is preferable as no turn ratios, etc., need then be considered.

Example. A Y-Y connected auto transformer interconnects a 66,000-volt system (system A) with a 114,000-volt system (system B), the neutral of the auto transformer being solidly grounded: see Fig. 26. An auxiliary delta winding is provided to lower the impedance of the transformer for line-to-neutral loads and also to supply a load.

The various constants of the circuits based on an output of 5000 kv-a. per phase are:

$Z_{at} = 10.6$ per cent

$Z_{bt} = 8.3$ per cent

$Z_{ab} = 8.65$ per cent

Let the generating system impedances for 5000 kv-a. per phase be

$Z_A = 3$ per cent

$Z_B = 2$ per cent

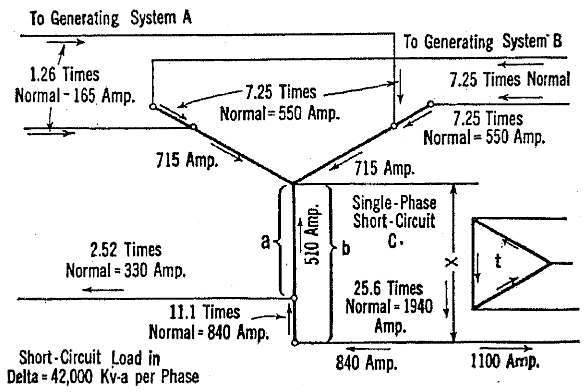

FIG. 26

If one of the high-voltage lines (system B) becomes grounded, (short circuit at C), what will be the short-circuit current and kv-a. and how will they divide between the two systems?

The total impedance between generating system A and circuit C (Fig. 26) ignoring system B, by equation (**46**) which is based on (Fig. 24).

$$Z_{AC} = 2/3 \times 8.65 + 1/3 \times 8.3 + 2/3 \times 3 = 10.5 \text{ per cent}$$

The impedance between system B and circuit C

ignoring system A, is, by equation (**45**) (changing letter a to b, to $A\,B$) which is based on (Fig. 23).

$Z_{BC} = 1/3 \times 8.3 + 2/3 \times 2 = 4.1$ per cent

By equation (**51**)

$Z_{AB} = 2/3\,(3 + 2 + 8.65) = 9.1$ per cent

From these follow the equivalent impedances of the respective circuits: (see Fig. 3c)

$$Z_A' = \frac{9.1 + 10.5 - 4.1}{2} = 7.75 \text{ per cent}$$

$$Z_B' = \frac{9.1 + 4.1 - 10.5}{2} = 1.35 \text{ per cent}$$

$$Z_C' = \frac{10.5 + 4.1 - 9.1}{2} = 2.75 \text{ per cent}$$

The impedance of the total combination effective for the circuit C is, by equation (**24**),

$$Z_{short} = \frac{10.5 \times 4.1 - 2.75^2}{9.1} = 3.9 \text{ per cent}$$

With an effective impedance of 3.9 per cent at a 5000 kv-a. load, evidently the short-circuit kv-a. at 100 per cent system voltage will be 100/3.9 times, that is, 25.6 times 5000 kv-a., or 128,000 kv-a.; and the current *in the short-circuit* will be 25.6 times the normal line current corresponding to 5000 kv-a. per phase, or $25.6 \times 75.8 = 1940$ amperes.

The part of this current and kv-a. furnished by each system is, by formulas (**21**) and (**22**),

Part of System $A = Z_B'/Z_{AB} = 1.35/9.1 = 0.148$
$= 14.8$ per cent $= 0.148 \times 128{,}000$ kv-a.
$= 19{,}000$ kv-a.

Part by System $B = 100 - 14.8 = 85.2$ per cent
$= 0.852 \times 128{,}000$ kv-a. $= 109{,}000$ kv-a.

The currents in the two systems (see Fig. 26) may be obtained either from their share of the short-circuit current or from their share of the short-circuit kv-a. as follows:

System A, delivering 19,000 kv-a. single-phase at 86.6 per cent of 66,000-volt line voltage will have a current of $19{,}000/0.866 \times 66 = 330$ amperes on one line, and half of this in each of the other two lines acting as joint return to the first line (see Fig. 26), System B, delivering 109,000 kv-a. single-phase at 86.6 per cent of 114,000 volts line voltage, will have a current of $109{,}000/0.866 \times 114 = 1100$ amperes in one line, and half of this in each one of the other two lines jointly acting as return to the first line.

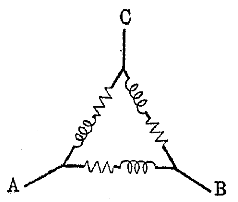
Appendix F

Theory of Four- and N-Circuit Transformers Equivalent Network

The star network described in the preceding pages is not the only equivalent network for a three-circuit transformer. The network could also be a mesh or delta (see Fig. 27) as well as a star or Y. Of course, the values of the links in the delta network are not the same as those in the Y network. For the same reason, the two physical interpretations which hold for the Y or star network do not hold for the delta or mesh network. It was on account of its simpler physical interpretation and also simpler mathematical manipulation that only the Y network was considered in the theory of the three-circuit transformer. However, the mesh network is here mentioned as an introduction to the N-circuit transformer, because it appears that the alternatives available in the case of the three-circuit transformer are not available in the case of N-circuit transformers: that is, the simplification afforded by the use of a star instead of a mesh network is not open to higher number of circuits, but an essentially mesh network must be used.

In constructing equivalent network, the following conditions must be satisfied:

1. The diagram must have as many terminal points as there are circuits.
2. The diagram must be symmetrical for every one of these terminals.
3. Since in an N-circuit transformer there are $N\,(N-1)/2$ leakage impedances to be reckoned with,



Equivalent Mesh Network of Three Circuit Transformer

Fig. 27

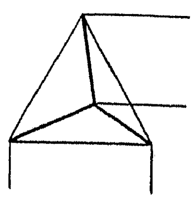


Fig. 28

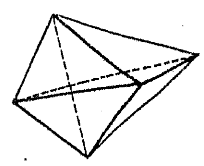

Fig. 29

therefore, the equivalent network must have $N\,(N-1)/2$ variables or impedance links. Diagrams for a number of such circuits, up to eight circuits, are tabulated below. All the diagrams, except the first, are represented by three-dimensional figures, like basket work, to bring out clearly their symmetry. Of course, the essential facts are the number of terminals and the number of links. That the figure is three-dimensional has no further significance whatever, beyond aiding in seeing the symmetry, and may just as well be considered a flat diagram if desired. Every pair of terminals or "corners" are supposed to be connected by a line representing one impedance link. Some of the lines which would be invisible in a solid are omitted so as not to obscure the general appearance of the figure.

Fig.	27	28	29	30	31	32
Number of circuits	3	4	5	6	7	8
" " terminals or corners	3	4	5	6	7	8
" " links	3	6	10	15	21	28
Links terminating at each corner	2	3	4	5	6	7

The value of each impedance link has to be solved as follows:

Considering Fig. 27,

$$\frac{1}{1/Z' + \dfrac{1}{Z'' + Z'''}} = Z_{AB}$$

$$\frac{1}{1/Z''' + \dfrac{1}{Z' + Z''}} = Z_{AC}$$

$$\frac{1}{1/Z'' + \dfrac{1}{Z' + Z'''}} = Z_{BC}$$

Since the number of the impedance links increases faster than the square of the number of the external circuits, these equations increase in complexity very rapidly with increasing number of external circuits. In practical problems some of the labor can be saved by the use of a short-circuit calculating board, but the constants to be set-up on the board, *i. e.*, the values of the impedance links, have to be calculated.

The problem of the N-circuit transformer can be simplified if, instead of solving for the most general case in which no assumption is made as to which circuit or circuits are primary and which secondary, the nature of each circuit and its load is known, as will be illustrated below.

Four-Circuit Transformers. In considering the effect of the load in one secondary on other windings, a primary winding is always implied. In a three-circuit transformer this is unmistakable, because, in speaking of the mutual impedance between one secondary winding and another, there is only one winding left to act as primary. But in a four-circuit transformer, since there are two other circuits besides the two designated in the subscript of M_{ab}, the third circuit must be

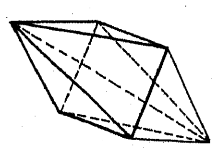

FIG. 30

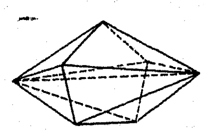

FIG. 31

explicitly stated, such as M_{ab-c} or M_{ab-d}. The general formula for M then is:

$$M_{ab-c} = \frac{X_{ac} + X_{bc} - X_{ab}}{2}$$

$$M_{ab-d} = \frac{X_{ad} + X_{bd} - X_{ab}}{2}$$

etc. Similarly for the resistance components.

Assume that A, B and C are secondary, D primary. The total vector impedance drop in any secondary due to simultaneous loads in all the secondaries will be,

$$e_a = I_a Z_{ad} + I_b M_{ab-d} + I_c M_{ac-d}$$
$$e_b = I_a M_{ab-d} + I_b Z_{bd} + I_c M_{bc-d}$$
$$e_c = I_a M_{ac-d} + I_b M_{bc-d} + I_c Z_{cd}$$

The extension to N-circuit transformers is evident: thus, calling the primary P, and the secondaries a, b, c, etc.

$$e_a = I_a Z_{ap} + I_b M_{ab-p} + I_c M_{ac-p} + I_d M_{ad-p} + \ldots \text{etc.}$$

A point of refinement to be considered in these

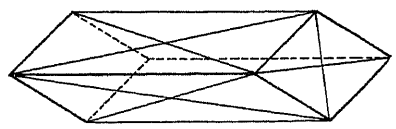

FIG. 32

equations is this, that in obtaining the impedance drop in A, the power factors of the loads in every circuit should be referred to the terminal voltage of A, not to the terminal voltages of the respective circuits. If referred to the terminal voltage of the respective circuits, the result will be only approximate.

Appendix F

COLLECTED FORMULAS AND SYMBOLS

1. *Equivalent Impedance.* Given the total impedance of each pair of windings or circuits as primary secondary, the equivalent impedance of each individual winding or circuit is,

$$Z_a = \frac{Z_{ab} + Z_{ac} - Z_{bc}}{2}$$

$$Z_b = \frac{Z_{ab} + Z_{bc} - Z_{ac}}{2}$$

$$Z_c = \frac{Z_{ac} + Z_{bc} - Z_{ab}}{2}$$

These equations are vectorial. To obtain the resistance components, substitute R instead of Z; for the reactance components, X instead of Z.

If the calculation is to be made in terms of ohmic values, all the values to be substituted above should be "converted" or reduced to a common voltage basis. If the data are available in percentage form, they may be directly substituted.

When a circuit has an independent winding, and stray losses are negligible or easily estimated, the effective resistance of the circuit is the same as the effective resistance of its winding.

In auto transformers and other complicated connections, care should be taken that the impedance data used should be those effective at the terminals of the circuits under consideration.

2. *Regulation.* The equivalent impedance of each circuit is conceived of as the impedance between itself

and the magnetic neutral of the unit, as shown in the diagrams of equivalent networks. Hence,

Calculate (*a*), the regulation from each secondary terminal to the neutral, and (*b*), from the neutral to each primary terminal, by the following formula

$$\% \text{ Reg.} = k\, m\, \%\, I\, R + k\, n\, \%\, I\, X + \frac{(k\, m\, \%\, I\, X - k\, n\, \%\, I\, R)^2}{200}$$

in which k is the ratio of actual load or current in the branch to that load or current on which the $\%\, I\, R$ and $\%\, I\, X$ of the branch are based, m is the power factor of the load in the branch, and n its reactive factor. Regulation may be positive or negative and its algebraic sign must not be ignored. For secondary and tertiary circuits, k, m and n are ordinarily given, but for the primary they must be calculated, and the following equations may be used. Designating primary by "1," secondary by "2" and tertiary by "3."

$$(k\, m)_1 = (k\, m)_2 + (k\, m_3) \quad \text{Approx.}$$
$$(k\, n)_1 = (k\, n)_2 + (k\, n)_3 \quad \text{Approx.}$$

or, more precisely.

$$(k\, m)_1 = k_2 \left(m_2 + k_2 \frac{\%\, I\, R_2}{100} \right) + k_3 \left(m_3 + \frac{k_3\, \%\, I\, R_3}{100} \right)$$

$$(k\, n)_1 = k_2 \left(n_2 + \frac{k_2\, \%\, I\, X_2}{100} \right) + k_3 \left(n_3 + \frac{k_3\, \%\, I\, X_3}{100} \right)$$

$$\% \text{ Reg}_{12} = \% \text{ Reg}_{1n} + \% \text{ Reg}_{n2}$$
$$\% \text{ Reg}_{13} = \% \text{ Reg}_{1n} + \% \text{ Reg}_{n3}$$
$$\% \text{ Reg}_{23} = \% \text{ Reg}_{2n} - \% \text{ Reg}_{3n}$$

ALTERNATIVE METHOD

The following alternative method of calculating regulation may be preferred by some. This gives the total regulation of either secondary, $\% \text{ Reg}_{12}$, or tertiary, $\% \text{ Reg}_{13}$, in one step:

$$\% \text{ Reg}_{12} = k_2\, m_2\, \%\, I\, R_{12} + k_2\, n_2\, \%\, I\, X_{12} + k_3\, s_3\, \%\, I\, R_1 + k_3\, t_3\, \%\, I\, X_1 + \frac{(k_2\, m_2\, \%\, I\, X_{12} - k_2\, n_2\, \%\, I\, R_{12} + k_3\, s_3\, \%\, I\, X_1 - k_3\, t_3\, \%\, I\, R_1)^2}{200}$$

$$\% \text{ Reg}_{13} = k_3\, m_3\, \%\, I\, R_{13} + k_3\, n_3\, \%\, I\, X_{13} + k_2\, s_2\, \%\, I\, R_1 + k_2\, t_2\, \%\, I\, X_1 + \frac{(k_3\, m_3\, \%\, I\, X_{13} - k_3\, n_3\, \%\, I\, R_{13} + k_2\, s_2\, \%\, I\, X_1 - k_2\, t_2\, \%\, I\, R_1)^2}{200}$$

in which formulae, k, m and n have the same meanings as before,

s_2 = Power factor of secondary load with respect to tertiary terminal voltage.
$= (m_2\, m_{23} - n_2\, n_{23})$. For m_{23} and n_{23} see below.

s_3 = Power factor of tertiary load with respect to secondary terminal voltage.
$= (m_3\, m_{23} + n_3\, n_{23})$.

t_2 = Reactive factor of secondary load with respect to tertiary terminal voltage.
$= (n_2\, m_{23} + m_2\, n_{23})$.

t_3 = Reactive factor of tertiary load with respect to secondary terminal voltage.
$= (n_3\, m_{23} - m_3\, n_{23})$.

n_{23} = Reactive factor (*i. e.*, sine) of the angle between secondary and tertiary terminal voltages.
$= 1/100\, (k_2\, m_2\, \%\, I\, X_2 + k_3\, n_3\, \%\, I\, R_3 - k_2\, n_2\, \%\, I\, R_2 - k_3\, m_3\, \%\, I\, X_3)$.

m_{23} = Power factor (*i. e.*, cosine) of the angle between secondary and tertiary terminal voltages.
$= \sqrt{1 - n_{23}^2}$

3. *Division of Load.* If A and B are two circuits similar in function, as both primary or both secondary, and if the division of total kv-a. load between them is not externally controlled, it takes place in accordance with the following formulas:

$$(\text{kv-a.})_A / (\text{kv-a.})_{total} = Z_B / Z_{AB}$$
$$(\text{kv-a.})_B / (\text{kv-a.})_{total} = Z_A / Z_{AB}$$

4. *Short-Circuit Impedance.* With two primary circuits A and B simultaneously excited, and with a short-circuit across secondary C, the effective impedance which determines the total short-circuit current and kv-a. is

$$Z_{short} = \frac{Z_{ac}\, Z_{bc} - Z_c^2}{Z_{ab}}$$

Although the equation is strictly vectorial, sufficiently close results may be obtained ordinarily by substituting reactance instead of resistance in this formula.

5. *Impedance of Generator Circuit.* Since generating systems are supposed to be equipped with proper voltage regulators to maintain the primary voltages constant, the impedances of generator circuits are ignored in the calculation of regulation, but they should not be ignored in the calculation of short circuits unless they are negligibly small. To include the impedance of the generating circuit, add it to the equivalent impedance of the primary to which it is connected.

6. For various cases of unsymmetrical loads and short circuits on symmetrical systems, refer to the body of the paper.

Discussion

P. L. Alger: Mr. Boyajian's theory of three-circuit transformers applies to the induction motor as well as to the transformer. His three-circuit transformer is the same in theory as the double-squirrel-cage induction motor, and the same phenomenon of a negative reactance which occurs in his diagrams also occurs in the equivalent circuit of the motor.

It is very interesting to review these analogies which occur between related branches of engineering and utilize them in extending one art to keep up with the others. I believe that this paper of Mr. Boyajian's may be of material assistance in extending our knowledge of the complicated phenomena of the multiple squirrel-cage induction motor.

H. L. Cole (by letter): The subject of multiple winding transformers is becoming of greater importance as the networks of power systems increase in number and size. Up to the last few years it has been of importance mainly to the design engineer, by whom the various loading and short-circuit conditions have to be studied in order that such special transformers will meet the electrical, mechanical and thermal conditions imposed upon them in service. The large number of applications of multiple winding transformers in recent years has shown the necessity of studying the relation of the transformer impedances to those of the rest of the system to which it is connected, as brought out by Mr. Boyajian. The paper covers a large field of study, and will prove a useful reference on the subject.

In Appendix E (V) there is one case of short-circuit conditions in which I do not entirely agree with the author's analysis. Equation (**46**), which gives the impedance between system A and circuit C as

$$Z_{AC} = 2/3\, Z_{ab} + 1/3\, Z_{bt} + 2/3\, Z_A$$

should be $Z_{AC} = 2/3\, Z_{ab} + 2/9\, Z_{at} + 1/9\, Z_{bt} + 2/3\, Z_A$

In this way, the effect of the impedance Z_{At}, which is a factor in limiting the current in circuit C, is taken into account.

A. Boyajian: I have checked and reaffirmed the correctness of the equation (**46**) which Mr. Cole has criticised. I am afraid that the alternative equation which he offers is in error.

My equation is given in a form suitable for all interleaved transformers (whether shell or core type), irrespective or whether the tertiary is between the primary and secondary or outside. The equation which Mr. Cole offers is in a form which I believe presupposes a definite location for the tertiary. If we correct the first term of his equation, changing it from $2/3\ Z_{at}$ into $4/9\ Z_{ab}$, it will fit the case of an external tertiary, and is then reducible into my equation. Thus, referring to the attached sketch, and making use of the principle that reactive kv-a. consumed, varies as the square of the current (as explained and illustrated in my paper), we get the following results:

(1), Since the density in the gap between a and b, on the vertical phase, is $^2/_3$ normal, the reactive kv-a. consumed thereby will be $4/9\ Z_{ab}$; (2) the density between b and t, on the vertical phase, is $\frac{1}{3}$ normal, and therefore the reactive kv-a. consumed thereby will be $1/9\ Z_{bt}$; (3), on the other two phases between a and t the density is $\frac{1}{3}$ normal, the reactive kv-a. consumed in each is 1/9 normal, and therefore for the two legs we have $2/9\ Z_{at}$. Adding these three items, the effective reactance of the transformer itself, exclusive of that of generating system A, will be,

$$Z_{eff} = \frac{4}{9} Z_{at} + \frac{2}{9} Z_{at} + \frac{1}{9} Z_{bt}$$

This equation differs from that of Mr. Cole in the coefficient of the first term, having 4/9 instead of 2/3, and is reducible into equation (**46**). Thus, since

$$Z_{at} = Z_{ab} + Z_{bt}$$

to a very close approximation; making this substitution,

$$Z_{eff} = \frac{4}{9} Z_{ab} + \frac{2}{9} (Z_{ab} + Z_{bt}) + \frac{1}{9} Z_{bt}$$

$$= \frac{2}{3} Z_{ab} + \frac{1}{3} Z_{bt}$$

which is equation (**46**), less $2/3\ Z_A$, the impedance of the generating circuit.

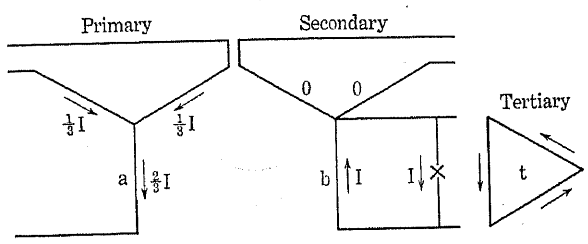

FIG. 1

If the tertiary delta be assumed located between primary and secondary, as shown in Fig. 24 of the paper, we get: (1), on vertical phase, between a and t, $4/9\ Z_{at}$; (2), between b and t, Z_{bt}; and, (3), in the other two phases, $2/9\ Z_{at}$. Adding these three items,

$$Z_{eff} = \frac{4}{9} Z_{at} + Z_{bt} + \frac{2}{9} Z_{at}$$

$$= \frac{2}{3} Z_{at} + Z_{bt}$$

But, $Z_{at} = Z_{ab} - Z_{bt}$. Hence, making this substitution,

$$Z_{eff} = \frac{2}{3} Z_{ab} + \frac{1}{3} Z_{bt}$$

which again is equation (**46**), less $2/3\ Z_A$, the impedance of the generating circuit.

Equation (**46**) being thus applicable to a very close approximation to the case of the inside as well as of the outside tertiary, it is applicable in general, and is desirable on account of its simplicity. It is also evident that Z_{at} enters into the equation indirectly, in terms of Z_{ab} and Z_{bt}, by virtue of its relationship to them.

Hydroelectric Practises and Equipment of the South

O. G. THURLOW AND J. A. SIRNIT
Non-member Member, A. I. E. E.
Both of Alabama Power Co., Birmingham, Ala.

UNTIL a short time ago little thought was given to the hydroelectric possibilities in the South and still less was its economic value appreciated. Coal was cheap and easily obtainable. Consequently, power could be generated cheaper with coal than by water. It is, therefore, an everlasting tribute to those pioneers with vision and courage, who in the face of such adverse conditions ventured into developing water powers and laid the foundations for the great hydroelectric developments that we have today in the South.

Hydraulic Power Resources of the South

The rivers of the Southeastern section of the country and their tributaries, originating on the southern part of the Appalachian Highlands, not having the perpetual snows, depend solely upon the seasonal and periodical precipitation for maintaining their flow. The average annual precipitation, which is greater than in any other part of the United States, ranges between 40 in. and 80 in.

Although this region is for the most part heavily timbered, which tends to prevent sudden run-offs and equalize the river flows, the rivers are subject to high variations in flow. The daily hydrograph of the Coosa River at Lock 12 for the year 1922, illustrates clearly the fluctuations of the river, and is typical of most of the southern rivers. Some rivers have even a greater flow variation, as for example, the Tennessee River, which has a flow ranging from 7200 second ft. minimum to 430,000 second ft. maximum, recorded at Florence, Alabama.

The ratio of rainfall to the run-off has also almost as wide a variation as the river flow itself. It varies with the location and also with the amount of rainfall. While at the headwaters the ratio is 3:2 or better, in the lower foothills it varies from 4:1 to 2:1, the highest ratio prevailing in dry seasons or years, the lowest in wet periods.

The following table gives rainfall and run-off data on the Upper Coosa basin for different representative years:

Year	Rainfall Inches	Run-off Inches	Approximate Ratio
1904—dry	40	9.5	4:1
1906—wet	63	30	2:1
1912— "	63	30	2:1
1916—average	47	18	2½:1

For the most part, these rivers yield only run-off river power with very little primary, but a large amount of secondary power when supplemented with steam power or power from storage reservoirs, can be utilized wholly or in part to good advantage. Practically every river on its headwaters or on its tributaries has one or more possibilities for developing storage reservoirs, a number of which has already been developed. The principal storage developments already in operation are those of the Southern Power Company on the headwaters of Catawba River with a storage capacity of 13,500,000,000 cu. ft. and Georgia Railway and Power Company on the Tallulah River, one at Burton with 5,280,000,000 cu. ft. and one at Mathis containing 1,369,000,000 cu. ft. of storage.

The Alabama Power Company has now in course of development a storage project on the Tallapoosa River at Cherokee Bluffs that will, when completed, have a storage capacity of 60,000,000,000 cu. ft. and will be able to develop approximately 136,000,000 kw-hr.

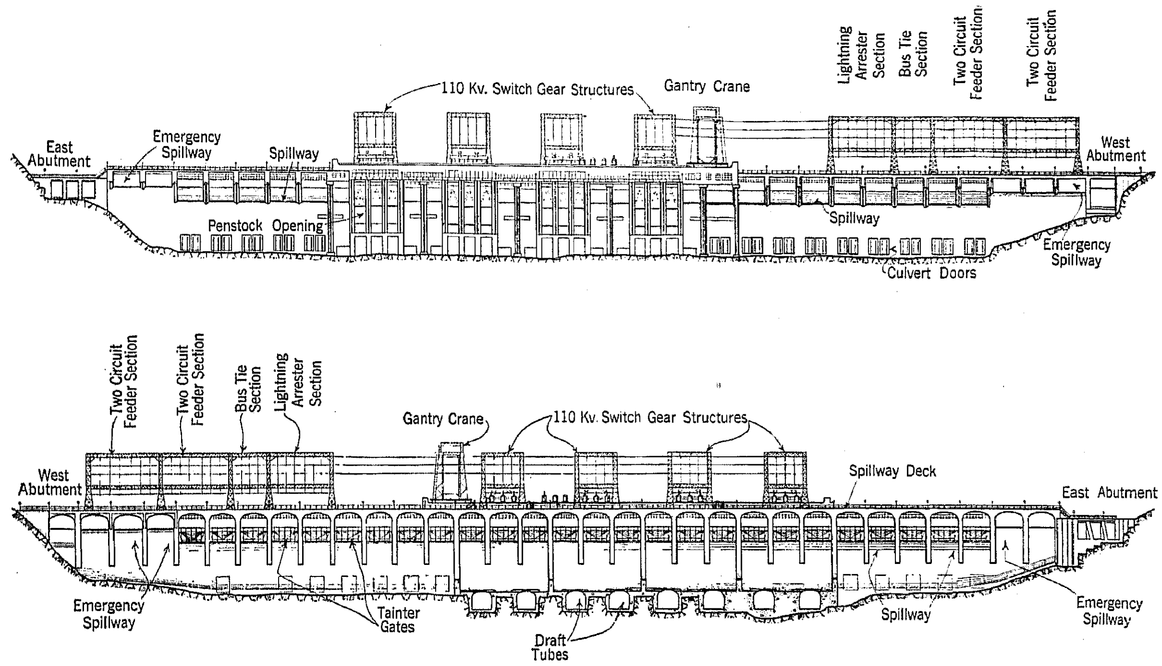
Design of Power Plants

The design of hydroelectric generating plants in the south does not differ materially from the design of similar plants elsewhere, and since practically all the developments are of recent date, with few exceptions, the plants are of modern design and construction. The generating units are of vertical type and in sizes ranging up to 30,000 horse power, depending on water-flow and head.

The majority of the southern hydroelectric plants are low-head developments with exception of the Tallulah Plant of the Georgia Railway and Power Company on the Tallulah River which has a head of 600 ft. and the Ocoee Plant of the Tennessee Power Company on the Ocoee River, with a head of 254 ft. These can be classed as medium high-head developments.

A departure from the conventional design of low-head power houses is represented in the Mitchell Dam Plant of the Alabama Power Company on the Coosa River. As it is well known, the run-of-river plant suffers an appreciable reduction of operating head during flood periods, and to overcome this disadvantage engineers have been forced to install a greater number of generating units where it was possible to do so, to compensate for the loss in capacity of each unit. Of course, such a procedure necessarily makes the installation more expensive with the resulting increase of production costs. In some instances provisions had to be made for admitting water into the draft tube through jets of relatively high velocity which, by accelerating the velocity of the combined turbine discharge and jet water through the draft tube, produces a negative head.

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.



Elevation of Dam and Powerhouse Looking Up-Stream

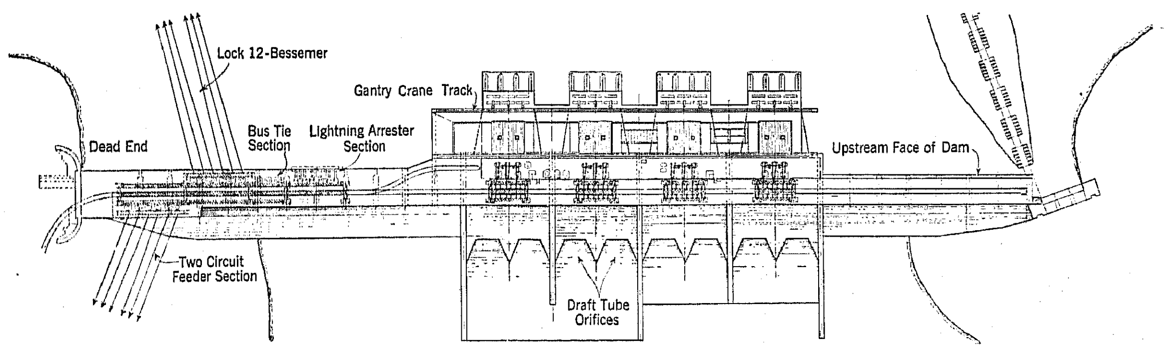


Fig. 1—26 Spillway Gates 30 ft. Wide by 15 ft. Deep—930 ft. Spillway, Including Piers

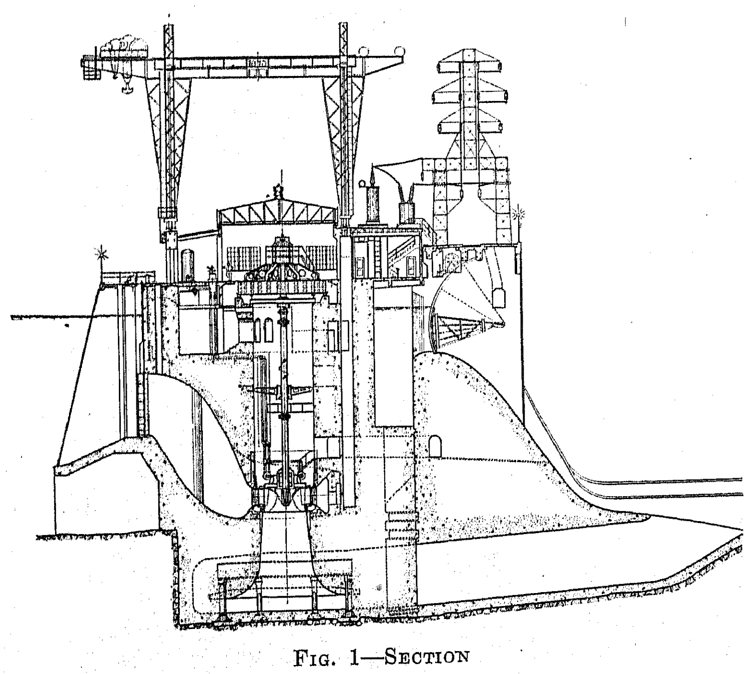

Fig. 1—Section

In designing Mitchell Dam Plant, the idea was conceived that the most effective way to maintain the normal head on the waterwheel, and thereby the full capacity of the unit during flood periods, would be to remove the excess tail-water head from the discharge opening. This resulted in the development of what is now known as the Thurlow back-water suppressor. The introduction of this feature called for an entire change in the general design of the power plant, causing a departure from the established conventional practise.

The principal and most outstanding feature in this plant is the location of the power units on separate foundations in the river on the upstream side of the dam. (See Fig. 1.)

The usual power house building is entirely eliminated. The generator room is covered by a low movable roof, which is designed in two sections, joined on the transverse line and mounted on wheels; each section moving in opposite direction. In normal operation the generator room is completely enclosed, but for handling large parts of machinery, this roof can be opened and a

gantry crane utilized for performing the necessary work.

The entire operating floor is on one floor level. The generators, governors, switchboard, low-tension switching, bus galleries and offices are easily reached without climbing stairs or ladders. This materially adds to the convenience of operators and makes supervision and inspection of the plant and its machinery more effective.

An elevator is also provided with each unit for use of the attendants in inspection of the turbine bearings and main shaft.

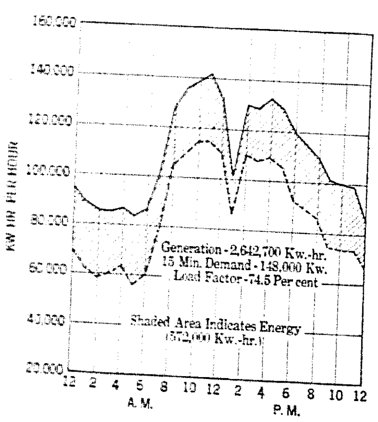

Fig. 3

This power house is designed for operation on the unit system, that is, each generator and its bank of step-up transformers are connected as a unit. There is, however, also a transfer bus provided which enables parallel operation of all or any number of units and from which the station service power and lighting is obtained.

Southern Super-Power System

Comparatively little has been mentioned in print about the inter-connected system of the Southeastern States, yet it comprises one of the largest systems in the United States.

While the proposed Eastern super-power zone is still under discussion, a virtual super-power system has been in existence in the South for several years covering the States of Alabama, Georgia, Tennessee, North and South Carolina. The Southern zone consists of the inter-connected system of seven independent companies as follows:

Alabama Power Company
Columbus Power Company
Georgia Railway and Power Company
Central Georgia Power Company
Tennessee Power Company
Southern Power Company
Carolina Power and Light Company

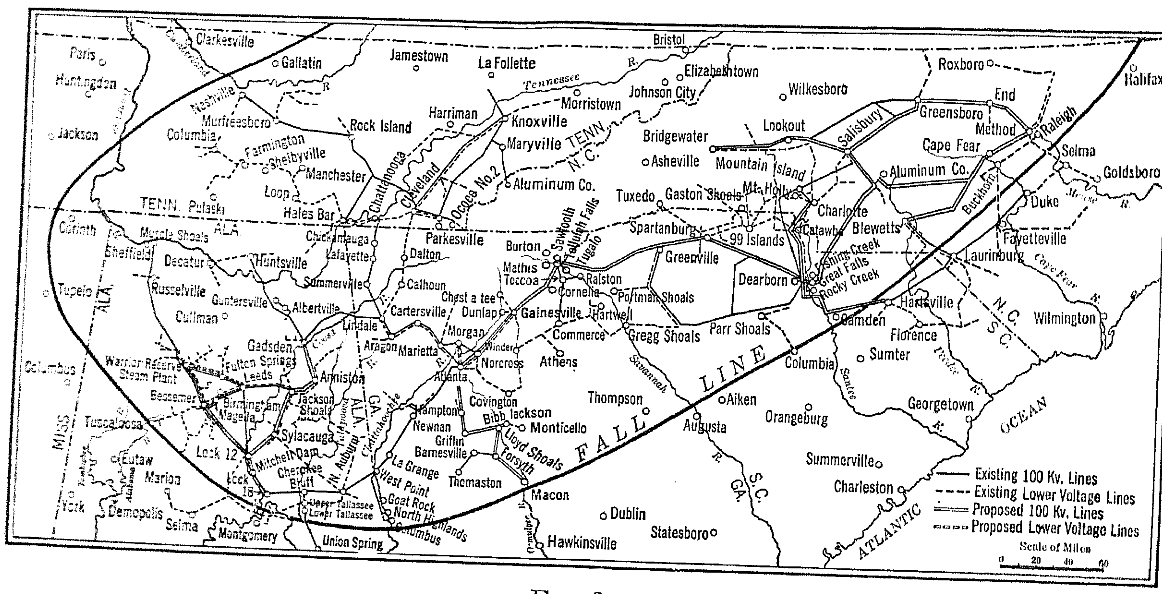

Fig. 2

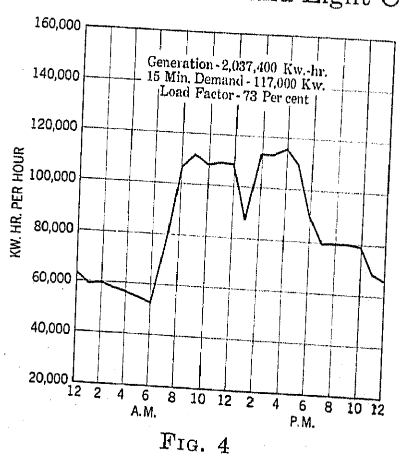

Fig. 4

A map of the Southeastern States showing the territory covered by these systems is shown in Fig. 2.

It will be noted that the inter-connected system forms a complete network over a territory approximately 600 mi. long, and 300 mi. wide at its greatest width.

All large plants, hydro and steam, are connected to this system with an aggregate capacity of about 1,100,900 kw.

The table below shows the various plants with the capacities of the different power companies, that are either in operation or will be in the near future.

POWER-GENERATING STATIONS OF THE POWER COMPANIES IN THE SOUTHEASTERN SECTION

Hydroelectric stations	Kw.	Steam electric stations	Kw.
Alabama Power Company

The main trunk-line is over 800 mi. long with several thousand miles of branch lines connected to it.

The inter-connection of these systems was accomplished by the building of tie lines and the installation of sufficient transformer and switching capacity at the tie-in points, to take care of the exchanged energy. Few changes had to be made in the individual systems themselves, as, fortunately, all the companies involved had already standardized on a frequency of 60 cycles and most of them operated their principal transmission lines at 110,000 volts.

Although energy has been transmitted a distance of about 600 miles on this inter-connected system, the use of high-voltage trunk-lines of the order of 220,000 volts has not been found necessary. It is obvious, of course, that no great bulk of power could be directly transmitted a distance of 800 mi. at 110,000 volts, but by a process of relaying the energy from generating stations to adjacent load centers, the same benefits have been accomplished. For instance, assume that the Carolina Power & Light Company at the extreme northeastern end of the inter-connected system desires to secure a block of power which is to be supplied by the Alabama Power Company. The latter company delivers the required amount of power to the Georgia Railway and Power Company at the Georgia-Alabama State Line, which will be absorbed on the Georgia system in that vicinity. The Georgia Railway and Power Company will then transmit energy from its Tallulah Falls Plant, at the other extreme end of its system, to the Southern Power Company. This Company will in turn absorb this energy locally and transmit a like amount from generating stations in the vicinity of the tie point of the Carolina Power and Light Company. The systems, relaying the energy, of course, deduct an amount sufficient to cover transmission losses, costs of transmission, etc.

During the Fall of 1921 several of the Southeastern power companies, recognizing the possibilities accruing from the inter-connection of the systems and anticipating a power shortage during the dry weather seasons, arranged to secure the use of the then idle steam plan at Muscle Shoals, Alabama. Accordingly, the Alabama Power Company leased this plant from the United States Government, and that Company in turn contracted with several of the other companies to hold in reserve a certain capacity which could be used by these companies at any time upon reasonable demand.

The Muscle Shoals steam plant is located in the extreme northwestern section of Alabama, and con-

nects with the Alabama Power Company's system through a 90-mi., 110,000-volt, single-circuit, transmission line at the Warrior River steam plant. Although the Muscle Shoals steam plant has a generating capacity of 60,000 kw., the amount available for distribution by the Alabama Power Company is limited to 30,000 kw. by the transmission line capacity between Muscle Shoals and Gorgas Steam Plant.

The value and importance of this arrangement and of the inter-connection were clearly demonstrated in 1922, when during an abnormally dry season in the Southeastern section, relief was given to companies in the Carolinas and Georgia. Some of the companies would have had to curtail power to their customers, had they not been able to secure this standby power. A typical load curve, when power was being delivered from Alabama to the Georgia companies and the Carolinas for 24 hours of the day is shown in Fig. 3, where the unshaded area indicates normal system load on the Alabama Power Company's system, and the shaded area the energy delivered to other systems. For comparison,

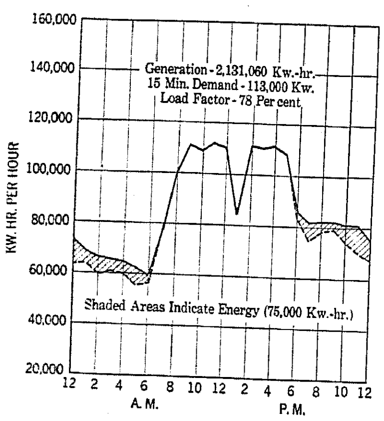

FIG. 5

a typical system load curve of the Alabama Power Company's system for a day when no interchange of energy took place is shown in Fig. 4.

Since the principal reserve capacity of the inter-connected system is at Muscle Shoals, the relaying of large blocks of power to date has been mainly from Alabama to Georgia and to the Carolinas. There has, however, been considerable power interchanged between some of the neighboring companies, but we can only speak of those in which the Alabama Power Company's system took part, namely, between it and the Georgia Railway and Power Company. The benefits derived by inter-connection of large power systems have been further demonstrated by the result of the interchange between these two companies. The hydro plants of the Alabama Power Company are run-of-river plants with comparatively small storage reservoirs, and the flow of the Coosa River on which these plants are situated, is subject to wide variations. The bulk of the Company's load during the low water seasons of the year is carried by steam generating stations. The principal hydro plants of the Georgia Railway and Power Company on the other hand, are backed by storage reservoirs having a capacity to take care of normal seasonal variations in river flow.

During certain seasons of the year it is possible to co-ordinate the operation of the Georgia and the Alabama Plants to secure maximum efficiency on each system. For instance, during the season when there is a surplus of water in the run-of-river plants, and when water is being stored at the reservoir plants, power is supplied from the Alabama system to the Georgia system during the off-peak hours—the normal load on the Alabama system during off-peak hours being considerably less than the capacity of its hydro plants. This interchange, therefore, permits the operation of the flow-of-river plants at a very high load factor and conserves water at storage plants.

During the peak load hours it, of course, becomes necessary for each system to carry its own load and the storage plant draws down a certain amount of its stored water. A typical load curve on the Alabama Power Company's system when supplying off-peak power to Georgia is shown in Fig. 5. By referring to Fig. 4 it will be noted that considerable improvement is made in the load factor on the Alabama Power Company's system. Another method of operation which has proven of advantage is that of supplying energy from the storage plants to the Alabama systems during peak hours, and during the off-peak hours power is returned from the Alabama system to the Georgia system. This reduces steam plant operation and permits the operation of run-of-river plants at high load factor.

Load dispatching on the inter-connected system is quite a simple matter, the principal requirements being close co-operation between dispatchers of the various systems, and sensitive governors in the main generating plants. The Georgia Railway and Power Company, being located centrally with respect to other systems, usually receives and relays the load orders to and from the various companies. An effort is made to predict load requirements several days in advance in order to prevent the unnecessary operation of steam plants.

It is, of course, essential that all systems maintain a frequency of about 60 cycles before successful interchange can be obtained. The frequency is in reality controlled by the system supplying the power, and the load swings of the entire inter-connected system are shared equally between the systems. The installation of accurate frequency-indicating instruments have materially assisted in the operation of the system. Several of the companies have installed at their principal stations frequency devices known as Warren master clocks.

Another requirement of interchanging power between systems is that of maintaining proper voltage conditions in order to bring about the proper distribution of the reactive current among the several sys-

tems. The bulk of the load carried on these systems is at a power factor ranging from 80 to 90 per cent and, therefore, the total reactive component of the load is rather large. For instance, at 80 per cent power factor the reactive component is 60 per cent. At times it is necessary to operate generators under light load or even no-load conditions for voltage boosting purposes.

The application of proper relays on all the systems is essential, in that a line or piece of apparatus in trouble should be immediately disconnected so that the remaining system may be operated without further disturbance.

This inter-connection has also proved of advantage in increasing the reliability of service. Line or apparatus failures upon isolated systems naturally cause interruptions to customers. Upon inter-connected systems it is nearly always possible for the combined generating capacity to take care of any reasonable number of failures. This possibility has been well demonstrated by the use of the tie between Georgia and Alabama in emergency cases. In 1923 a severe sleet storm in northwest Georgia broke down some of the lines west of Atlanta, and the load in western Georgia was immediately picked up and carried from the Alabama Power Company's system until repairs could be made. Likewise, interruptions to customers in Alabama have been prevented by use of the tie-line.

In addition to interchange between power systems, benefits have also been derived from the interchange of industrial plant and central station energy. Such interchange, to a limited extent, has been accomplished between the Alabama Power Company and Tennessee Coal, Iron and Railroad Company. This company generates a considerable portion of its power requirements from the exhaust steam of its rolling mill engines and from steam obtained from boilers fired by blast furnace gas which would perhaps otherwise be wasted.

Besides steel mills, there are other industrial establishments which can undertake inter-connected operation with central stations to advantage. Among such industries would be those requiring heat in the form of low-pressure steam, in the production of which electrical energy can be generated as a by-product. When more by-product energy is being generated than required, the surplus could be disposed of to the central station company, and vice versa, when a deficiency occurred the additional energy required would be purchased from the central station.

As the load on power systems continues to increase, the benefits of inter-connection will become more and more pronounced. To summarize, some of these benefits are as follows:

1. Reliability of service.
2. Reduction of total reserve capacity.
3. Economies due to diversity of stream flow in different water sheds.
4. Economies due to diversity of load factors.

Discussion

For discussion of this paper see page 569.

Hydroelectric Practises and Equipment

on the Pacific Coast

BY SVEND BARFOED

Member, A. I. E. E.

Chief Engineer, Frank G. Baum, San Francisco, Cal.

Review of the Subject.—The paper takes up the physical features having deciding influence on design and construction of hydroelectric plants. It describes the mountain system of the region, the precipitation, the runoff, the streams suitable for power development, and the major characteristics of the development; then takes up a little more in detail the structural features, such as reservoirs and diversion dams, the conduit system, surge tanks and forebays, pressure pipes, power houses and equipment. The choice of impulse and reaction turbines is discussed and some performance curves given; this followed by conditions imposed upon modern plants by the transmission line; switch gear is briefly discussed, followed by a resume on transmission lines and their control. Finally, some results which have been obtained are related, and the paper ends up with the hope that hydroelectric developments and distribution will continue as in the past, rather than have it undertaken by competing municipalities, which by ambitious advertising of cheap power (tax free) would endeavor to attract industries and people to their crowded areas.

It is felt that the hydroelectric power industry on the Pacific Coast has distributed the benefits of cheap electricity to the small and large community alike, tending to more stable development of the entire region.

THE Pacific Coast is taken to mean the three states that border directly on the Pacific Ocean—Washington, Oregon and California. They have a shore line of over 1500 miles and within their borders the climatical, meteorlogical and topographical features vary to an extraordinary degree and almost any climate from the subtropical to the artic may be found. Due recognizance is taken of these facts in the planning and execution of hydroelectric plants and a great variety of types of structures have been built to meet them.

Mountain System

From north to south two parallel mountain chains, separated by great interior valleys, extend from the Canadian border nearly to the Mexican line. Along the ocean is the Coast Range, densely covered with forests in the northern part which gradually taper off towards the south and finally cease in the extreme southern portion where desert conditions prevail. About 100 miles inland is the more elevated and more massive mountain chain called in Washington and Oregon the Cascades and in California, the Sierra-Nevadas. The forest cover is here also much heavier in the north, with the coniferous timber line gradually receding in the south where timber is found only at the highest elevations.

The two mountain chains merge into each other at two points, one in the Siskiyous in southern Oregon and northern California, and the second in the Tehachapi at the lower end of the San Joaquin Valley in California.

These mountain chains, together with the ocean, are the great actors in the distribution of precipitation over the land. The total range in precipitation is from less than one inch in the south to over 130 inches in the north.

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

Precipitation

Precipitation generally occurs when an area of low atmospheric pressure appears off the southern Alaskan coast and travels in a diagonal path southeasterly across the continent. This low pressure area draws, from the ocean to the south and southwest, air currents which have become heavily laden with moisture from contact with the ocean's surface. During the wet season the land is cooler than the ocean, southerly from it, and the wind, passing over the land, is cooled and gives up its moisture as rain or snow. Near the coast, with the exception of the higher mountains, the precipitation occurs chiefly in the form of rain, also as rain in the large valleys between the mountain ranges, and generally as snow in the Cascades and Sierras. In the south there is a decidedly wet and dry season, with the dry season much the longer, while in the north the difference between the wet and dry seasons is not so pronounced and the wet season is much the longer. There are modifications from local sources. Dry is summer; wet is winter.

The more sparsely the occurrence of precipitation, the greater is the seasonal variation in total amount from year to year.

Runoff

The runoff of the precipitated moisture from the mountain areas is influenced by the structure of the earth's crust, by plant growth, by form of precipitation (rain or snow), by temperature, wind and duration of storms. Some of these features are singly dominating in various sections. The most pronounced is in the lava fields of eastern Oregon and northeastern California. Much of this lava cover is porous to such an extent that there is very little surface runoff, the water at once sinking into the ground and appearing later in the stream channels well regulated by nature. In the granite Sierras there is a minimum of percolation, the heavy snow covers retard the runoff in varying de-

gree, and this natural storage of water is highly important in maintaining stream flows well into the summer months. In the Cascades heavy humus covers and snow have similar effect.

Streams

The western slope of the mountains receives a greater amount of moisture than the eastern. As a general rule, power streams flow west and the greatest number of large developed power sites are found on the western slope of the interior mountain range. There are exceptions to this rule, of course.

South of the Tehachapi the streams have not sufficient flow to make any large power developments, but it is here that some of the early high head plants were built and much of the art was learned.

The largest rivers of the Pacific Coast are the Columbia and the Colorado. They have drainage areas far outside the region and have cut their way through the mountain ranges and plateaus to reach the ocean. These two streams have not been utilized on their main courses and are the great store houses of future power in the west.

Fig. 1—Natural Storage

Storage Reservoirs

Over a large part of the territory, the variation in stream flow has made storage reservoirs necessary for economical power production. The degree to which this has been carried has varied from a maximum in the southern part to a minimum in the regions of the lava-covered area. Also in the north, due to the better distribution and greater amount of the precipitation, the building of storage reservoirs is, at the present time, of relatively less importance than in the south. Storage will grow in importance with time, when streams will be utilized for a greater proportion of the average flow. South of the Tehachapi storage reservoirs have been built large enough to regulate stream flows for 10-year periods or more. The water is here, however, stored primarily for irrigation and whatever power can be had is considered a by-product. Further north in the granite Sierras the regulation of streams is often not complete and storage reservoirs within reasonable cost are relatively small. Here many reservoirs have been built for both power and irrigation, and as far as economically feasible, they have been dimensioned to regulate for the variation of stream flow of one season. The snow melts off uniformly by the end of June, quite independently of the amount. In dry years there is often a deficiency which must be made up by operation of steam plants.

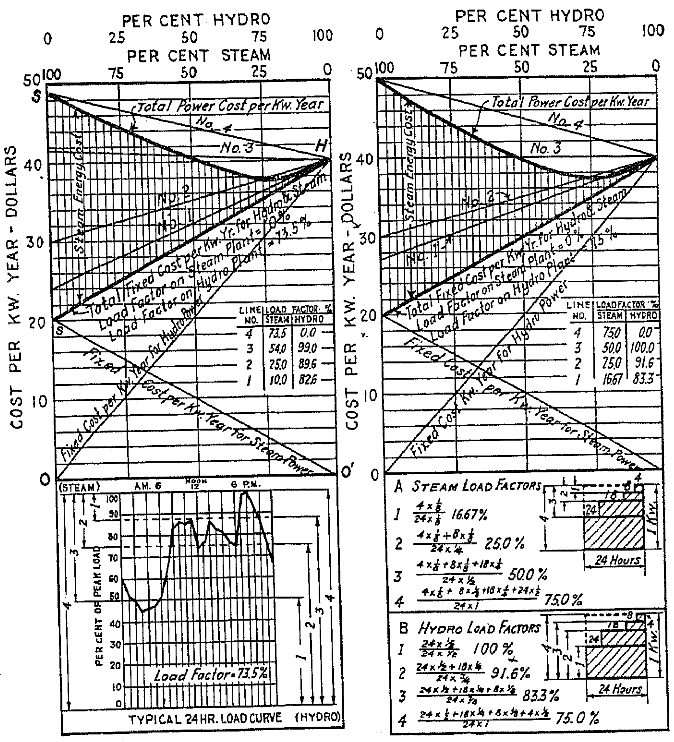

Fig. 2—Economic Division of Water Power and Steam

(A) Steam Load Factors:

(1) 99.0%
(2) 89.6%
(3) 82.6%
(4) 73.5%

75 0% TOTAL LOAD FACTOR

Assume All Load Over 87.5% Taken by Steam
Steamload Factor (1) = 10.0%
Hydroload Factor (3) = 82.6%

$$\begin{pmatrix}\text{Steam Energy}\\ \text{Cost Per}\\ \text{Kw. Year}\end{pmatrix} = \begin{pmatrix}\text{Percent of}\\ \text{Peakload}\\ \text{on Steam}\end{pmatrix} \times \begin{pmatrix}\text{Steam}\\ \text{Load Factor}\\ \text{Percent}\end{pmatrix} \times \$40$$

$$12.5\% \times 10\% \times \$40 = \$0.50 \text{ Per Kw. Year}$$

Cost of the Steam Energy Generated.

This added to line $s\ H$ (representing the total Fixed Cost of Hydro & Steam) at the proper abscissae, gives a point on the Curved Line $S\ H$ which represents the sum of Fixed & Energy Charges for any division of the Load.

NOTE:

(A) Steam load factors are derived by working from top of Diagram down, making steam supplant hydro in increasing amount.

(B) Hydroload factors are derived by working from bottom of diagram up, making hydro supplant steam in increasing amount.

BASIS:

Hydro cost per kw. year = \$40.
Steam fixed cost per kw. year = \$20.
Steam energy cost per kw. year and 100% load factor of steam plant = \$40.
Demand costs = Fixed costs for hydro and steam, including interest, maintenance and depreciation, and also all operators, coal, water, etc., to bring the plant up to speed and voltage. ready for business.
Energy costs are only those costs which increase with kw-hrs. output.

Large reservoirs have been built in the Sierras for irrigation purposes, city water supplies and for storage of auriferous gravel after gold has been extracted by

hydraulicing. Power is now generally developed through the head created by the dams and can as a rule be profitably disposed of to a nearby network of a utility.

In much of the Sierra territory, water is extensively used for irrigation. The demand for power and irrigation does not coincide throughout the entire irrigation season and a certain amount of conflict exists. In some cases this can be remedied by after-storage and floodstorage at elevations below power developments. The state of prosperity of the irrigationists and the stand taken by yellow newspapers and local demagogues have much to do with each particular case, but eventually, necessity will demand conservation of all water resources and a fair use to the greatest number.

Character of Developments

A great variety of types of hydroelectric plants have been built in this large territory and each new location has its own peculiar problems to solve, governed principally by the following conditions and requirements: Topography, storage of flood water, size of the transmission network into which it feeds, size of the plant itself, loadfactor of the power market, time characteristic of the water supply, etc. For example, plants which have a natural uniform water supply are natural base-load plants, and those which depend on storage are built to handle relatively low-load factors

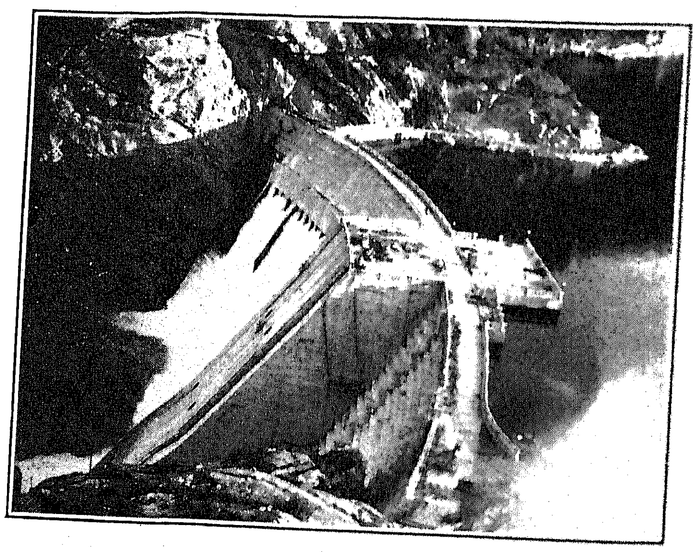

Fig. 5—O'Shaunessy Dam

Dam is built to a height of 226½ ft. above stream level, the ultimate height above stream level will be 312 ft. The foundation extends 118 ft. below stream level. Present structure contains 375,000 cu. yd. of concrete and will store 67 billion gallons of water, and ultimately will store 113 billion gallons.

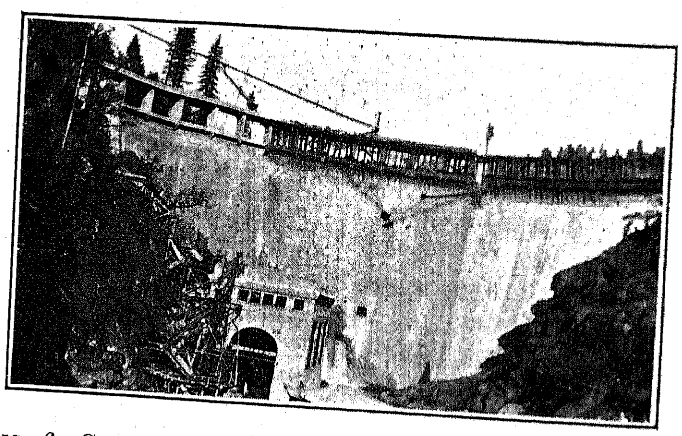

Fig. 6—Constant Angle Arch Dam with Power House at Bullards Bar
Dam stores gravel after gold has been extracted by hydraulicking. Power sold to Public Utility.
Height of Dam from Foundation: 183 ft. To Bridge Floor: 202½ ft.

Installed Capacity: 8,000 kv-a.

in varying degree. The lower the load factor for which a plant may be built, the greater its construction cost per average unit of power, and a condition is approached where it pays to operate a steam plant to carry peak loads in conjunction with a hydro plant. The division of load between hydro and steam is best worked out by laws of economy and an example is given in diagrammatic form in Fig. 2.

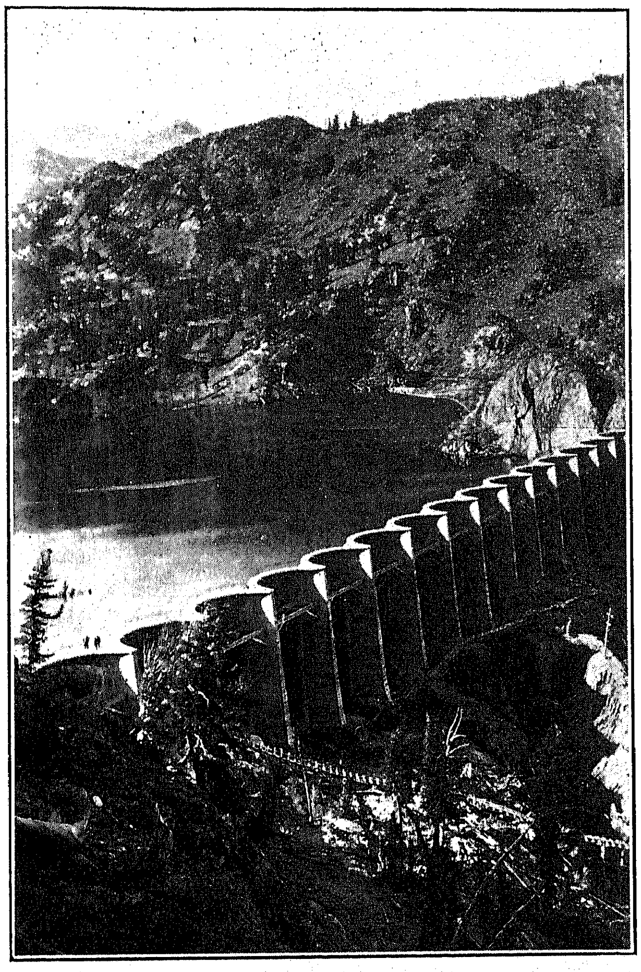

FIG. 7—MULTIPLE ARCH DAM AT GEM LAKE

Constructed at an elevation of 9050 ft. on the eastern slope of the Sierrsa in the vicinity of Mono Lake.
Height: 84 ft.

Span of Arches: 40 ft.
Stores water for Southern Sierras Power Co.

FIG. 8—ROLLER SECTION AND SLUICE GATES IN DIVERSION DAM FOR UPPER FALLS STATION, SPOKANE, WASHINGTON WATER POWER CO.

Steam plants are further considered to have the important function to give service insurance for large load centers and to build up the load on a system during intervals of construction of hydro plants. The use of steam plants is not uniform over the entire area. Some of the utilities of eastern Washington get along without them. This is possible when the location of the water power is favorable, transmission short, and water supply certain every year, or the minimum flow is above the requirements.

FIG. 9—ELDORADO CONDUIT

Concrete-Lined Ditch with Wood Flume in Distance
Western States Gas & Electric Co.

Interconnection between companies is becoming quite general, although the amount of power which is interchanged is not very great. The equipment required for a true interchange of power is not in all cases suitable without modification, and the interconnected lines are small in capacity.

Structural Features

Dams. Storage and diversion dams of all types have been built, the choice of type being generally determined by foundation conditions, available construction material, spillway requirements, overflow, and the psychological effect on human beings. The design of dams must now be approved by state authorities. In the early days, water systems were developed

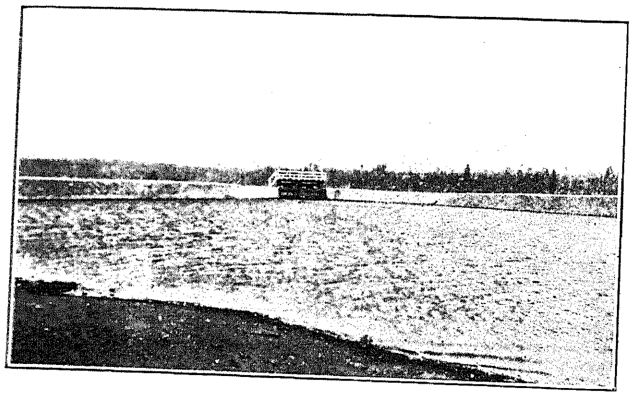

Fig. 11—Forebay
At End of Open Canal.
Connects to 10 ft. Diameter Pressure Pipe.

for washing gold-bearing gravel, and dams built for this purpose are now functioning for the more modern use of power and irrigation. Some of these old dams were forerunners of what is known as the rockfill type of dam. The gravity type of masonry dam has been used here under similar conditions as elsewhere and

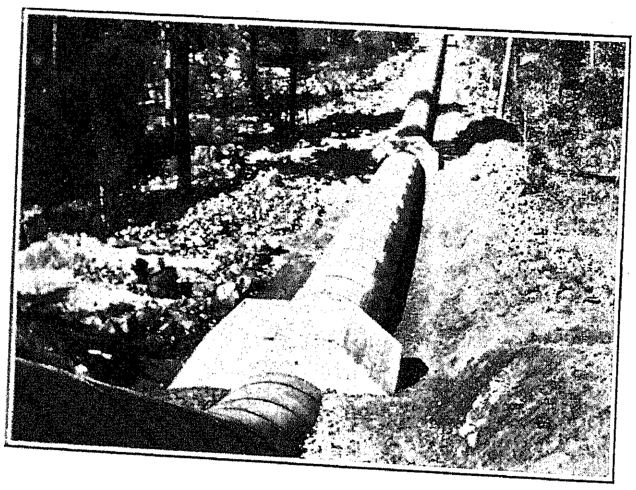

Fig. 12
Riveted Steel Pressure Pipe 9 ft. Diameter.

recently built in large size for power, irrigation and water supply. The earthfill dam is often found and is characterized by the kind of material and method of construction. In regions favored with a good quality of uniform earth, the method is to spread the material in shallow layers and to compact them by wetting and rolling. With a material requiring segregation, the hydraulic-fill method is much in favor. Core walls are used, should more pervious material be encountered.

Since the cost of storage dams is a large item in the total cost of construction, the desirability for a reduction in cost has brought out some new types, namely,

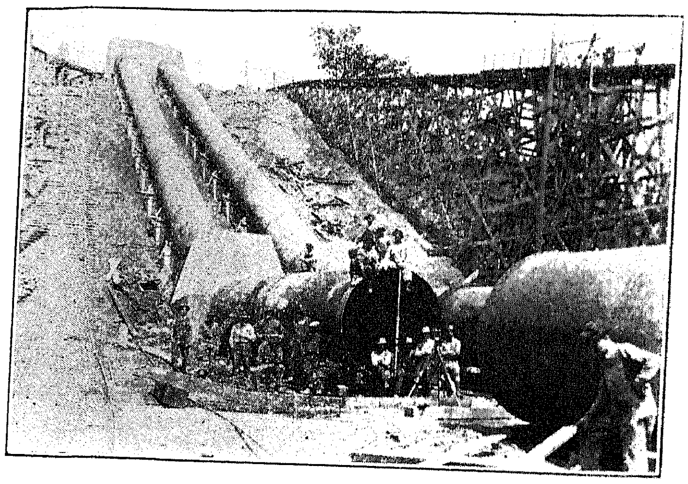

Fig. 13—Pipe Line Construction (Welded)
Pipes are here 8 ft. in Diameter. Expansion joints just below anchors.
Pit River No. 1 Development of Pacific Gas & Electric Company.

the multiple-arch dam and the constant-angle arch dam.

The multiple-arch dam consists of a number of inclined arches, resting on buttresses spaced uniformly across the site. The constant-angle arch dam is a single arch and is especially suited to a V shaped, rather

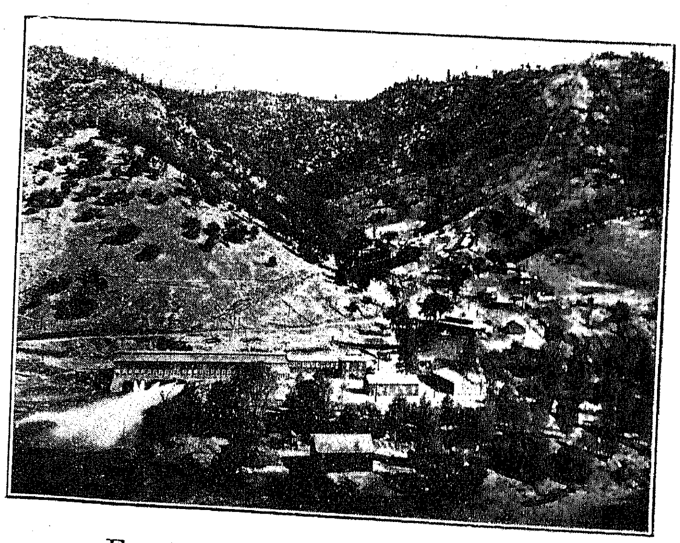

Fig. 14—Electra Power House

narrow canyon. It is built up of a series of superimposed arch slices, which, as far as possible, are subtended by an angle of 133 degrees. This gives a minimum of masonry for a given unit of stress, considering the arch slices are uniformly loaded in a radial direc-

tion. This type of dam is in use with overflows as high as twenty feet. Both types require an unyielding rock foundation. Considerable investigation has been made in a theoretical way of the stress distribution in these new types of dams, and some experimental work on a large scale is now underway to supplement the work already done. This is highly to be commended since the material (concrete) is, from

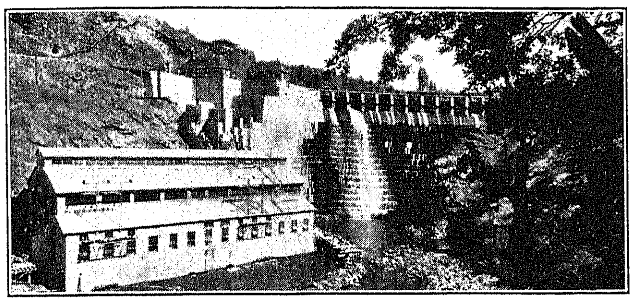

Fig. 15—Copco Power House and Dam
California-Oregon Power Co.

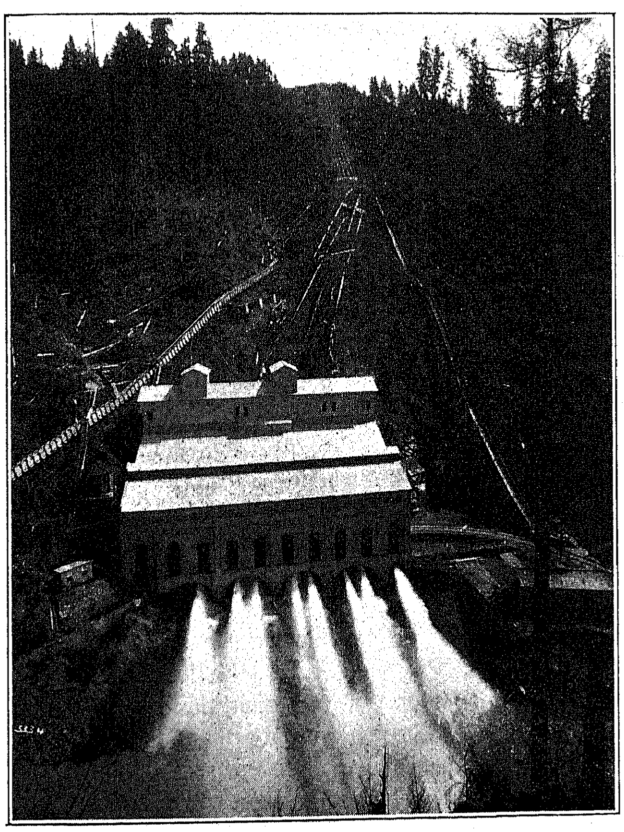

Fig. 16—Electron Power House
Puget Sound Power & Light Company.

the nature of its manufacture, not in the same class as, for instance, steel or cast iron. More than 20 dams of these two types have been built in the west and none has failed. The reduction in cost over a gravity type of dam is due to correct placing of the material to transmit the load to the foundations. In the gravity type the bulk of the material acts merely as weight.

Conduit System

Since the majority of the plants built are of the medium and high-head type, conduits or aqueducts are used to concentrate the fall of the stream at a favorable point. In some cases, such conduits are of considerable length, one, for example, being 24 miles long for a static head of 1900 feet, but in more favorable locations the same head may be created by a conduit of but a few miles in length.

Under the subject of "dams" it was mentioned that water systems were built in the early days for mining purposes. Water released at the dam was taken for many miles in ditch and flume, built along the mountain side to the place of use. Many of these old ditches have been repaired and enlarged since the days of hydraulic mining and now serve for hydroelectric development.

The conduit system has undergone a certain amount

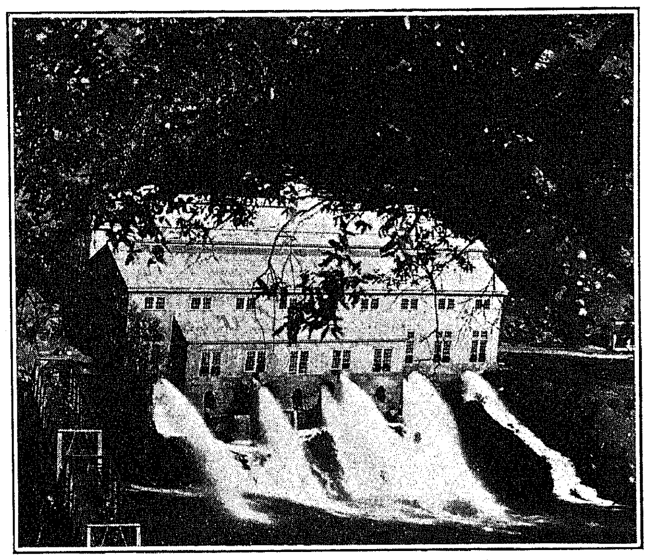

Fig. 17—Stanislaus Power House
Head: 1498 ft. Installed capacity: 40,000 kw. Sierra & San Francisco Power Co.

of evolution, and types of structures have tended toward more permanent construction. Some of the governing factors in the selection of conduit types have been length, topography, climatic conditions, construction cost and service conditions. The size of a conduit for economic power production is so determined that the annual charges, plus the value of the lost power due to friction, are a minimum. Closed and open conduits are used, each having its field. Where the climate is severe, with much snow and danger from slides, modern plants use tunnel, where less severe, pipe lines of steel, concrete or wood are used. The closed system may or may not be operated under pressure. Some plants have open systems, irrespective of above considerations, but generally the open system is used where the conduit is long and the climate mild.

When a conduit is of the closed type and not too long,

it generally terminates in a surge tank; when of the open type, in a forebay. In a closed conduit the cross section should be large enough to carry the maximum load, which at any time may come on the plant. In the open conduit it need only be large enough to carry the average flow of water demanded during 24 hrs., the peak load being carried by the forebay.

Surge Tanks and Forebays

The closed conduit with surge tank has come into

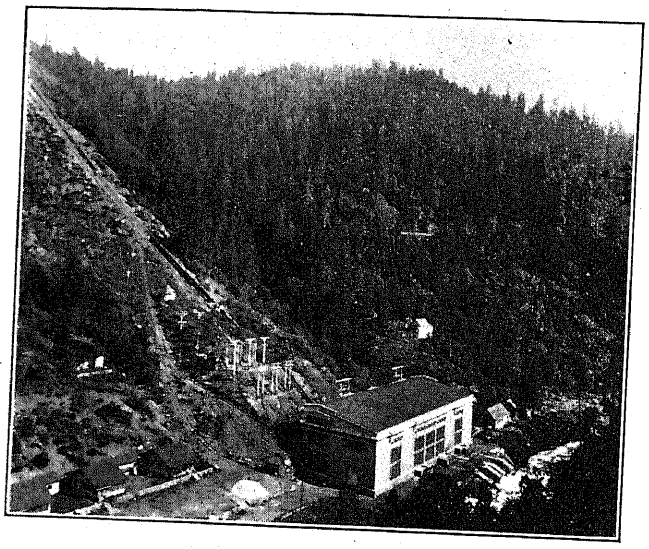

Fig. 18—Drum Power House
Head: 1375 Ft. 3 Units of 12,500 kv-a. Total 37,500 kv-a. Pacific Gas & Electric Co.

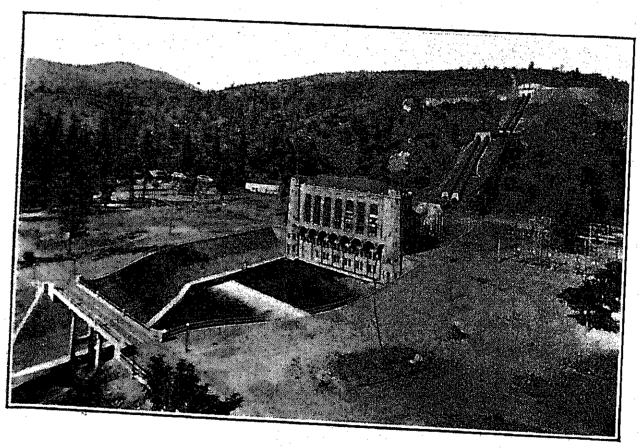

Fig. 19—Pit River No. 1 Power House
Head: 454 ft. Installed Capacity: 70,000 kv-a. Pacific Gas & Electric Company.

more general use during the last few years and the theory of the function of surge tanks in operation is now well understood. The tanks are given various shapes, depending on the selected duty cycle, which is given by the time characteristic of load changes and the general operating conditions of a system, including accidents and the failings of operators. The difficulty in selecting the proper surge tank is not so much with the theory as it is with the duty cycle. It has been built as a plain cylinder, a truncated cone right side up or inverted, or of the shape of an hour glass, Fig. 10.

Some tanks are built with their rims at an elevation high enough to stop completely the flow in the conduit upon complete rejection of load, while others have the rim developed as a spillway with capacity ranging from small amounts nearly to full capacity of the conduit. The conditions found at the intake of the conduit is often the deciding factor, namely, where stored water must be conserved in a reservoir and a cessation of flow desired or where there is no reservoir but the intake is directly on the stream and conservation of water is no object.

Forebays in connection with open canal systems of considerable length are, if possible, made larger than required for 24-hour regulation, in order to give service insurance, should the conduit system become inoperative due to snow or landslides, etc. Unless topographic conditions are favorable, the requirements for forebay construction often necessitate large expenditures. They may be formed by a gully closed by a

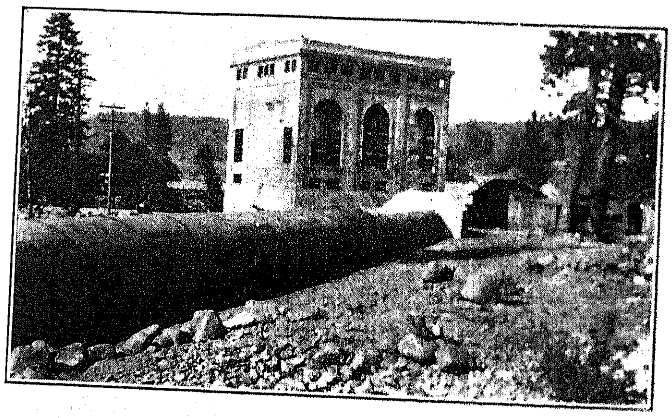

Fig. 20—Hat Creek No. 1 Power House
Pacific Gas & Electric Co. 210 ft. Head. Capacity: 10,000 Kv-a.

dam of any type, or by an excavation made in a suitable and obliging mountaintop, or merely an enlargement of the canal section along the hillside. All forebays, except where the conduit is very short, are equipped with a spillway, generally in the form of a weir, on one or both sides of the conduit just before the forebay is entered. Where water carries sand or grit in suspension, sandtraps are provided. They are designed to retard the water to a velocity which will permit suspended matter to sink to the bottom and to skim off the top layer of clear water.

Pressure Pipes

In most developments the pressure pipe is a considerable item in the total installation and for high heads and long lines it is one of the most important ones, and is given very careful consideration in design, installation and operation. In the great majority of cases and nearly always for heads greater than 150 feet, the pressure pipes are made of steel. Wood stave pipe

has been used to some extent and concrete pipes are few. A combination is sometimes used of wood-stave construction in the upper part and steel below. Skill and care are required in the installation of wood-stave pipe and, if properly done and the staves kept completely saturated, the pipe will give good service for an indefinite time. It is preferred to keep the staves away from the soil by means of cradles of concrete or durable wood (cedar and redwood). Steel pipes are either riveted or hammerwelded. Riveted pipe has been used since the beginning and given excellent service, Fig. 12. The welded pipe was imported to a small extent before the war, but is now made in this country, and some of the recently built plants have used this type for both high and medium heads, Fig. 13.

In pipe of large diameter and light or medium metal,

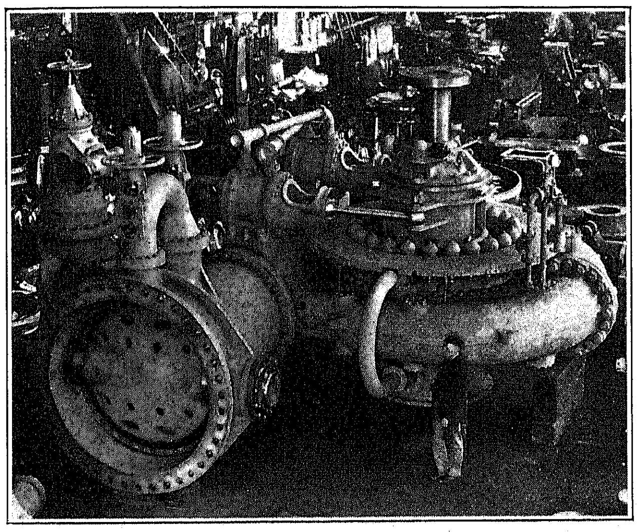

Fig. 21—High Head Reaction Turbine

Capacity: 35,000 Horse power
Effective Head: 857 ft.
Speed: 514 rev. per min.

To be installed in the Oak Grove Power House of the Portland (Ore.) Railway, Light & Power Co. This is at present the world's highest head reaction turbine.

the loss in head, due to friction, is about equal for the two kinds of pipe, but when riveted pipe is small in diameter and the metal heavy, the space occupied by straps and rivetheads is relatively large and the loss greater than for welded pipe which has flanged joints and presents a smooth bore throughout.

Welded pipe is installed with greater ease and, due to the fact that expansion joints can readily be furnished with the pipe and of the same material, it need not be buried. Being above ground, its condition from the outside is always known and repair and painting work greatly facilitated.

Riveted pipe is often installed in an excavated trench and expansion joints are not required. Some installations, with pipe partly buried, use expansion joints of built-up material which have given good service.

The location in the field of a pipe line is very important, but often conditions are such that there is but one choice and the design and construction must over-

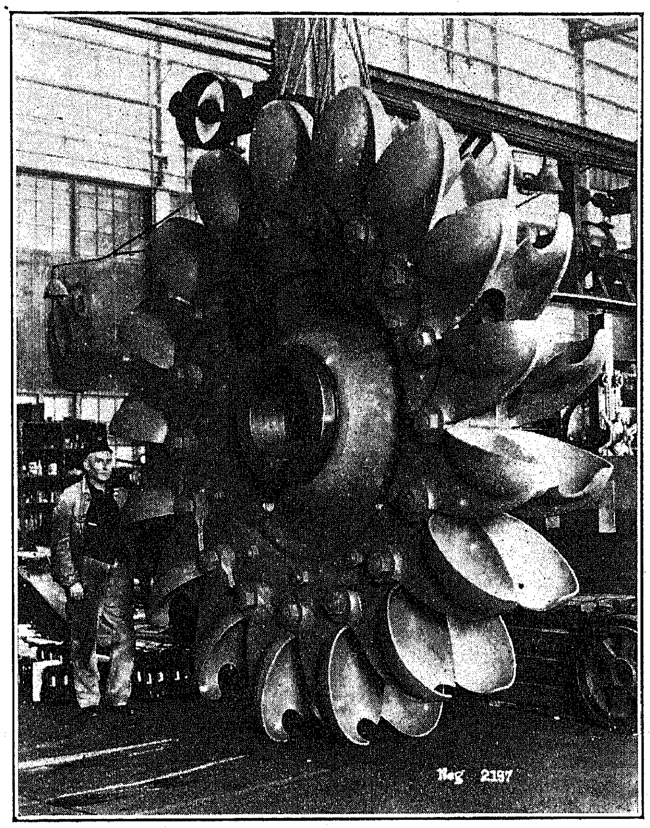

Fig. 22—Impulse Wheel

Capacity of wheel: 12,500 horse power. Two wheels will be mounted on same shaft with generator between them.
Effective head: 1,250 ft. Speed: 257 rev. per min.
Will be installed in Mocassin Power House of Hetch Hetchy development for San Francisco water supply.

Effective Head 780 to 820 ft.

come many difficulties. Anchors and their location are of much greater importance with the pipe above

ground than with pipe buried. Pipe lines without expansion joints are suited best to a broken profile and horizontal angles; pipes having expansion joints are suited best to a straight course between intake of pipe and turbine.

In the design and manufacture of riveted pipe the best boiler shop practise is followed and, due to the experience gained with the great number of pipe lines

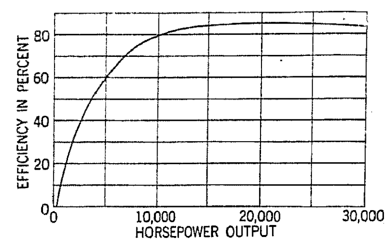

FIG. 24—EFFICIENCY CURVE FOR 25,000-HORSE POWER IMPULSE TURBINE

Effective head 1250 ft. Speed 257 rev. per min.
The Pelton Water Wheel Co., San Francisco, Cal.

installed, the art of building riveted pipe is highly developed on the coast. For the lighter sections, plates are lapriveted in both longitudinal and circumferential joints, and the best practise is to make the downstream end of a course an inside one; for heavier work buttriveting is used. The efficiency of a joint is determined by rules similar to those which govern for boilers. By efficiency is meant the ratio

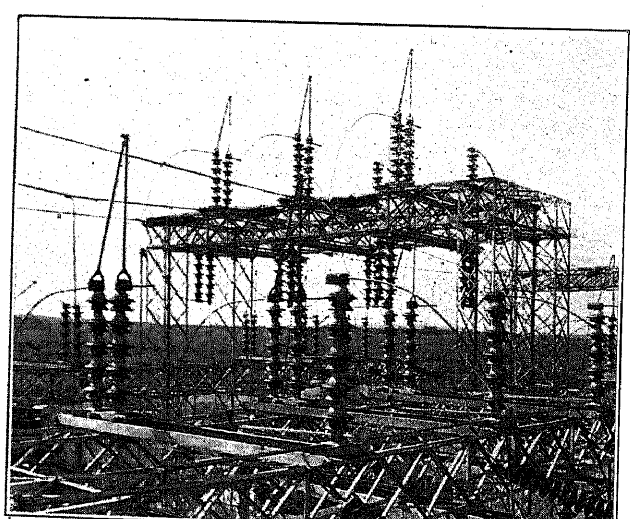

FIG. 25—220,000-VOLT DISCONNECTING SWITCHES
Pacific Gas & Electric Co.

which the strength of a unit length of a riveted joint has to the same unit length of the solid plate.

Careful tests and inspection are made of the rolled material for both riveted and welded pipe, and it is considered imperative to test with suitable overpressure every section of welded pipe at the manufacturer's shop before shipment. In spite of this care, defective material and workmanship creep in and some pipes have burst and caused damage, but the cause of bursting may not always have been due to defects, but to faulty operation or failure of relief valves.

Long pipe lines contain moving water columns of thousands of tons weight, which must never get out of control. If control is lost, disaster is swift and certain. Aside from the control obtained through the governor, stop-gates or valves are placed in long lines both at top and bottom. For short lines and single-unit plants the valve at the bottom is sometimes omitted. In the older plants the gates at the top were simple devices often made of wood; in later plants, valves have been introduced directly in the pipe line, just after leaving the forebay or surgetank. Both slide valves and butterfly valves are used, and the latter seem to be gaining in favor and so far have given very good results. The butterfly valve is sufficiently tight when carefully made, and the body of its closing disc can be made of efficient form with respect to the flowing water.

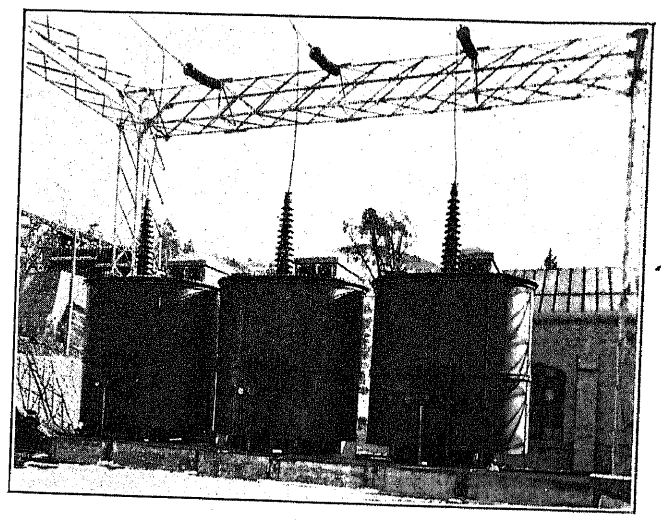

FIG. 26—50,000-KV-A. BANK OF TRANSFORMERS
11,000 volts to 220,000 volts. Grounded neutral, single terminal. At Pit River No. 1 Power House. Pacific Gas & Electric Co.

At the power house end slide valves, butterfly valves and plunger valves have been used with uniformly good results, with the exception of the control for the plunger valve, which has not been positive and powerful enough to the degree required by the high pressures and long lines used here.

POWER HOUSE AND EQUIPMENT

Building. The architectural treatment of power house exteriors and interiors is given considerable attention. It is not always that engineer and architect agree. A power house is neither a bungalow, a spanish hacienda, or a cross between an armory and a church, but should receive its characteristic lines from what it contains and from the purpose it fulfills. When such a view is coupled with the inspiration to be had from nature at the site, a proper basis is laid for a good solution.

Turbines and Waterwheels. Until a comparatively few years ago, plants in the southern half of the territory used the impulse turbine almost exclusively, while in the northern territory, due to more moderate heads, the reaction turbine was generally used. A turning point came with the installation of the Centerville turbine in 1906, which was the pioneer high head machine (559 ft.) with a maximum capacity of 9000 horse power. Since then reaction turbines have continued to extend in use for the higher heads which were formerly covered by the impulse turbine. The reason for this change is the better efficiency which may be obtained and the full use of the available head by means of the draft tube. Before the advent of the successful thrustbearings almost all plants had horizontal shaft arrangements, but now the large modern installations of reaction turbines are vertical. The impulse turbine, however, continues to be arranged with a horizontal shaft.

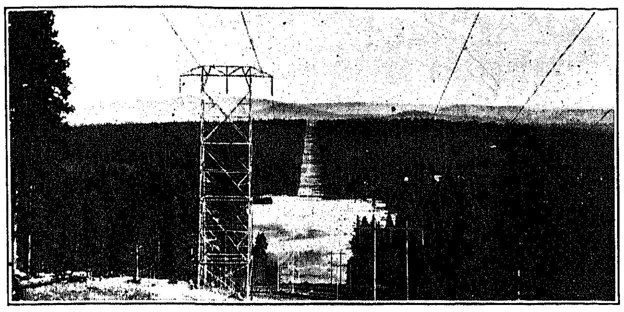

Fig. 27—Pit River Transmission Line
220,000 volts.

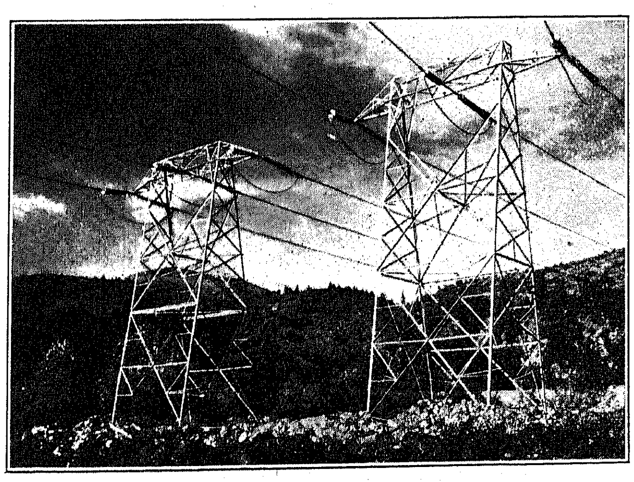

Fig. 28—Anchor Towers, 220-kv. Lines
Moderately severe climatic conditions. 19 ft. center to center of conductors. Pit River Lines. Pacific Gas & Electric Company.

With the higher heads, the reaction wheel is exposed to a great pressure difference between inlet and outlet of the runner, and manufacturers give much attention to details of the leakage path. A recent development is the rubber seal ring. By virtue of water lubrication, which is excellent for rubber, the clearance between the running and stationary parts can be made so small that the surfaces may be said to touch. This development is undergoing time trial on wheels in service and is being watched with interest.

There has been some trouble from vibrations in large reaction turbines, indicating that the water passages do not transform the energy correctly. There may be many causes for this, but it would seem that a turbine must be carefully proportioned to give its output at best efficiency with the amount of water available; not for example with one and one-half times this amount, for if the additional water is to be had only occasionally, the turbine at all other times is working with a poor efficiency. Draft tubes may be the originators of much of the vibration and although there has been great improvement in draft-tube design, some draft tubes do not give the correct impression when viewed in action on large units. Whatever the swirl of the water in the draft tube may be, the tendency to form vortices should be suppressed completely.

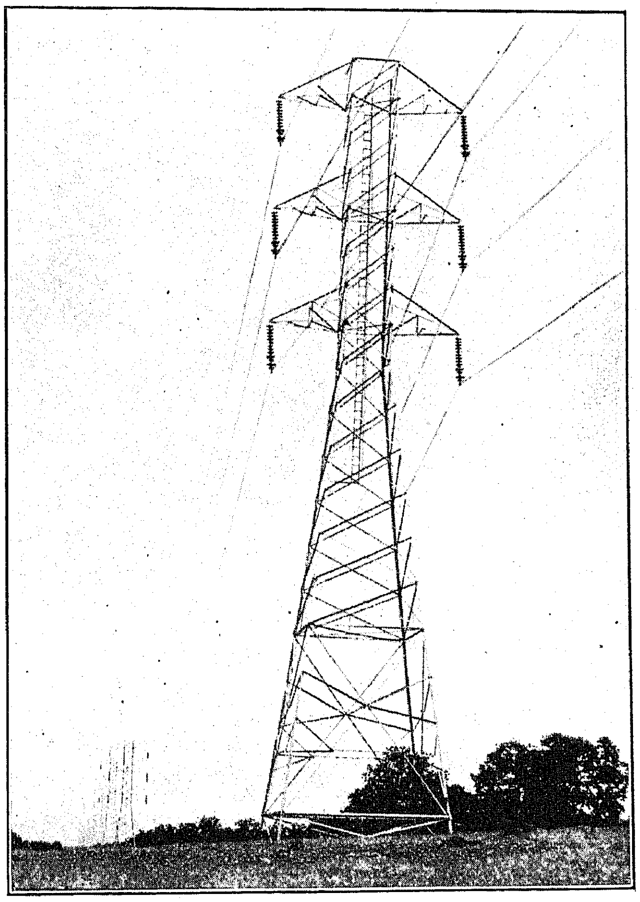

Fig. 29—220,000-Volt Pit River Line
Length of line: 202 mil. Double-circuit transmission tower. Pacific Gas & Electric Company.

For the higher heads and long pipe lines relief valves are used, and depending upon the conditions, are proportioned to discharge from 100 per cent to lesser

amounts of the water used by the turbine. The opening of the valve is mostly governor controlled and opens synchronously with the closing of the turbine guide vanes. The closing is gradual at a predetermined rate given by the desired pressure rise, which is arrived at through computation and by experimental adjustment. In some plants with moderate head and short lines operation has been satisfactory without relief valves. Depending upon the head, the writer uses as a guide the following permissible pressure rises:

For heads up to
150 feet ....40 to 50 per cent
500 " ....20 to 25 per cent
over 800 " ....15 to 20 per cent

The energy of the spouting jet from the relief valves

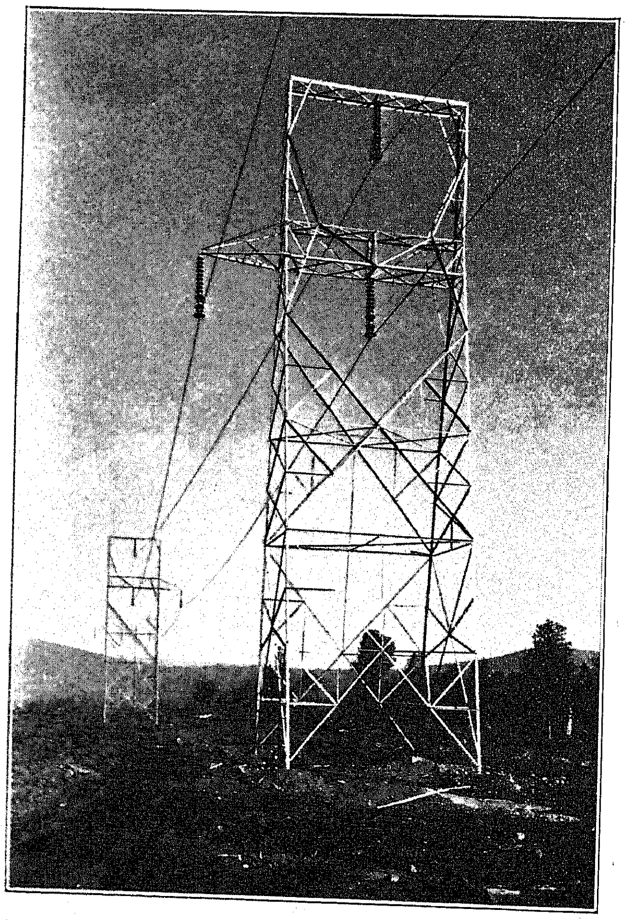

FIG. 30—TRANPOSITION
220,000-Volt Pit River Line. Pacific Gas & Electric Company.

is either dissipated by free discharge or absorbed by vortex baffle chambers. In restricted locations good results are obtained by vertical discharge of the jet into baffles, which direct the jet through an angle of 270 deg. towards the center of the jet from all sides.

The impulse wheel will probably hold its place for heads above 1000 ft. for a long time to come, units of 30,000 horse power are in use at that head, but conditions for best efficiency improve with increasing head. Some efficiency curves are given for both types of wheels to show what is being accomplished at these high heads, Figs. 23-24. The impulse wheel is used for units of small capacity at much lower heads; they have few moving parts and are rugged in these sizes and for that reason preferred for exciter drive.

The governing of impulse wheels is accomplished in different ways. The jet may be deflected by movement of the nozzle body itself, or by a jet deflector which cuts into the stream, or by movement of the needle. When the movement of the needle is under the control

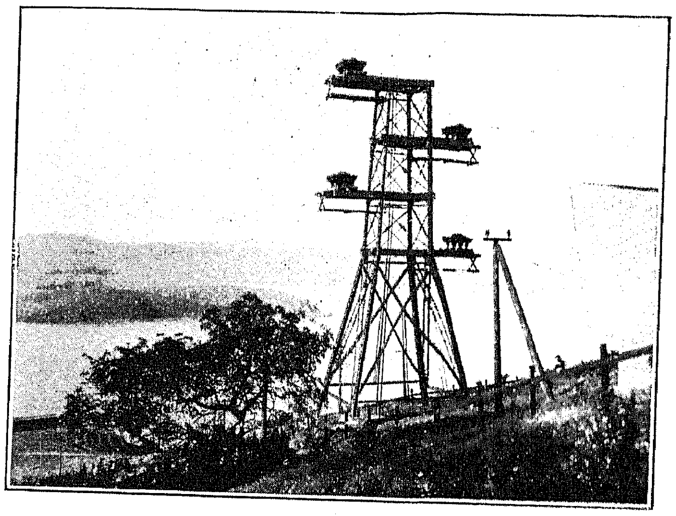

FIG. 31—CARQUINEZ CROSSING
Pacific Gas and Electric Company.

of the governor, an auxiliary nozzle is added, the needle of which is opened when the main needle closes to follow a reduction in load. The closing of the auxiliary needle takes place at a predetermined and adjustable rate through the intervention of a dashpot and heavy springs.

Generators. 60 cycles is the standard frequency, with the exception of a large utility in the south. This utility uses 50 cycles, but has some equipment suitable for both 50 and 60-cycle operation.

The mechanical arrangement of generators is given by the prime mover and is in all respects similar to installations elsewhere. In large plants, by means of suitable housings and ducts, the cooling air is given a definite path to and from the outside, independent of generator room. This method makes the control of air currents in case of accident and the installation of fire extinguishers much easier. Clean air can usually be had without filtering.

As transmission voltages increase and lines become longer, a certain number of the generators of a hydroelectric transmission system are required to handle the charging current of an unloaded line. This charging current is a magnetizing current which produces a field superimposed on the field of the rotating direct current magnets and in phase therewith. The excitation from the exciter machines is, therefore, lowered

for this condition as much as possible, yet it must be positive and definite. The sum must not be great enough to raise the voltage further, which would increase the charging current and build up a still higher voltage. The resulting kv-a. load on the generator must not exceed its capacity.

It has been proposed for many years, and it is now becoming common practise, to protect generators against internal electrical breakdown by means of balanced relays. Governors are usually provided with a load-limiting device, and in addition, when a fault develops in the winding, they are actuated to automatically close the turbine guide vanes to reduce the flow of energy to the fault.

The arrangement of the exciter varies almost with each plant and is considered in connection with its selected prime mover or drive. In some of the large modern plants with the vertical shaft arrangement of the main units, the exciter is mounted directly on top of these and may have a capacity to excite all units or only the machine to which it is attached, depending upon the number of main units in the plant. A reserve exciter set is usually provided in either case, driven independently by a separate small hydraulic turbine and an induction motor. The control of excitation currents for long high-capacity lines is by broad range regulators and both hand and automatically-controlled field rheostats, and has reference to the expected changes in load, the arrangement of synchronous condensers in the network, and the particular characteristics of the line.

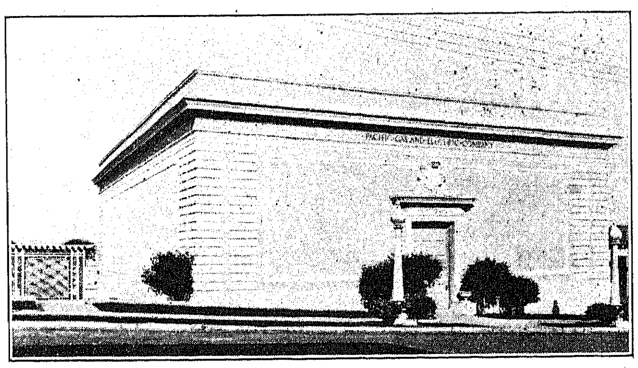

Fig. 32—Typical City Substation
Station K in San Francisco of Pacific Gas & Electric Company.

Switch Gear. All low-tension switch gear, as well as its arrangement, is of the same design as found elsewhere in the country. In some recent installations, all oil switches between the generators and transformers are omitted, resulting in remarkable simplicity. The isolated-phase system has not yet been employed.

The high-tension gear is more and more being installed out of doors for potentials of 110 kv. and higher, and with properly selected insulation, results have been good. The oil switches and breakers for high voltages assume truly large proportions, and the quantity of oil they contain may be as much as for a 20,000-kv-a. transformer. Most of these oil switches have two breaks per pole, some have four or more, and the movement of the contacts may be either vertical or horizontal. Switches are in use with or without the so-called explosion pots. High-tension oil switches may be due for some improvement; they are fitted with ponderous mechanisms and have slow acceleration of moving contacts. It is not expected that the

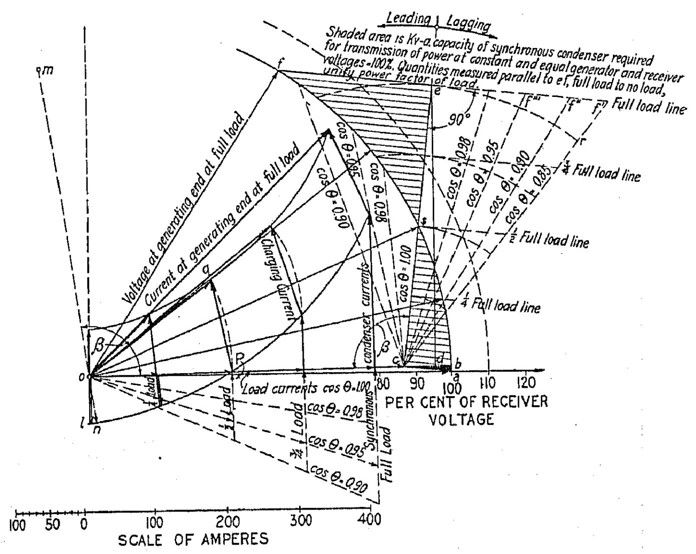

Fig. 33—Regulation Diagram for Transmission Lines

size of oil-switch containers can be much reduced, because of the a priori requirement for electrical clearances.

The chief reason for placing the high-tension gear in the open is, of course, the reduction which may be obtained in first cost, due to the elimination of large housing structures. Some companies use an arrangement whereby a high-tension oil switch may be by-passed by means of disconnecting switches, so that the line may be kept in service while the switch is isolated for inspection, cleaning and repairing. High tension disconnecting switches are generally operated from the ground by grounded mechanisms; that is to say, the ground end of an insulator assembly is usually the point of application for operating, not the live end. Some companies, however, prefer the live end. High-tension oil switches and disconnecting switches have been manufactured on the coast for many years, which is the result of a need made necessary by the early high-tension transmission lines in California. High-tension switch yard arrangements are kept as simple as possible, in order that operators may have clear evidence of operations.

Transformers. With the higher voltages and where it is not too difficult to provide the necessary space, transformers are often installed out-of-doors with the high-tension switch gear. The question of safe insula-

tions in the bushings outside the tank is one which time alone can answer, and some day transformers may be moved inside again.

The grounded 3-phase transmission system is almost universally used, the desire being to secure a stable neutral and fixed potentials from terminals to neutral. The transformers are almost exclusively single-phase, and generally at generating end transformers are two-winding with delta connection on the low-tension side. Usually both terminals of the high-tension windings are brought out, but in some recent high-voltage work one terminal was grounded to the case, so only one terminal is conspicuous through the high-tension bushing. At the receiving end both two-winding and three-winding transformers are used, depending upon connections to other high voltage lines. If connected to other high-voltage lines, the three-winding arrangement is required for star-star connected auto transformers, the third winding serving for circulation of the single-phase triple-harmonic currents and for operation of synchronous condensers. In extra high-voltage work the space required for insulation and electrical clearance from winding to winding, becomes larger and the electro-magnetic interaction of the windings is influenced thereby, and particularly for transformers with a number of taps, care is required in the design to secure the desired regulation and potential distribution. The two-winding transformer is better off in this respect than the three-winding transformer, and an endeavor is being made to reduce to a minimum the number of taps on important transformers.

Transmission System of Pacific Gas & Electric Company.

Transmission Lines

In the beginning, all transmission lines were constructed with wooden poles and pin type insulators up to 60,000 volts, but with the adoption of 100,000 volts, the suspension-type insulators with steel tower construction came into use. In the north, where there is an excellent timber supply, the wooden pole construction is still used for the highest voltages. If development were planned far enough in advance of construction so as to take advantage of careful impregnating methods for preserving timber, there would be small reason, indeed, for not using wood pole construction for any type of line. The popular call for permanent construction, as argued from a civil engineering standpoint, is responsible for the development of the steel tower. In the southern half of the territory the steel tower is used for lines of all kinds, but chiefly from 60,000 volts up. The type of tower used, except for minor details, is the same as used in other parts of the country. Where climatic conditions are favorable it is possible to use a vertical arrangement of the conductors, but where less favorable, they are either offset or arranged in a horizontal plane. The most severe conditions to be met with are found in certain districts in the lower regions of the Columbia River, in the vicinity of Portland.

Insulation of high-tension lines has received a renewed and rather extensive investigation, due to the advent of the 220-kv. lines. This work has not ended, and the companies are engaged in collecting facts concerning the operation of this last develpoment in transmission.

High-voltage lines are controlled by aid of rotating synchronous machinery, located at terminal substations. For this purpose there is installed and under order on the Pacific Coast at least 300,000 kv-a. in synchronous condensers. At the present stage of the transmission art, some of the lines could not be controlled in any other way. A simple diagram is given in Fig. 33, by which a clear vision is obtained of the

factor involved in the control of high-voltage lines. A description of this diagram was given in the A. I. E. E. TRANSACTIONS, 1922, page 790, the notation is the same. High voltages are necessary, as it is not possible to transmit large blocks of power economically over long distances in any other way.

SOME RESULTS OBTAINED

It has been previously remarked that the most important hydroelectric plants were located on the western slope of the interior mountain range. The large centers of population which furnished the principal market for power were mostly located on the coast or in the great interior valleys. So, from the very beginning, it was necessary to transmit the power at high voltages over lines of great length, traversing the territory generally from east to west and from northeast to southwest. As these transmission lines passed through the country, it was possible for various industries and the lesser centers of population to avail themselves of electric service, the result of which is a diversified use of electricity fully as great in the small cities as in the large.

Other than serving the large centers of population, the earlier transmission lines furnished power to the important mining industries of California, and the average motor installation for this purpose has always been very large. A little later came the extensive use of the electric motor in pumping water for irrigation, first from wells and more recently directly from the stream or river by means of large pumping plants. Due to the universal use of electricity, the rates for light and power have tended to become uniform over large territories, so that the location of industrial plants is not primarily chosen because of cheap power in any one center. The advantage of such rates is that they tend to prevent population from thronging to congested areas, where the difficulties arising from social conditions are becoming a problem.

It is hoped for the future that the development and distribution of hydroelectric power will continue as in the past, rather than have it undertaken by competing municipalities which, by ambitious advertising of cheap power (tax free), would endeavor to attract industries and people to their already crowded areas.

It is felt that the hydroelectric power industry on the Pacific Coast has distributed the benefits of cheap electricity to the small and large community alike, tending towards a more stable development of the entire region.

The writer wishes to express his thanks to the Power Companies and others who furnished the photographs and the data given with each.

Discussion

For discussion of this paper see page 569.

Recent Developments in Hydroelectric Equipment

BY WILLIAM MONROE WHITE
Member, A. I. E. E.
Mgr. and Chief Engr. Hydraulic Dept., Allis-Chalmers Mfg. Co., Milwaukee, Wis.

OUR times in this century have often been referred to as the Age of Power. The interest now shown in hydroelectric developments almost justifies our renaming the present age "The Hydroelectric Age."

Remarkable industrial growth has occurred in several sections of our country which have had available cheap hydroelectric power.

The Alabama Power Co., conceived by broad-minded men and nurtured by far-seeing capitalists, is seeking to serve the people of the state of Alabama and adjacent sections, and to provide the very sinews by which the energetic and forehanded business men, within the range of its spreading transmission lines, may develop and establish businesses and industries which will mean prosperity and better living conditions for all. One unit in this great plan of development has recently been placed in regular operation at Mitchell Dam on the Coosa River. For one who is familiar with the hydroelectric developments of North America and who has an appreciation for the genius of those who conceive and build such properties, it is inspiring to stand upon the wooded hills, overlooking the site of Mitchell Dam, and to view the manner in which men have fashioned a mountain of concrete between abutting hills, in combination with foundations, waterways, backwater suppressors, superstructure and buildings for housing the hydroelectric machinery, and yet all

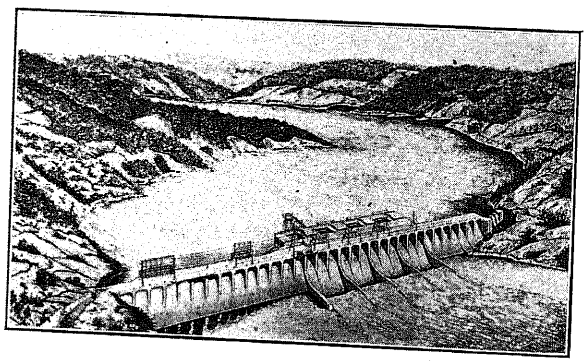

FIG. 1

so devised within the narrow limits of the river's channel at this point, so that no serious obstacle is interposed to the passing of floods which frequently deluge the basin drained by the Coosa River.

The main purpose of this paper is to present to the engineers some facts relating to recent developments in hydroelectric machinery, such as that installed at the power house at Mitchell Dam for economically producing power from falling water. There are installed and now in operation at Mitchell Dam three waterwheels designed and built by the Allis-Chalmers Mfg. Co. of Milwaukee, Wisconsin, each of a capacity of 24,000 horse power when operating under a head of 70 ft., and running at a speed of 100 rev. per min.

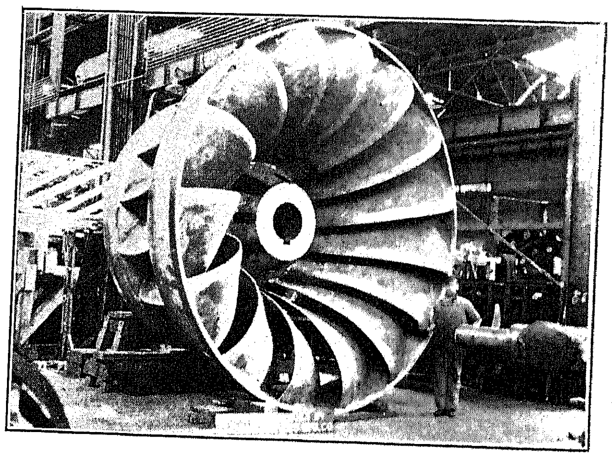

FIG. 2—IRON RUNNER—WEIGHT 105,000 LB. ALABAMA POWER CO. MITCHELL DAM PROJECT

Each of these units is installed in a structure located on the upstream side of the dam, fashioned with waterways of ample capacity, leading to and from the turbine and with walls that support the superstructure. The waterwheels must be located near the level of the tailwater. The generator and electrical equipment are desirably located above the elevation of high water upstream from the dam. This necessitates a considerable distance between the waterwheel and the generator. Notwithstanding this unusual requirement, wheels of normal rational design have been incorporated in the plant, each having a single runner of cast iron, 130 in. in diameter weighing 100,000 lb. This runner is shown in Fig. 2. Fig. 3 shows the shop assembly of the cast iron speed ring and movable cast steel guide vanes for one of the units. Each unit is equipped with outside operating mechanism controlled by cylinders located at the bottom of the pit, and operated by governor actuators located on the generator floor.

The main shaft, 25 in. in diameter of forged steel hollow bored, is divided into three lengths and has a total length of 80 ft. The governor flyballs are direct-connected to this shaft and control the governor actuator by means of a connecting rod. Each governor

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

actuator is supplied with oil by a rotary gear pump with a capacity of 150 gal. per min. at 150 lb. pressure.

The turbine pit can be reached either by an elevator or by a stairway. The elevator is located between the turbines in a vertical shaft which opens into a horizontal tunnel connecting the three turbine pits.

The Thurlow backwater suppressor[1] installed for the first time, utilizes flood water to increase the head on the turbines. The units have been thoroughly tried

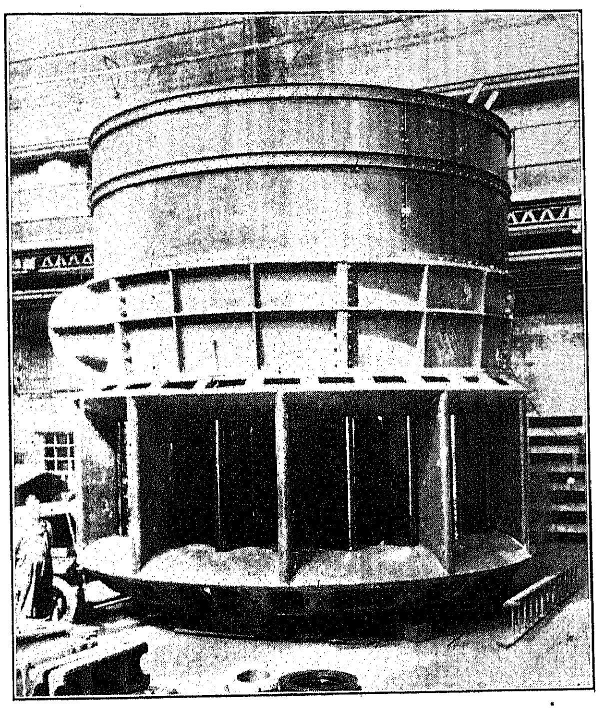

Fig. 3—Concrete Spiral Cased Turbines

out and the backwater suppressor greatly exceeded expectations. Another feature is the outdoor gantry crane and the sliding roof of the power house covering the generators. Two of the units are equipped with the White hydraucone and one with a flattened elbow draft tube. The hydraucone is a concentric form of draft tube which changes the direction of flow of water discharged from the runner in a very short length of tube and at the same time regains energy by changing velocity head into pressure head, with very small losses, due to the fact that it is formed to correspond to the natural shape of a jet of water striking a flat plate or a cone. The engineers of the Alabama Power Company were instrumental in having a large number of comparative draft tube tests made, the report of which was read at the January A. S. C. E. Meeting. It is interesting to note that these tests made by disinterested engineers showed the superiority of the hydraucone type of tube over the elbow type. The writer has advocated this design since 1916.

Recently the first of three 70,000-horse power hydroelectric units was placed in operation at the plant of the Niagara Falls Power Company on the American side at Niagara Falls, New York. It is estimated that the operation of this one unit will release for other duties approximately 1500 men daily, who heretofore had been engaged in mining, hoisting, loading, hauling, switching and firing coal under boilers in order to develop this same amount of energy. Fig. 4 shows a sectional view of the 70,000-horse power combined hydroelectric unit which the Allis-Chalmers Mfg. Company now has under construction for the Niagara Falls Power Company for Station No. 3-C. Two of these turbines are of the Wm. Cramp & Sons manufacture, two of the generators are of the General Electric manufacture and the third complete unit, turbine, governor and generator is of the Allis-Chalmers manufacture. Probably a brief description of these, the largest power-producing units in the world, will further serve to give a general idea of the present day trend in the field of hydroelectric development.

The water for these units is conducted from the forebay at the top of the cliff through butterfly valves connected to concrete lined tunnels driven through the solid rock. At the lower end, a plate steel section of penstock is imbedded in the tunnel and 21-ft. 6-in.-

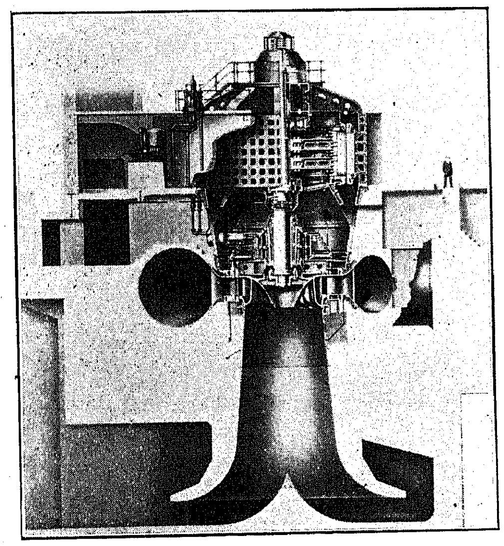

Fig. 4—Largest Power Generating Unit for Niagara Falls Power Company

diameter Johnson type valves are used for shutting off the water from the turbines. The casings on two of the turbines are of cast steel made in sections and bolted together. The third unit is of the circular-section plate-steel type riveted to a cast steel speed ring made in sections. The turbines operate under 213 ft. effective head at 107 rev. per min.

All three units will be equipped with the concentric type of draft tube regainer of the hydraucone or Moody spreading type. The principal features of the Allis-Chalmers hydraulic turbine are a cast steel runner

1. J. A. Sirnit's Paper on "Hydroelectric Power Plant Design" in A. S. M. E. *Transactions*, 1922, Vol. 44.

made in one piece approximately 180 in. in diameter, weighing about 100,000 lb.; a main shaft 34 in. in diameter of forged steel, hollow bored, provided with forged flanges on both the upper and lower end, the runner being bolted to the lower flange with steel-fitted bolts and a main turbine guide bearing of the adjustable, lignum-vitae type, lubricated with water drawn from a settling reservoir at the top of the cliff. The guide bearing is built with four adjustable shoes so that they may be taken up in any direction to compensate for wear. The guide vanes are of cast steel with upper and lower stems cast integral. The upper stems extend through bronze bushings in the cover plate where they are connected to the shifting ring by means of levers and breaking links. These breaking links are so designed that they will give way either in tension or compression when some obstruction prevents the opening or closing of the guide vanes.

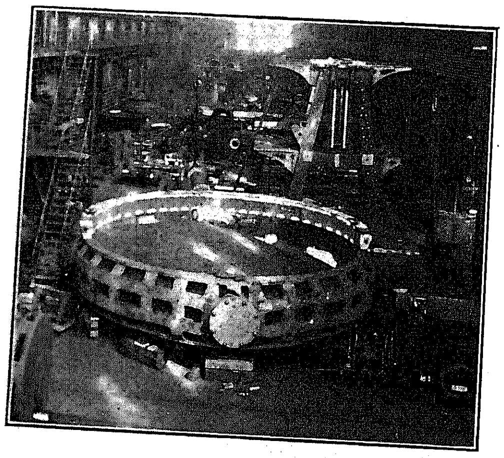

FIG. 5—BUTTERFLY VALVE. ASSEMBLY OF HOUSING WICKET AND OPERATING SHAFT

The generators are rated 65,000 kv-a., 13,200-volts, 25-cycle. The rotors are of cast steel built up in sections with pole pieces bolted to the rim. An auxiliary generator of 650-kw. capacity is mounted within the generator just above the main rotor. This is to provide current for the auxiliary apparatus such as oil pumps, motor-generator sets, cranes, lights, etc. The entire rotating weight of over 700,000 lb. is carried on the Kingsbury thrust bearing. The exterior design of all three generators is practically identical in order to preserve uniformity, although the design of the coils and winding is made independently by the engineers of the General Electric Company and the Allis-Chalmers Mfg. Company.

At the upper end of the penstock, instead of the customary type of square head gate, three 23 ft. 6 in.-diameter butterfly valves are used to shut off the water. They have cast iron housings made in sections and cast steel and plate steel wickets turning on forged steel pivots. The axes of the butterfly valves are set vertically, the operating mechanism being located on the deck above the water level. These valves, which establish a new record for size, are to operate under a head of about 50 ft. Figs. 5-6 show different views of the valves being assembled in the shops of the Allis-Chalmers Mfg. Company.

The largest single contract ever placed for hydraulic machinery is that recently placed by the Quebec

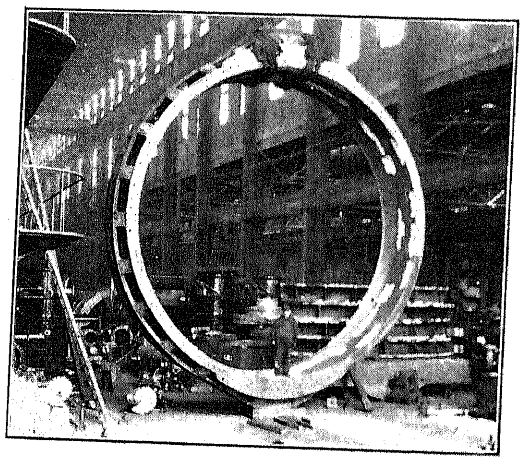

FIG. 6—BUTTERFLY VALVE HOUSING

Development Company covering eight complete 45,000-horse power turbines to operate under 110 ft. head, at 112½ rev. per min., to be installed near Lake St. John in the Province of Quebec, on the Saguenay River, about 125 miles due North of the City of Quebec. The major parts of four additional units are also being installed so that the final power house will consist of 12 units of a total capacity of 500,000 horse power. These units will be of the plate-steel spiral-cased type. Fig. 7 shows a view of the first one of the 12 gigantic casings being erected in the Toronto shops of the Canadian Allis-Chalmers Limited. The inlet diameter is 20 ft. The plate thickness is ⅞ in. at the inlet

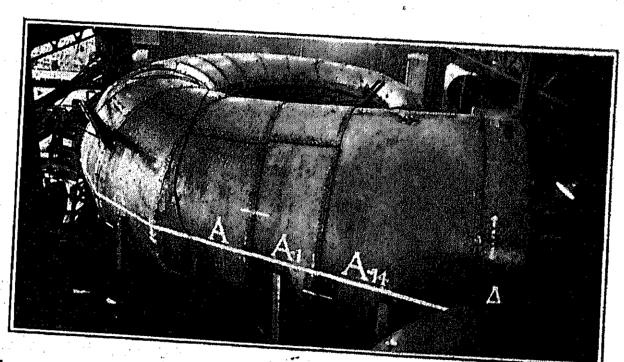

FIG. 7—PLATE STEEL CIRCULAR SECTION SPIRAL CASING. ONE OF TWELVE 40,000 H. P. SINGLE-RUNNER VERTICAL SHAFT TURBINES FOR QUEBEC DEVELOPMENT CO., LTD.

tapering down to ½ in. at the smaller end of the casing.

The past year has seen advances not only in the larger sized hydroelectric units, but even the 200 and 300-horse power open-flume turbines have been improved because of the knowledge gained in constructing larger units. The high-speed Nagler type of runner

is being adopted almost universally, improvements in efficiency having been obtained which make it compare very favorably in that regard with the slower-speed Francis type of runner which it replaces. This, when taken in combination with the improved efficiency of the higher-speed generator at lower cost gives it a distinct advantage. Because of its higher speed, the energy remaining in the water discharged from these runners represents a large percentage of the total. For this reason the design of the draft-tube regainer must be considered carefully. Many tests have been conducted to determine the type of draft tube that will give the best performance with these runners. Frequently the available space, especially in reconstruction projects, is very limited, but wherever conditions allow, we find that the most efficient results are obtained with the concentric or hydraucone type of regainer. Fig. 8 shows a number of high-speed runners being manufactured in the shops of the Allis-Chalmers Company at one time during the past year.

The plate-steel built-up guide vanes used with these

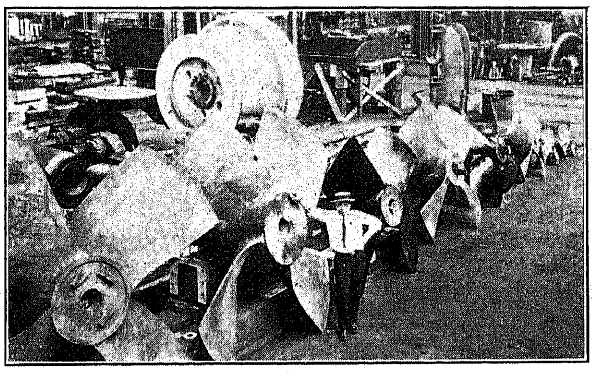

Fig. 8—Nagler High-Speed Runner of Various Sizes, Types and Characteristics for Low Head Developments

high-speed runners have been found to be a distinct improvement. In several cases sticks or pulp wood have become lodged between the vanes distorting the plates considerably. If the old type of cast iron vanes had been used they would have been broken, but with the plate steel construction it was only necessary to remove the damaged vanes and straighten them.

The design of the concrete spiral-casing type of machine has received its share of attention and much time and thought have been expended in improving and simplifying their construction. The writer is in favor of placing the nose of the casing even with, or down stream from, the centerline at the side of the unit. This shortens the path of the water, enables the units to be placed closer together and provides additional thickness in the separating walls between the units where it is most needed. Great care must be exercised in constructing the concrete spiral casing and a large amount of reinforcing steel must be used to properly strengthen it, especially above 60 ft. head. For this reason the writer has long recommended the use of the plate-steel spiral casing for heads as low as 50 ft. For normal settings very little more steel is required to build the spiral casing than is used for the reinforcing of the concrete spirals. It can be readily put together in the field and mass concrete poured around it, doing away entirely with the complicated wooden forms which must be built by expert carpenter or pattern makers. Since the plate steel casings are entirely self-supporting, they may be left practically uncovered. They may be set one almost touching the other, thus decreasing the power house length and doing away with the heavy concrete dividing wall which is necessary with the concrete spiral setting to obtain sufficient strength in case one unit is drained while an adjacent one is in operation. Our Company has constructed plate steel spiral casings for heads as low as 30 ft., and probably established a record for high-head plate-steel spirals during the last year in those built for the New England Power Company, Davis Bridge Plant, developing 19,500 horse power each under 345 ft. head.

A striking example of the use of the plate-steel spiral casing for medium heads is the 20,000-horse power unit for the West Kootenay Power and Light Company to operate under 70 ft. head. In this case, the saving by shortening the distance between the centerline of units, thus decreasing the amount of excavation in the solid rock required for the power house practically paid for the additional cost of the plate steel casing, not taking into account the saving in reinforcing steel and labor in building the forms and constructing the concrete casing.

In the high-head field, undoubtedly, a new record has been established in using a Francis type of turbine for 850 ft. head, these being the Oak Grove turbines of the Portland Railway, Light & Power Company now being constructed by the Pelton Company, where they will use the Moody type of draft tube and rubber sealing rings on the runner and guide vanes.

Impulse turbines have apparently established no new records during the past season, although an additional 30,000-horse power turbine, recently designed and constructed by the Allis-Chalmers Mfg. Company is now being installed in the Caribou Plant of the Great Western Power Company. This is the world's record both for horse power and size of machine, for this type of unit. Experiments conducted in the hydraulic laboratory of our Company upon several different designs of buckets and impulse wheel settings, have proven conclusively that the efficiency of a well-designed impulse unit compares very favorably with that of the best type of Francis wheel and even surpasses it at part gate.

Governors

No radical changes have been made in the fundamental features of hydraulic turbine governors during the last ten years, although many improvements have

been made with the view of simplifying and making this equipment more reliable. The governor equipment for the 70,000-horse power Niagara Falls turbine is similar to that used with the 37,500-horse power units installed in 1919. The flyballs are mounted directly on the main shaft and their motion is transmitted to the governor stand located on the upper generator floor. A large number of plants have been placed in operation, using a motor to drive the flyballs, thus doing away with jack shafts and belts. Fairly satisfactory results have been obtained, although there is always danger of losing the driving current in case of trouble with the generator, in which case the turbine gates will open wide instead of closing. To eliminate this danger a small independent generator mounted on the waterwheel shaft driving only the flyball motor would be ideal, but the cost makes it prohibitive for general use.

In the large power systems existing at the present time, the instantaneous load fluctuations reach such a small per cent of the total output of the system, that there is little actual work for a governor. Their existence is only justified as a safety device, for in case of electrical trouble they will shut the machine down quickly. An interesting development has been the installation of several hydroelectric units not equipped with governors. The generators and oiling systems were designed to withstand prolonged runaway, the units delivering current into a fairly large power system, and regulation being provided by the governor-equipped units in other stations on the system. Sufficient leeway is maintained in the governor-equipped station to pick up any rapid increase in load, slow fluctuations being controlled by manual adjustment of the units not equipped with governors. The three 5500-horse power, 65-ft. head, vertical units of the Brown Company at Berlin, New Hampshire, are the best examples of a complete installation without governors.

Automatic Equipment

Automatic-control equipment for hydroelectric installation has drawn more and more attention during the past few years. We give below the principal functions which the various types of automatic equipment furnished with our governors perform.

Emergency Stop Device

This is a safety feature which is being used on nearly all of the large installations and enables the operator at the switchboard to shut the turbine gates and stop the machine quickly without requiring the assistance of the second or third operator. This is accomplished by closing a switch on the switchboard, energizing a solenoid mounted on the governor stand, which immediately causes the pilot valve to be lifted into the closed position and held there, thus bringing the turbine gates to the full closed position in the minimum time allowable. This emergency stop device may also be connected to temperature indicators in the turbine or generator bearings, or generator windings, to overload or differential relays, or any other recording or indicating device used to indicate abnormal conditions.

Remote-Control Equipment

This equipment is designed to be used with large units where it is especially desirable to have the machine under the direct control of the switchboard operator, even during starting up and stopping, instead of having the second operator start the machine and bring it up to speed by hand as is the common custom. By means of the electrically operated synchronizing device and remote-control load-limiting device the switchboard operator may open the gates slowly and bring the unit up to speed from dead stop, indicating instruments on the switchboard showing him at all times the exact position of the turbine gates and the load-limit setting. With this equipment it is not necessary for the second attendant to touch the governor and the unit may be separated from the line, shut down completely and the brakes applied by the switchboard

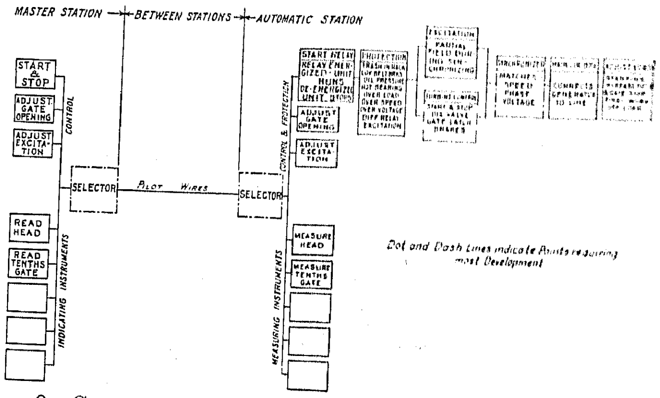

Fig. 9—General Scheme of Complete Automatic Remote Control System

operator. This same equipment may be used for controlling a distant unit from another station, although it will require more connecting wires between the two stations than with the full automatic control equipment.

Full Automatic Control

The most general type of automatic remote control is illustrated by the chart shown in Fig. 9. The features which are present at the master station are shown at the left of the sheet. They consist of the control switches by which operations are performed at the automatic station, indicating instruments which show conditions existing at the automatic station, and a selector mechanism by which these various functions can occur without an excessive number of pilot wires between stations. Pilot wires connect the two stations.

The right half of the diagram shows the equipment at the automatic station. Two types of operations are controlled by the selector. The upper part of the diagram shows those required to control and protect

the unit. The lower part shows the measuring devices which work in conjunction with the indicating instruments at the master station.

In any system power is required at the automatic station before it can be started, so that either the incoming lines must be energized or a storage battery provided.

Operation

Consider the method by which the system operates. To start, the selector at the master station is set by hand or by float to the start position and the starting switch closed. In response, the starting relay at the automatic station picks up. If the protective devices indicate that the machine is in running condition, the turbine starts and the alternator is then synchronized and connected to the line. The time required for starting is one or two minutes.

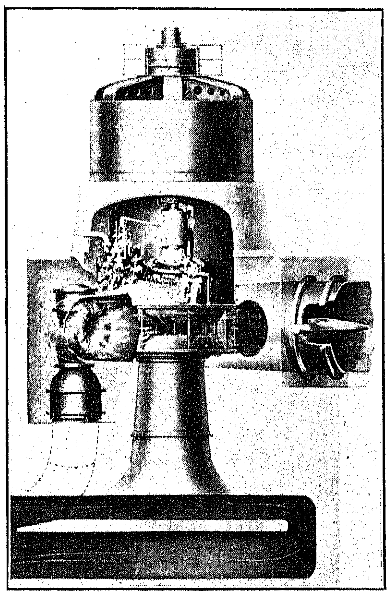

Fig. 10—Sectional View of Hydroelectric Unit, Showing Butterfly Valve, Pressure Regulator, Hydraucone and Integral Type Governor

If desired, equipment may be furnished for adjusting the turbine gates by means of the load-limiting device arranged for remote control. The usual indicating instruments are for head and gate opening but others may be added if desirable.

Power Houses

For the larger type of vertical hydroelectric unit, the one-floor station shown in Fig. 10 seems ideal. The butterfly valve with sealing rings shuts off the water at the inlet of the casing. A governor-actuated pressure regulator prevents excessive pressure rises, due to the use of a long penstock. The plate-steel spiral casing is riveted to a cast-steel speed ring. The governor is of the integral type with the flyball mounted directly on the main shaft and the governor stand located on one of the regulating cylinders, thus doing away with long runs of piping. The generator is supported on a concrete barrel and there is only one floor in the power house, so that one attendant may watch both the electrical and governor equipment. The unit is equipped with the White hydraucone, which type of draft tube has become very popular in the last five years.

From 1911 to 1916, a large number of experiments were made on various types of draft tubes, particularly the hydraucone with runners covering a wide range of specific speeds. Between the years 1913 and 1918, the Nagler was being developed and improved high-speed runner. The insistent demand at that time for higher speeds under low heads was responsible for the rapid advances made in its design. Following this, we made simplifications and improvements in control equipment, including direct-connected flyballs, integrals governors, remote control for butterfly and gate valves, and sealing rings to prevent leakage through butterfly valves.

Recently, attention has been directed our to power house arrangement. The increasing size of units, and the high cost of trained operators have greatly influenced the modern power house design. Every power house arrangement is studied with a view to greater accessibility, increased convenience and the least number of operators. Thus it is necessary to make many changes but with each change are embodied a greater simplicity and sturdiness of design.

Hydroelectric power is the most important source of energy this country has at the present time, so let us give to its proper development the time and thought which it deserves.

Discussion

For discussion of this paper see page 459.

Acceptance Tests for Hydroelectric Plants

BY FRANK H. ROGERS

Wm. Cramp & Sons, Ship & Engine Bldg. Co., Philadelphia, Pa.

TESTS made at site on hydroelectric units are important from the viewpoint of acceptance or rejection of the machinery and are of great value to the power company as the data thus obtained, permit the most economical operation of the units. It is recognized that in most plants water economy is vital, so that high efficiencies of both generator and water turbine must be secured over the range in flow and head occurring at the site. For this reason, the efficiency guarantees made in the various proposals received are rightly given consideration in awarding contracts for the machinery. In any given plant, a fair yearly income value can readily be calculated for each per cent gain in efficiency and such value capitalized at say 10 per cent shows the additional money which can properly be spent for the machines developing the higher efficiency. As contracts are frequently awarded on this basis, tests should be made to determine whether these guarantees have been met.

From the data secured by tests made at site, tables and curves are prepared, which permit the operators to properly divide the load between the various units, resulting in the maximum possible kilowatt hours output for a given flow of water.

In a number of plants, especially those located on international streams, a definite quantity or flow of water is permitted the power company. The water consumption is sometimes checked by taking measurements of flow at stated intervals, with the corresponding output of the generators, and from these readings the total flow is estimated from the total output over a given period. Such a method is both inaccurate and expensive and is unnecessary if efficiency tests are made, for then the generators are actually calibrated water meters and the flow can be determined accurately from the kilowatt output. This phase of the matter will be taken up later in more detail.

METHODS OF TEST

In this article the writer will deal primarily with the methods of testing hydraulic turbines. For many years there was no standard and as most of the contracts contained little or no information as to testing, the engineer who conducted the tests used his own ideas and his own instruments, calibrated at times, but more often used with assumed coefficients. The head on the turbine was measured at various points and the velocity heads in the conduits were often neglected. Hence it is little wonder that arguments arose between the power companies and the manufacturers as to the results obtained. Furthermore, there being no standard, the efficiencies secured at one plant bore no relation to those obtained at another plant.

To remedy these difficulties, a Testing Code for Hydraulic Turbines was prepared under the auspices of the Machinery Builders Society in October, 1917. This code was actually compiled by the engineers of the leading turbine manufacturers in the United States. After completion, a draft of this code was sent to about fifty consulting engineers and engineers of the power companies interested in this line of work. Many valuable suggestions were thus obtained, so that the final code adopted represents the consensus of opinion of a large majority of the manufacturers and engineers in the hydraulic field. Since 1917, this code has been in general use and has been attached to practically all contracts for hydraulic turbines.

A similar code was presented in May, 1922 by the Committee on Power Test Codes of the American Society of Mechanical Engineers under the title of Test Code for Hydraulic Power Plants and Their Equipment. This code is similar and agrees on all cardinal points with the Machinery Builders' Code. It is more general in its scope, covering the testing of the entire plant such as canal, forebay, and penstock, as well as the turbine, and also contains rather full instructions as to the form of preparing tables showing data and results. The methods of measuring power output, water consumption, head and speed are covered by a supplementary code on instruments and apparatus.

As both of these codes have been published, there is no necessity of a detailed description of the methods of testing contained therein, but it might be of interest to briefly outline the various quantities to be measured, in order to determine the turbine efficiency and the instruments and apparatus for making such measurements.

TURBINE EFFICIENCY

The turbine efficiency is defined as the ratio of the brake horse power, or the power delivered by the turbine shaft, to the water horse power, or the energy delivered by the water to the turbine:

$$E = \frac{B\,H\,P}{W\,H\,P} \tag{1}$$

The water horse power is given by the formula:

$$W\,H\,P = \frac{Q \times W \times H}{550} \tag{2}$$

in which

Q = Flow in cubic feet per second
W = Weight of water in pounds per cubic foot
H = Effective head on turbine.

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

Measurement of Brake Horse Power

In the case of hydroelectric units which will be considered in this article, the brake horse power is determined from the generator output divided by the generator efficiency. Therefore, the generator efficiency must be determined by tests made in the shops of the builder or after installation, either by the direct measurement of input and output, or by the separate loss measurement, the electrical measurements being made in accordance with the Standards of the American Institute of Electrical Engineers 1921, Revision.

The generator efficiency is given by the following formula:

$$\text{Eff.} = \frac{\text{Kw. output at generator terminals}}{\left\{\begin{matrix}\text{Kw.}\\ \text{output}\end{matrix}\right\} + \left\{\begin{matrix}I^2 R\\ \text{armature}\end{matrix}\right\} + \left\{\begin{matrix}\text{Open circuit}\\ \text{core loss}\end{matrix}\right\} + \left\{\begin{matrix}\text{Stray}\\ \text{load losses}\end{matrix}\right\} + \left\{\begin{matrix}\text{Windage}\\ \text{and friction}\end{matrix}\right\}} \tag{3}$$

The above formula is based on the assumption that the generator is separately excited both during the efficiency tests made on the generator and the efficiency tests made on the turbine.

In determining the windage and friction, core loss and stray load losses, the generator may be driven by an independent motor, or where a direct-connected exciter is used, by its own exciter as a motor. If this method cannot be used, it is then possible to obtain these losses by a retardation test. In making such a test the turbine shaft and runner should be disconnected so as to eliminate the windage and friction losses of the turbine shaft and runner. In many plants it is impracticable to disconnect the turbine shaft, due to the fact that frequently no lower generator bearing is furnished. In such cases the windage and friction of the turbine shaft and runner may be calculated from the following formula:

$$K\,W = K\,B\,D^4\,N^3 \tag{4}$$

in which $K\,W$ = Windage and friction loss of shaft and runner

B = Height of turbine distributor in feet

D = Entrance diameter of runner in feet measured at centerline of distributor

N = Revolutions per second

K = Empirical coefficient.

It has been found by actual tests made that a close value for K is 0.000115.

One of the methods used in determining this coefficient was rather interesting and might be worth mentioning. In the Holtwood plant of the Pennsylvania Water and Power Company, the turbines are of the vertical shaft, two-runner type, and it was possible to disconnect the lower runner, so that in the first test, the total windage and friction loss included the generator loss plus the loss for two turbine runners. After disconnecting the lower runner, the test was repeated and in this case, the total windage and friction loss represented the generator loss plus the loss due to one runner. By subtracting these two losses the difference gave the windage and friction loss of one turbine runner and thus gave a ready means of determining the correct windage and friction loss of the generator alone.

Measurement of Head

The effective head on the turbine is the difference

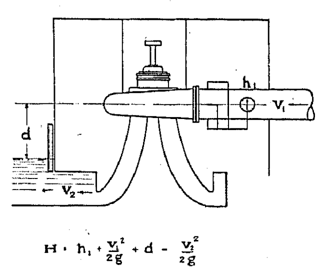

Fig. 1—Effective Head on Hydraulic Turbines

between the total energy contained in the water immediately before its entrance to the turbine and the total energy in the water immediately after its discharge from the draft tube. The total energy at any point is the pressure head plus the velocity head and hence:

$$H = \left\{h_1 + \frac{V_1^2}{2\,g}\right\} - \left\{h_2 + \frac{V_2^2}{2\,g}\right\} \tag{5}$$

If the datum plane is taken at the centerline of the casing and d is the distance from this plane to tailwater,

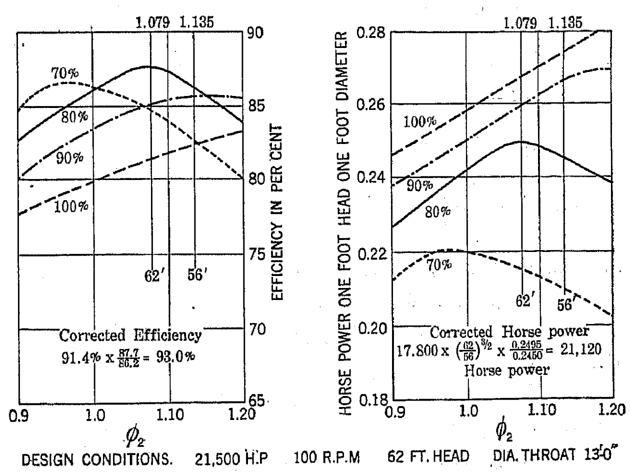

Fig. 2—Performance Curves of Turbine from Laboratory Tests

$$H = h_1 + \frac{V_1^2}{2\,g} + d - \frac{V_2^2}{2\,g} \tag{6}$$

Fig. 1 shows the location of the gages and the velocities to be considered in determining the effective head. At least four piezometers should be provided near the casing intake and connected independently to a calibrated pressure gage, a mercury manometer, or open

glass tubes on a gage board, depending on the conditions. A board, rod or float gage should be located in the tailrace near the draft tube discharge at points reasonably free from local disturbances. It is often found advisable to locate rods or float gages in stilling boxes.

The turbine should be tested at the head and speed specified in the contract. If it is found that the actual head existing during the test differs from the contract head, the speed should be adjusted to correspond. It is a well known principle that if the speed of a turbine is changed in proportion to the square root of the ratio of the heads, the horse power will change in proportion to the three-halves power of the ratio of the heads and the turbine efficiency will remain constant. Therefore, if during the test the load on the generator is made up of a water rheostat, or if it is permissible to operate the generator at different frequencies, the proper correction can be made for any variations in head and the results are absolutely reliable. If, on the other hand, the generator is delivering load to a system where the cycles and hence the speed are fixed, it is impracticable to correctly adjust the speed to suit the head. In such cases the values of power and efficiency as shown by the test must be corrected on the basis of test curves of the same or homologous turbine made at a testing flume. In tests conducted in laboratories, runs are made at each gate opening for a wide range in speeds, and curves are prepared showing speed-power and speed-efficiency for each gate opening. Fig. 2 shows sample curves of such tests. The value ϕ_2 plotted as abscissae is called the speed characteristic and its value is given by the formula:

$$\phi_2 = \frac{V_P}{\sqrt{2\,g\,H}} \tag{7}$$

or ϕ_2 = The ratio of the peripheral speed of the runner to the spouting velocity due to the total effective head.

As an example, consider a turbine designed for a normal full-load output of 21,500 horse power under a head of 62 ft. at a speed of 100 rev. per min. The rated diameter of the runner = 13′ – 0″ and therefore from the above formula $\phi_2 = 1.079$.

Assume for one of the test points actually obtained the following values:

Gate opening	= 80 per cent
Horse power	= 17,800
Effective head	= 56 ft.
Rev. per min.	= 100
Turbine efficiency	= 91.4 per cent

For the above conditions of head and speed, the value during the test of ϕ_2 is given by

$$\phi_2 = 1.079 \times \sqrt{62/56} = 1.135$$

By referring to the two curves shown in Fig. 2 at the two values of ϕ_2, we obtain the ratios to apply to the horse power and efficiency to correct for the speed and then step up the horse power by the three halves power of the ratio of the heads to obtain the results under contract conditions.

Thus $H\,P = 17{,}800 \times (0.2495/0.2450) \times (62/56)^{3/2} = 21{,}120$

$$E = 91.4 \times (87.7/86.2 = 93.0\%$$

Measurement of Quantity of Water

The determination of the quantity of water flowing to the turbine is usually considered the most difficult of all measurements and is undoubtedly the most interesting. Many different methods of quantity determination are used, depending on local conditions, among which might be mentioned: Venturi meter, weir, Pitot tube, current meter, salt solution, screen or diaphragm, color velocity, salt velocity and the Gibson method.

Most of these methods are well known but it might be worthwhile pointing out some interesting features of the Pitot tube and current meter and giving a short description of the salt velocity and Gibson methods, as the two latter, while of very recent origin, have been thoroughly tried out and found to give a high degree of accuracy and reliability.

Pitot Tube

The Pitot tube method should be used in conduits or penstocks where reasonably straight and smooth flow may be expected to occur. Therefore, the tube should be installed in a straight line of penstock, the traverse section being at least ten pipe diameters from any upstream bend and five pipe diameters from any downstream bend or disturbance.

If the axis of the Pitot tube opening is parallel to the direction of stream line flow, the water will rise in the tube to a height exactly equal to the pressure head, plus the velocity head existing at the point of the tube. That the Pitot tube correctly reads velocity head can be readily proven theoretically and this fact has been demonstrated many times by tests made both by still water ratings and in flowing water from nozzles. If the pressure head is read from piezometers in the sides of the penstock, the difference between the tube reading and the piezometer reading, is the velocity head from which the velocity is obtained by the well-known formula:

$$V = \sqrt{2\,g\,h} \tag{8}$$

Fig. 3 shows a type of tube frequently used and on the right side the connections between the Pitot tubes, piezometers, and gage board. Where a considerable straight run of penstock is available resulting in good flow conditions, only two Pitot tubes need be used and four piezometer openings, all connected to independent tubes on the same gage board. Traverses are made across the penstock by both tubes and at each point all six gages are read and the difference between the tube and average piezometer readings, gives the veloc-

ity head from which the velocity for each area of the penstock can be plotted.

The penstock is divided into a number of equal-area annular rings as shown in Fig. 4, the center circle having an area equal to one-half of the area of each annular ring. The tube stations are located at the center of area of each ring and at the center of the pipe, so that each reading taken is of equal weight. The velocities in feet per second are plotted against areas in square feet, so that the area of the diagram, as obtained by a planimeter, gives the quantity of flow in cubic feet per

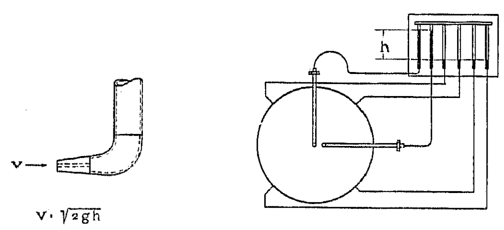

FIG. 3—PITOT TUBE AND GAUGE BOARD CONNECTIONS

second. Where two tubes are used, the average of the two quantities thus obtained is taken as the true quantity. In the case of short penstocks where the flow may be disturbed, additional tubes are used to determine the velocities on radii between the two main tubes. In spite of the fact that the Pitot tube both theoretically and actually reads the correct velocity head, it has been found by many experimenters that the quantity as indicated by the tubes is always greater than the actual flow by from 1 per cent to 4 per cent. depending on local conditions. For example, tests made at Niagara

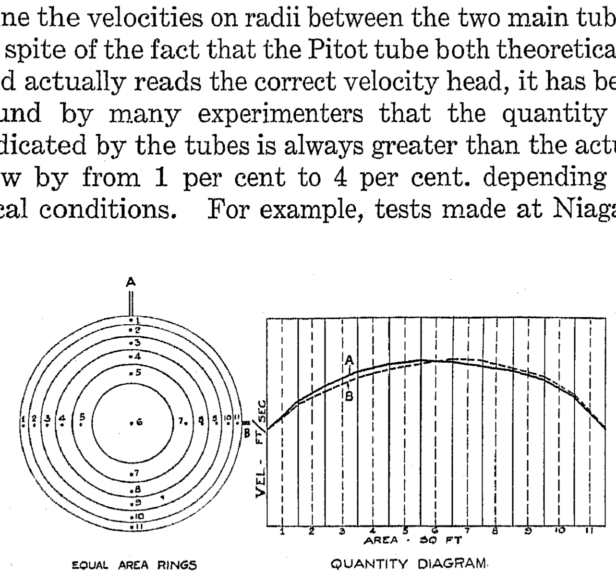

FIG. 4—PITOT TUBE STATIONS AND QUANTITY DIAGRAM

Falls in 1908, in a 5-ft. diameter penstock with Pitot tubes and checked by weir measurements, showed that the quantity obtained from the tubes was about 2 per cent greater than that given by the weir, requiring a quantity coefficient of 0.9755 for the Pitot tube method. A careful series of tests was also made at the hydraulic laboratory of the University of Pennsylvania, measuring the velocities in a 7-in. diameter pipe by Pitot tubes and at the same time measuring the actual flow in large weighing tanks. In these tests, the quantity coefficient of the tube varied from 0.968 to 0.997, depending on the velocity, the coefficient approaching unity as the velocity increased.

Engineers were, therefore, confronted by two facts separately proven, but contradictory.

(1) The Pitot tube gives the correct velocity head without calibration when the axis of the tube is parallel to the stream line flow.

(2) The quantity of water flowing in a conduit as obtained from Pitot tubes gives results always greater than the true flow.

To solve this enigma, a series of tests was made by the writer in 1910 at the Testing Flume of the Rensselaer Polytechnic Institute at Troy, New York. Various types of tubes were tested as shown in Fig. 5. The tubes were attached to a car propelled on tracks above the flume and readings of the tubes were compared with

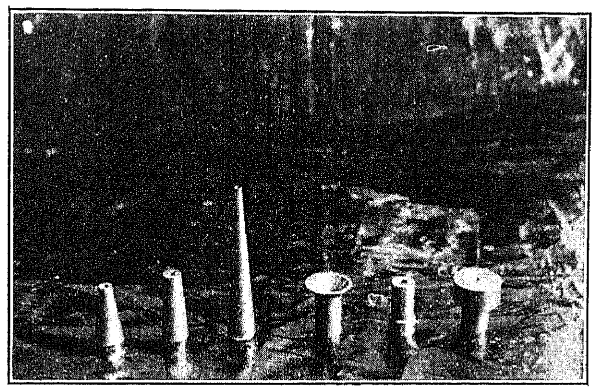

FIG. 5—TYPES OF PITOT TUBE NOZZLES

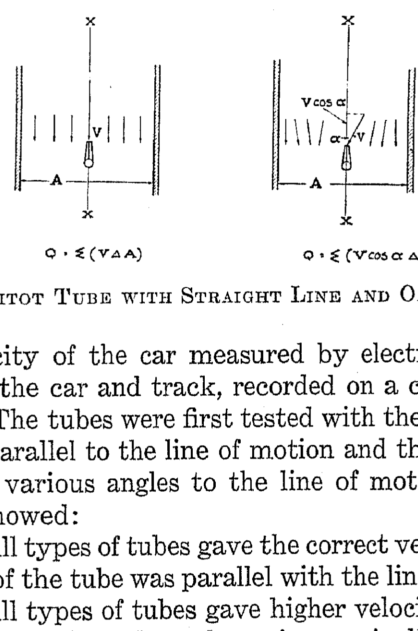

FIG. 6—PITOT TUBE WITH STRAIGHT LINE AND OBLIQUE FLOW

the velocity of the car measured by electric contacts between the car and track, recorded on a chronograph drum. The tubes were first tested with the axes of the nozzles parallel to the line of motion and then with the tubes at various angles to the line of motion. These results showed:

(1) All types of tubes gave the correct velocity when the axis of the tube was parallel with the line of motion.

(2) All types of tubes gave higher velocity than the resolved velocity when the axis was inclined to the direction of motion.

Fig. 6, shows on the left hand side, a tube inserted in a pipe, the axis being parallel to the centerline of the pipe for all positions of the traverse and with straight line flow assumed, so that the quantity is determined from

$$Q = \Sigma\,(V\,\Delta\,A) \qquad (9)$$

and hence the velocity required is the velocity normal to the area A. The pipe shown on the right side indicates a condition of oblique flow and in this case as the quantity is given by:

$$Q = \Sigma\,(V \cos \alpha\, \Delta\, A) \tag{10}$$

the velocity required from the tube reading is the resolved velocity at each point or $V \cos \alpha$.

Now the Pitot tube does not read velocity but velocity head, and hence when the water strikes the tube obliquely at a velocity of V, the tube should read a head of: $\dfrac{V^2}{2\,g} \cos \alpha$, as shown in Fig. 7. The velocity

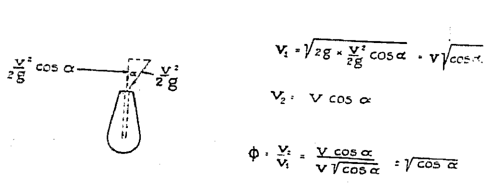

FIG. 7—VELOCITY GIVEN BY PITOT TUBE IN OBLIQUE FLOW

in feet per second calculated from this reading of the tube is given by

$$V_1 = \sqrt{2\,g \left(\frac{V^2}{2\,g} \cos \alpha\right)} = V\,\sqrt{\cos \alpha} \tag{11}$$

and it has been shown above that the velocity required to give the correct flow is

$$V_2 = V \cos \alpha \tag{12}$$

From the above it is evident that for conditions of oblique flow the Pitot tube readings will give velocities too great and hence in determining the quantity, the coefficient of the tube is given by:

$$\phi = V_2/V_1 = \frac{V \cos\ \alpha}{V\,\sqrt{\cos\ \alpha}} = \sqrt{\cos\ \alpha} \tag{13}$$

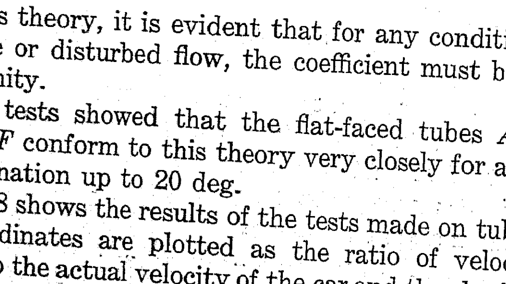

FIG. 8—TEST OF PITOT TUBE AT VARIOUS ANGLES OF INCLINATION TO THE FLOW

On this theory, it is evident that for any condition of oblique or disturbed flow, the coefficient must be less than unity.

The tests showed that the flat-faced tubes A, B, E and F conform to this theory very closely for angles of inclination up to 20 deg.

Fig. 8 shows the results of the tests made on tube B. The ordinates are plotted as the ratio of velocities reads to the actual velocity of the car and the abscissae, as angles of inclination. V_B shows velocities given by the tube B, V_T the theoretical velocity based on resolved pressure, and V_R the resolved velocity to give the correct flow. The tube coefficient ϕ is the ratio of V_R to V_B and varies from unity at zero degrees to 0.96 at 20 deg.

Absolute straight line stream flow is very difficult to produce in laboratory work and is never obtained in practise when water is flowing in pipes or open channels at ordinary velocities. The flowing mass of water is full of local whirls, so that at any given point the velocity varies both in direction and magnitude. Therefore under the usual conditions met in engineering, a coefficient less than unity must be used to correct the quantity obtained by Pitot tube measurements. This coefficient, however, has a small range in actual value, its limits for ordinary conditions being unity and 0.96. The Machinery Builders Code fixes the value at 0.976 as the average obtained from a large number of comparative tests, and the A. S. M. E. Code gives the coefficient as 0.98.

This latter code also mentions the Pitometer as a commercial adaptation of the Pitot principle and states that the coefficient for this instrument is furnished by

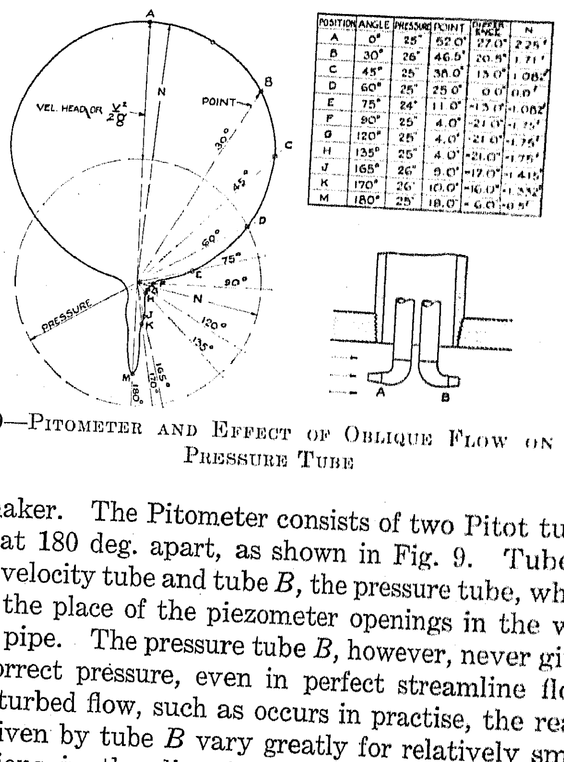

FIG. 9—PITOMETER AND EFFECT OF OBLIQUE FLOW ON THE PRESSURE TUBE

the maker. The Pitometer consists of two Pitot tubes fixed at 180 deg. apart, as shown in Fig. 9. Tube A is the velocity tube and tube B, the pressure tube, which takes the place of the piezometer openings in the wall of the pipe. The pressure tube B, however, never gives the correct pressure, even in perfect streamline flow. In disturbed flow, such as occurs in practise, the readings given by tube B vary greatly for relatively small variations in the direction of flow. This is clearly shown in the polar diagram at the left of Fig. 9. This was plotted by revolving a single Pitot tube through various angles from zero deg. to 180 deg. and comparing its readings with the true pressure as given by piezometers in the wall of the pipe. At 180 deg. or normal position of tube B with perfect flow and a velocity of 12 ft. per sec., tube B showed a pressure reading of 19 in. or 6 in. less than the true pressure, resulting for this assumption in an instrument coefficient of:

$$\phi = \frac{\sqrt{2\,g \times 2.25}}{\sqrt{2\,g \times (2.25 + 0.5)}} = 0.905$$

If the direction of flow varies but 10 deg. from normal, tube B shows a pressure reading 16 in. less than the true pressure, giving a coefficient of:

$$\phi = \frac{\sqrt{2\,g \times 2.25\ .\ (\cos 10°)}}{\sqrt{2\,g\ (2.25 \cos 10° + 1.332)}} = 0.875$$

It is thus evident that the coefficient obtained by still-water ratings will be very unreliable under flow conditions as met in practise.

Current Meters

Current meters have been used very widely for gaging the flow of streams and rivers and also in determining the flow in tests of hydraulic turbines where a canal or flume is available. Current meters should only be used where reasonably straight and smooth flow may be expected to occur, and therefore a long straight run of flume of rectangular cross section should be available. It is always preferable to locate the current meters on the intake side of the plant, rather than in the tailrace, as the flow conditions in the tailrace are usually very much more disturbed.

A great many experiments have been made to determine the accuracy of quantity measurements by current meters, using the still-water ratings of the meters and comparing the readings with the flow determined by some other method of measurement, and it has been found that the still-water ratings are not reliable as oblique or disturbed flow affects the readings of the meters in a somewhat similar manner to the effect of such flow on Pitot tubes. Unlike Pitot tubes, however, it is found that some types of flow meters read too high and other types too low. Thus the cup-type meters invariably read high and the screw type usually read low.

A series of very interesting tests was made by Benjamin F. Groat in connection with the tests on a 6000-horse power turbine at Massena, New York.[1] In these tests Mr. Groat used a Haskell meter of the screw type and a Price meter (large size) of the cup type. The meters were carefully rated from a boat to determine their coefficients. When actually used in the turbine test, however, it was found that a large constant difference in discharge determinations was obtained by means of the two types of meters. In the case of these two particular meters, it was found that the velocities, as determined from the still-water rating of the cup meter, were considerably in excess of the velocities as found from the similar rating of the screw meter and that if one-seventh of the difference between the two velocities was added to the velocity given by the screw meter, the result would be very close to the true velocity at the point in question.

A series of tests made in the Testing Flume of the Rensselaer Polytechnic Institute in 1912, also proved that current meters of the two types mentioned above will indicate velocities quite different from the actual velocities in conditions of oblique flow.[2]

The two meters used in these tests were a Price meter (small size) of the cup type, and a Buff and Berger screw meter of the Fteley-Stearns type. The two current meters were attached to the car in a similar manner to the Pitot tubes as previously described in this paper, and turned at various angles to the direction of motion of the car. The results of these tests are shown in Fig. 10, and are also plotted in a similar manner to the Pitot tube tests. It will be noted that as the angle of inclination is increased from zero degrees, the cup-type meter shown by curves R_L and R_R always registers higher velocities than the true velocity shown by curve $R_C = \cos\ \theta$, whereas the screw-type meter shown by curve R_M always shows lower readings than the true velocity. It is rather interesting to note from these curves that the cup-type meter gave different readings for velocities inclined to the right from those inclined to the left. For ordinary inclinations such as 15 or 20 deg. the true velocity lies about half-way between the velocities

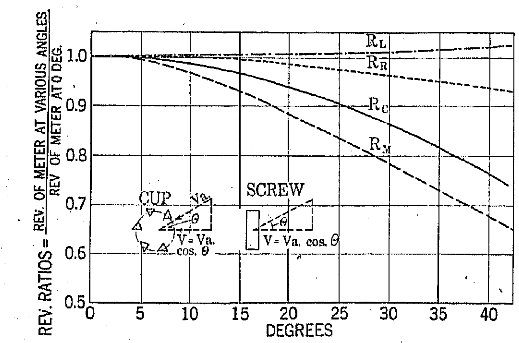

Fig. 10—Velocities by Current Meters in Oblique Flow

indicated by the two types of meters, but for greater degrees of inclination, the screw-type meter shows a less error on the negative side than the cup-type meter shows on the positive side.

It is therefore evident that where current meter measurements are to be made to determine the flow, it is necessary to use two types of meters in the test and to correct the readings from the data previously obtained from still-water ratings of these meters at various angles of inclination.

Salt Velocity Method

The Salt Velocity, sometimes termed the brine velocity or Allen method for measuring the flow of water, has been developed during the last three years by Professor Charles M. Allen of Worcester, Mass. Extensive investigations have been made at the Alden Hydraulic Laboratories of the Worcester Polytechnic Institute, checking the results obtained by a Venturi

1. See B. F. Groat's paper on "Pitot tube Formulas,—Facts and Fallacies" published in *Proceedings* of the Engineers Society of Western Pennsylvania, May, 1914.

2. These tests were described in a paper by L. F. Moody on "Measurement of the Velocity of Flowing Water," published in *Proceedings* of the Engineers Society of Western Pennsylvania, May, 1914.

meter and weir and a number of commercial tests have been conducted on units in power plants, notably the 20,000-horse power turbines of the Laurentide Power Co. at Grand Mere, Quebec, and the 41,000-horse power turbine of the Shawinigan Water and Power Company at Shawinigan Falls, Quebec.

A very complete and interesting description of this method, the results of the laboratory investigations and the commercial tests made, was given in a paper presented by Charles M. Allen and Edwin A. Taylor at the Annual Meeting of The American Society of Mechanical Engineers in New York, December 1923.[3] It may be of interest, however, to give a brief summary of the method and its manner of application in commercial plants.

The theory is simple and is expressed very clearly by the authors of the above-mentioned paper as follows:

"The Salt Velocity Method of Water Measurement is based on the fact that salt in solution increases the electrical conductivity of water. Salt solution is introduced near the upper end of the conduit and the passage of the solution across one or more pairs of electrodes at other points in the conduit is recorded graphically by electrical recording instruments. The passage of the salt solution between two points is accurately timed and the volume of the penstock between the same points is accurately determined. The discharge in cubic feet per second equals the volume in cubic feet divided by the time in seconds."

Therefore in making such a test, it is only necessary to provide for the introduction of the salt solution, two sets of electrodes, each consisting of two metallic bars insulated from each other, and a source of electrical energy, generally 110 volts d-c. or a-c. A recording ammeter or wattmeter is connected in the circuit of

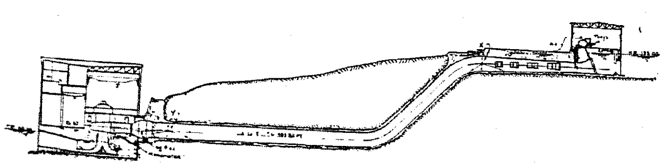

Fig. 11—Test of 41,000 Horse Power Shawinigan Unit by Allen Method

the electrodes and before the salt solution is introduced, the initial steady reading of the meter will be from one half to one ampere. When the salt solution reaches the first set of electrodes, the current passing between the two bars increases, due to the greater conductivity of the water, reaches a maximum value, and then decreases to normal again as the charge of salt passes by, thus producing on the chart, a humped curve. A similar curve is drawn by the meter when the salt solution passes the second set of electrodes. The time is also recorded on the same chart by a standard clock or seconds pendulum connected electrically to a pen or by a hot spark. The time between the centers of gravity of the two curves produced is the average time it has taken the water to travel the distance between the two sets of electrodes. The volume in cubic feet between the electrodes being accurately determined by physical measurements, the quantity flowing in cubic feet per second equals the volume divided by the time.

The general arrangement of the 41,000-horse power

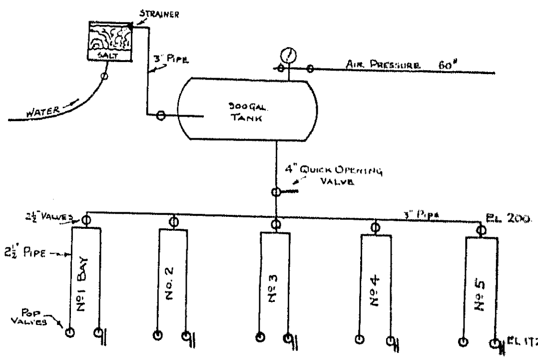

Fig. 12—Arrangement of Tanks for Allen Method

Shawinigan unit is shown in Fig. 11. The penstock was 20 ft. in diameter, about 500 ft. long and fed by five gathering tubes. The salt was introduced at the upper end and its passage recorded at electrodes X and Y. Fig. 12 is a diagram showing the mixing tank, pressure tank, quick opening valve, pop valves and piping. Two pop valves were located in each of the five bays and an introduction electrode was connected to one of the valves in each bay. The main electrodes at X and Y each consisted of two steel bars 4 in. wide, ½ in. thick, spaced 4 in. apart and extending across the horizontal centerline of the penstock as shown in Fig. 13. The electrodes used in the gathering tubes are shown in Fig. 14, and it was possible during the test to compare the discharge measured in these five tubes with the same discharge measured in the 20 ft. penstock between electrodes X and Y. The greatest variation was 0.7 per cent and the average of all discharges checked exactly.

A set of sample curves drawn by the recording Wattmeter is shown in Fig. 15, the upper curve being for practically full gate opening and the lower curve for 61 per cent gate opening of the turbine. The time in seconds is shown on these curves by the dots at the bottom of each curve. The numbers marked on these curves are the test numbers and show which curves are to be taken together for the calculation of the time of salt passage. Thus on the upper curve 250 Int. shows the time of introduction of the salt solution at the upper end of the penstock, 250 X shows the time the salt solution passed electrodes X, and 250 Y, the time the salt solution passed the electrodes Y. The centers of gravity of the curves at 250 X and 250 Y

3. An abstract of this paper "The Salt Velocity Method of Water Measurement" was printed in *Mechanical Engineering*, January, 1924.

are then determined and the time between these two centers of gravity reads from seconds indicated at the bottom of the curve.

The tests made on the 20,000-horse power Laurentide unit were of considerable interest, as this unit is provided with concrete volute casing and with short concrete penstock of varying cross section. This type of setting has always presented great difficulties for accurate water measurements, but the tests by the salt-velocity method were entirely satisfactory, repeat tests checking each other very closely and tests, made with varying apparatus and various methods of computation, giving the same final result. The general layout of this setting is shown in the diagram in Fig. 16. Eight pop valves were located in each of the three bays at the entrance to the penstock. Thus, 24 pop valves were arranged so as to give a uniform distribution of salt over the entire cross section. Six pairs of introduction electrodes were placed about 22 in. downstream from the plane of the pop valves.

The final electrodes shown at *A*, *B*, and *C*, were placed vertically at the lower end of the penstock about 3 ft. upstream from the entrance to the scroll case. These electrodes were of steel plate 4 in. wide by ½ in. thick, and were continuous, extending from the floor to the roof. A rather interesting photograph of the pop valves in operation is shown in Fig. 17. This photograph was taken with the penstock empty and under air pressure of 60 lb. per sq. in. The final electrodes near the entrance to the volute casing are also shown in Fig. 18. A set of sample curves taken during this test is shown in Fig. 19 for gate openings of the turbine of 85 per cent, 75 per cent, and 60 per cent. The center of gravity of the curves, made when the salt passed the introduction electrodes and the final electrodes, is shown by the vertical lines near the bottom of each curve.

The Gibson Method

While the Gibson method of water flow measurement has been fully described in a recent paper presented by Norman Gibson at the Annual Meeting of The American Society of Mechanical Engineers in New York City, December 1923,[4] a brief summary of

4. An abstract of this paper "The Gibson Method and Apparatus for measuring the Flow of Water in closed conduits," was printed in *Mechanical Engineering*, December, 1923.

the method and the underlying theory will be of interest.

The method makes use of two well-known principles: the first being Newton's second law of motion, that the force is equal to the product of the mass and the rate of change of velocity of that mass:

$$F = M \frac{d\,v}{d\,t} \tag{14}$$

This equation may also be written:

$$F\,d\,t = M\,d\,v \tag{15}$$

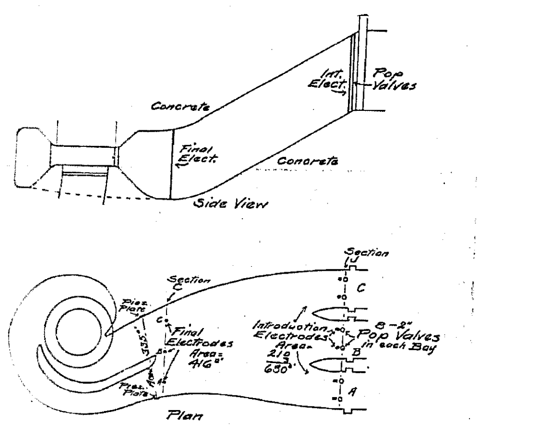

FIG. 16—TEST OF 20,000 HORSE POWER LAURENTIDE UNIT BY ALLEN METHOD

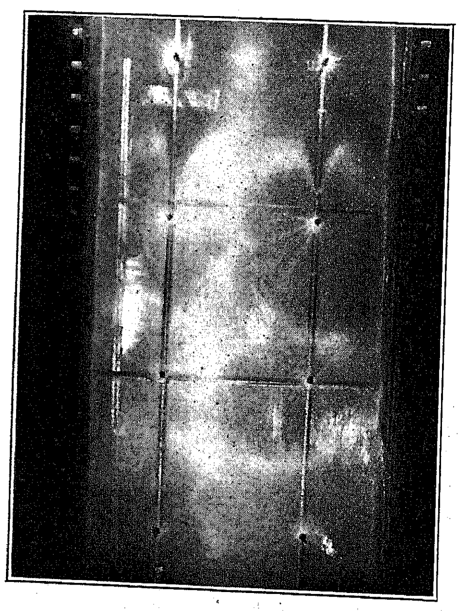

FIG. 17—TEST OF 20,000 HORSE POWER LAURENTIDE UNIT—POP VALVES IN OPERATION

which means that the impulse or the product of force by time is equal to the change in momentum or the product of the mass by the velocity change.

The second principle is the corollary of the first, *viz.*, the relation between the change of pressure and the change of velocity of a column of water expressed in terms of the velocity of the pressure waves which are propagated during the change from one end of the column to the other.

To apply this principle to the determination of the quantity of water flowing in a pipe of "uniform" cross section, consider that a valve or the gates of a turbine at the lower end are closed gradually in a given time, so that the velocity of the water in the pipe is gradually diminished and is finally stopped when the valve or turbine gates are fully closed. During closure, the pressure in the pipe rises and this pressure rise is the manifestation of the force exerted to stop the flow of the mass of water in the pipe. From the fundamental impulse equation (**15**), if the mass of the water in the pipe is known and the time taken to stop its flow and the "average" force exerted in doing so are measured, the velocity of the water, prior to the interruption of its flow, may be readily determined.

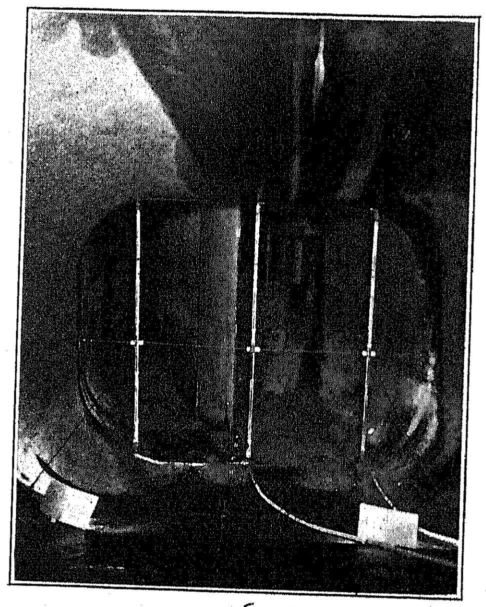

FIG. 18—TEST OF 20,000 HORSE POWER LAURENTIDE UNIT—FINAL ELECTRODES

Let: a = area of pipe in sq. ft.
L = length of pipe in ft.
Q = quantity flowing in cu. ft. per sec.
V = velocity in ft. per sec.
T = time to stop flow in sec.
P = average pressure rise, in ft. during time T
w = weight of water per cu. ft.
g. = accelleration due to gravity.

Then from equation (**15**)

$$P\,w\,a\,T = \frac{L a w}{g} \; X \; V \tag{16}$$

for which

$$V = g \frac{P\,T}{L} \tag{17}$$

The average pressure rise P and the time T are recorded by the specially designed Gibson apparatus, so that it is only necessary to measure the length L of the penstock, to determine the velocity V.

In practise, the test procedure consists of placing the desired amount of load on the unit, and for a period of time observing the head-water elevation, the tail-water elevation, casing pressure, speed, gate opening, and the various electrical measurements necessary to determine the generator output. At a given signal, the turbine gates are closed and the load taken up by the units operating in synchronism with it. The rate of closure need not be uniform, although this operation should take place as smoothly as possible. During the closure the flow in the penstock is being retarded and produces a change in pressure. A continuous record of this pressure change and the time of closure is made by the Gibson apparatus.

Fig. 20 is an illustration of this apparatus and Fig. 21 is a sectional view, showing the various parts in detail. Essentially, the process consists of photographing the oscillations of the mercury column D by means of the light from the lamp Z passing through the water-filled portion of the tube D and projected by the lens J upon a film wrapped around the drum N. A shutter A is used to protect the film when changing the drums. The drum is rotated at a constant speed by the small motor Q. Thus, a diagram (see Fig. 22) is obtained.

On this diagram A marks the beginning of the record, at O the pressure begins to rise as the turbine gates are being closed, at K the gates are fully closed and from K to C the column of water is being restored to equilibrium in a series of damped harmonic oscillations or waves. At Z there is an interval of time sufficiently long to allow these oscillations to subside, and then at F there is a short record which registers the pressure in the penstock under the then existing hydrostatic conditions. It will be observed that the narrow vertical spaces D, where the record has been obliterated, occur on the diagram at regular intervals. These form a record of time usually one second apart. This record is made by the pendulum K (Fig. 21) which swings in front of the aperture opposite the mercury column, thus cutting off the light from the diagram.

In working up the results of the test, it is necessary to delineate the diagram and determine the net area representing the change in momentum. This is accomplished in the following manner:

Referring to Fig. 23, the running condition at the particular gate opening of this test is shown at A on the diagram, and hence a line drawn parallel to the reference line E E will show this pressure. Another line drawn through F will give the static conditions existing after the closure, and therefore, the distance Y between these lines represents the friction and velocity head at this particular gate opening. The

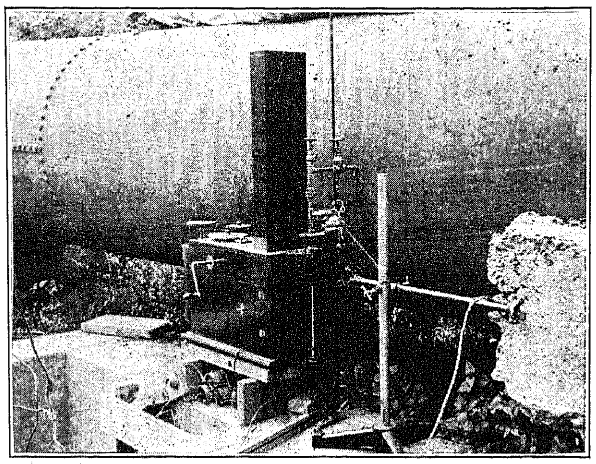

Fig. 20—Gibson Apparatus for Measuring Flow

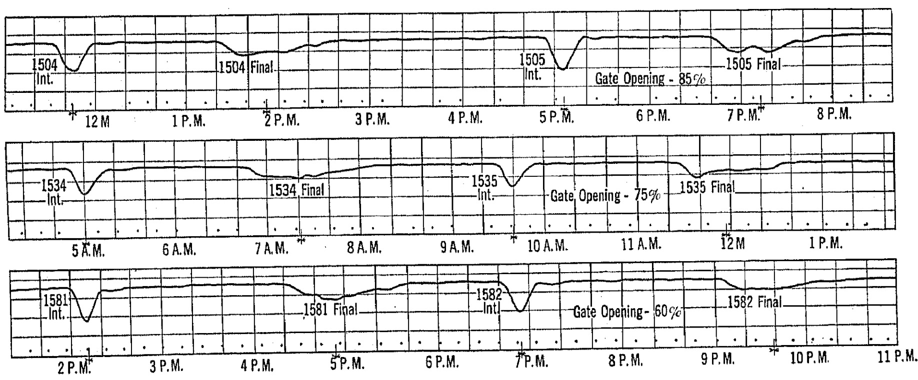

Fig. 19—Test of 20,000 Horse Power Laurentide Unit—Sample Curves

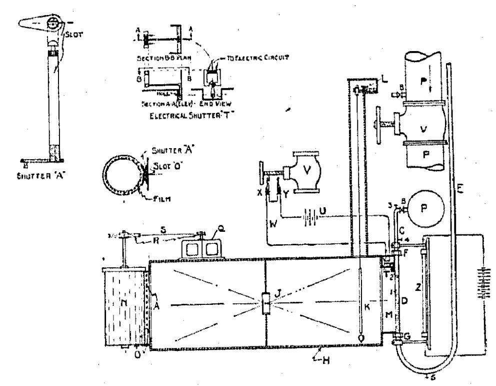

Fig. 21—Sectional View of Gibson Apparatus

point K at which the gates are completely closed is found from a study of the after waves $C\,C$ which, being damped harmonics, follow a general law. By reference to the ratio between successive waves, the distance from W to M may be determined, thus locating the end of the diagram.

In order to separate that part of the gross area of the diagram produced by the recovery of the velocity and

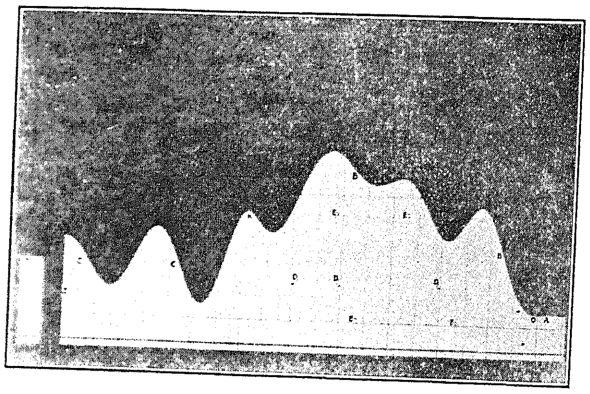

FIG. 22—TYPICAL PRESSURE—TIME DIAGRAM, BEFORE DELINEATION

friction heads, it will be remembered that both of these quantities are proportional to the square of the velocity. Therefore, by drawing an assumed recovery line $O\,M$ the diagram may be divided up into small areas a_1, a_2, a_3, etc., and the successive ordinates h_1, h_2, h_3, etc., obtained, from which the true recovery line $O\,N\,M$ may then be drawn. In numerous cases a record of the surges in the forebay must be taken,

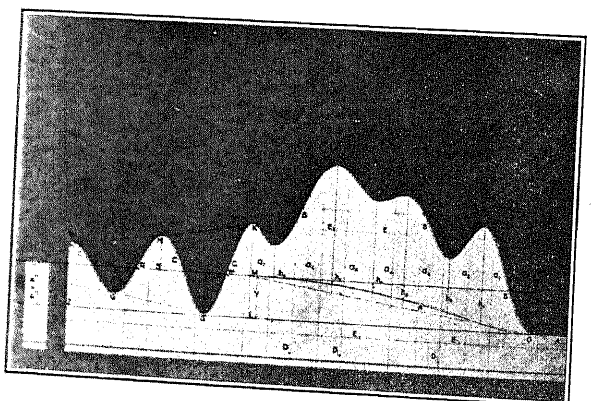

FIG. 23—TYPICAL PRESSURE—TIME DIAGRAM, AFTER DELINEATION

which are then plotted on the diagram and form a correction to the recovery line. The net area of the diagram, $O\,N\,M\,K\,B\,O$, is then measured, and corrected for shrinkage of the print and width of slot.

To substitute this area in equation **(17)** for $P\,T$, it must be corrected by the pressure and time scales used on the diagram so as to give the average pressure in feet of water multiplied by the time in seconds.

Let A = net area of diagram in sq. in.

r = vertical height in in. corresponding to one-ft. pressure rise

S = horizontal length in inches corresponding one sec. of time.

Then $P\,T = \dfrac{A}{r\,S}$, so that equation **(17)** becomes

$$V = \frac{g\,A}{r\,S\,L}$$

and if $K = g/r$

$$V = \frac{K\,A}{S\,L} \qquad \textbf{(18)}$$

For a penstock of uniform area throughout its entire length, this would be the form of the final equation, from which the quantity flowing in cubic feet per second would be determined by multiplying the value V by the area of the pipe in square feet.

In practise, however, the sections of the penstock are usually not of uniform area, but the penstock is made up of a series of different sections of lengths l_1, l_2, l_3, etc., having areas a_1, a_2, a_3, etc., respectively. In such a case the relations given in equation **(16)** hold for each section and the total impulse $P\,T$ for the combined pipe will equal

$$P\,T = 1/g\,(l_1\,v_1 + l_2\,v_2 + l_3\,v_3, \text{ etc.})$$

In this case it will be more convenient to solve directly for Q, which may be done by substituting Q/a_1, Q/a_2, Q/a_3, etc., for v_1, v_2, v_3, etc., thus:

$$P\,T = 1/g\,(l_1\,Q/a_1 + l_2\,Q/a_2 + l_3\,Q/a_3 \text{ etc.})$$

or $P\,T = Q/g \times \Sigma\, l/a$

If $\Sigma\, l/a = F$ and we solve for Q

$$Q = \frac{g\,P\,T}{F}$$

As previously explained $P\,T = \dfrac{A}{r\,S}$ and $K = g/r$.

Therefore, the final equation for penstocks of non-uniform area becomes:

$$Q = \frac{K\,A}{S\,F} \qquad \textbf{(19)}$$

It is thus seen that the quantity is determined from the net area of diagram A, the constants of the apparatus K and S and the physical dimension of the penstock. To the above quantity must be added the amount of leakage flowing through the guide vanes when they are in their closed position, for this amount of flow is not cut off by the closure of the gates. The total quantity is then obtained.

Power-discharge and efficiency-discharge curves of an actual test are shown in Figs. 24 and 25, and serve to illustrate the consistent results obtained with this method of measurement. It is of interest to note that satisfactory proof of the accuracy of this method was

obtained by thorough tests made in comparison with volumetric measurements at the hydraulic laboratory of Cornell University. The mean variation of all tests showed the Gibson method to be only 0.2 per cent high with respect to the volumetric measurement.

This precision is further demonstrated by the curve shown in Fig. 26 made on unit No. 4 at the Queenston Station of the Hydro-Electric Power Commission of Ontario. In this test two independent measurements of discharge were made by different observers, using separate instruments connected some distance apart

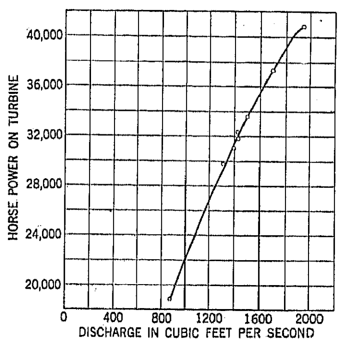

Fig. 24—Power-Discharge Curve of Unit No. 17 of The Niagara Falls Power Company. Tested by Gibson Method

on the penstock. The various constants which include the ratio of the pressure scales, the length of penstock and average areas of the penstock were all different, as shown by the table of constants. An inspection of these curves will illustrate in a convincing manner the close agreement between these independent measurements. Another curve (Fig. 27) shows the performance of a 10,000-horse power hydroelectric unit upon which two tests were made about two months apart, with an independent set of apparatus for each test. In the

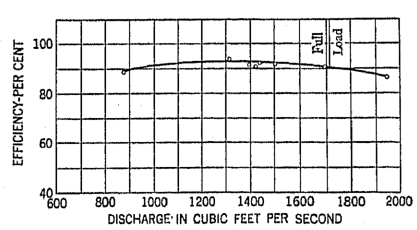

Fig. 25—Efficiency-Discharge Curve of Unit No. 17

first case, the Gibson apparatus No. 5 was connected below the elbow which would for the other methods of measurement be considered as a very undesirable location, owing to the disturbed flow around the bend in the penstock. In the second test, Gibson apparatus No. 1 was connected above the elbow. The lengths of the penstock were therefore different, as were the constants, but nevertheless, the power-discharge curve established by these two tests showed results to be practically identical.[5]

The ability, as demonstrated above, to make repeated tests on the same unit with identical results, using independent equipment attached at different points, not only serves as an indirect check on the work but gives weight to the idea that a waterwheel itself may be considered as a measuring device, and when once calibrated is an indicating flow meter. It is only necessary to establish the power-discharge or the gate-opening-discharge relation by a readily made and economical test such as this method presents. It may

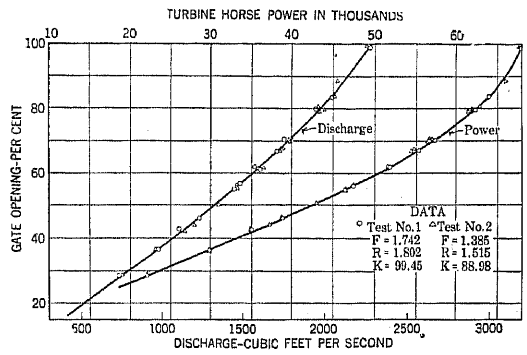

Fig. 26—Power-Discharge Curve of Unit No. 4, Queenston Station of Hydro-Electric Power Commission of Ontario—Check Tests by Gibson Method

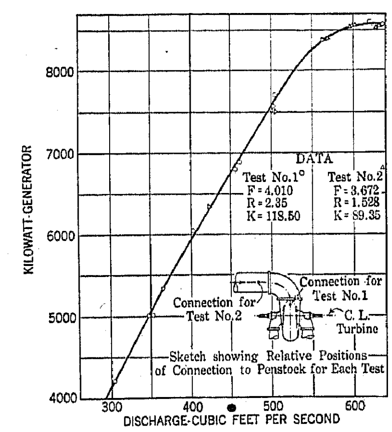

Fig. 27—Power-Discharge Curve of 10,000 Horse Power Unit of The Niagara Falls Power Company—Check Tests Gibson Method

then be desirable to re-calibrate after a period of about two or three years, or if any major repairs are made on the wheel.

Value of Test Data to Power Company

The data secured in accurate tests of hydroelectric units are of great value to the power company as they permit a comparison of the total kilowatt hours produced

5. The data on these tests were presented by E. B. Strowger of the Niagara Falls Power Company, in his discussion of Mr. Gibson's paper at the Annual Meeting of the American Society of Mechanical Engineers, December, 1923.

to the total water consumption for any given period, and this ratio is a direct measure of the economy of operation. In practically all plants, careful records are kept of kilowatt hours output, but in many stations, no careful check of water consumption is attempted. In some cases this neglect is undoubtedly due to excess water supply over plant requirements, so that the output of the station is a question merely of load demand or capacity of units, but such examples of under-developed sites are now rare, especially in the eastern part of this country. Today, the question of monthly or even daily flow of the stream throughout an average year is carefully studied and storage lakes or reservoirs built wherever possible to provide for the units a more constant flow throughout the year, than nature usually furnishes. Storage, therefore, permits over-development as compared to minimum stream flow or even average flow, and results in the use of a large part of the yearly flow of the stream in spite of seasonable variations. Water consumption of the units is therefore a vital matter in most plants and accurate records are kept.

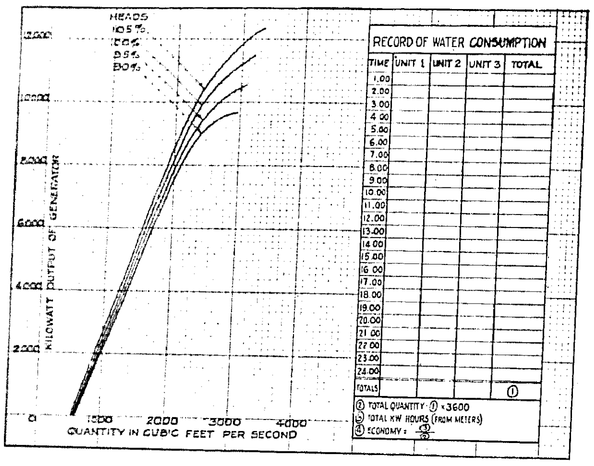

Fig. 28—Calibration Curves of Generator as Water Meter

Efficiency tests should be made on the units as soon as practicable after installation, and curves prepared showing discharge in cubic feet per second plotted against generator output. Typical curves are shown in Fig. 28 for a 10,700-kw. unit operating under a normal head of 60 ft. These curves are actually the calibration curves for the generator used as a water meter. If the head varies appreciably, several power-discharge curves are plotted, one for each head.

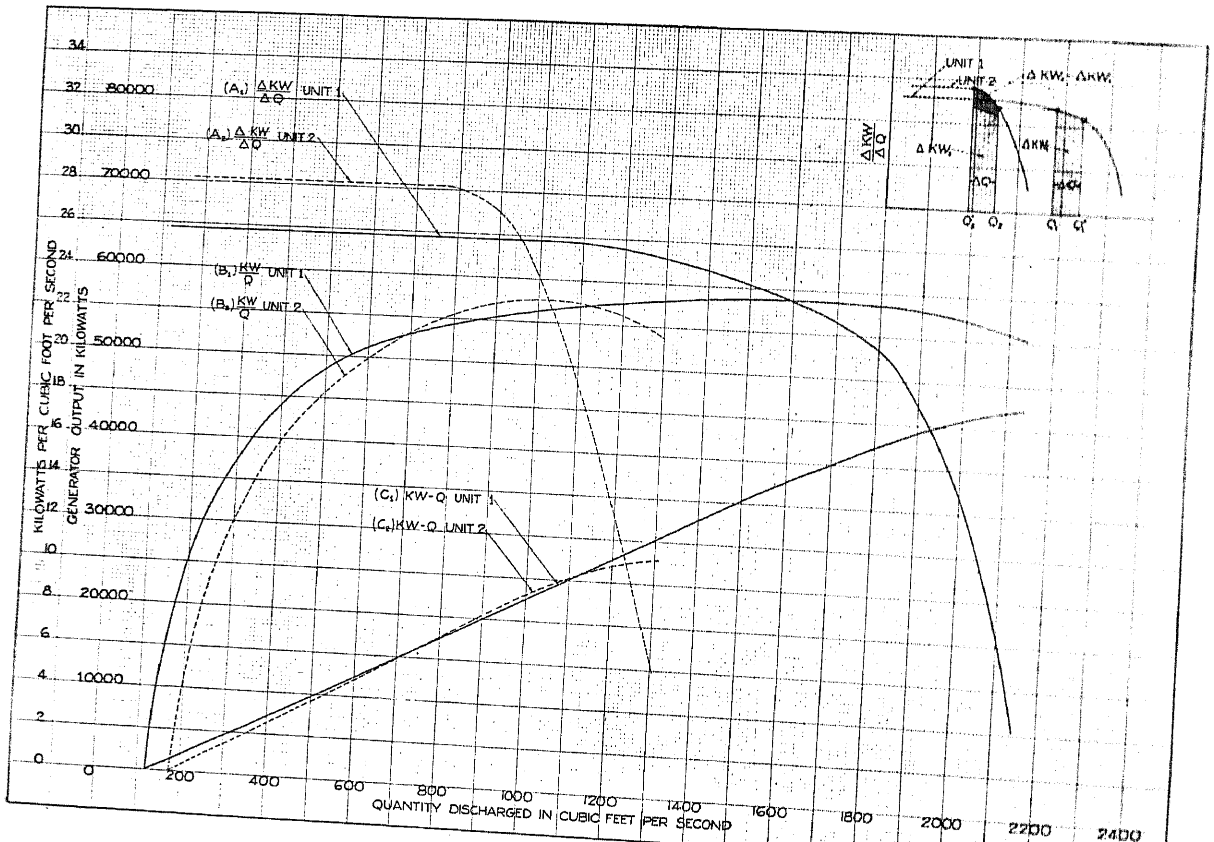

Fig. 29—Determination of Economical Division of Load between Two Units

Records of discharge are frequently kept, such as indicated on the right side of Fig. 28. The kilowatt meters are read on each machine at stated intervals, every hour or half hour as the case may demand, and the corresponding discharge, obtained from the curves, entered on the chart. By averaging the values of quantity and multiplying by 86,400, the total daily water consumption in cubic feet is obtained for each

unit and for the whole station. The total kilowatt hours divided by the total quantity shows the average economy for the 24-hour period.

Maximum economy results, of course, when each unit is operated at its point of maximum efficiency, giving a maximum power output per cubic foot of water, but this ideal condition only exists at one-load demand in a one-unit plant, two loads in a two-unit plant, etc. The actual problem to be solved is, therefore, the correct division of the total load demand between the various units in the plant so as to secure maximum economy.

In plants containing the same size units of exactly the same design, it can readily be shown that the total load should be divided equally between all units in operation. Where the units are of different sizes and of different characteristics, the problem is a little more complicated. Fig. 29 will serve as an example of a plant containing two units, one of 44,000-kw. capacity with low-speed type runner and the other unit of 26,000-kw. capacity with a much higher speed type runner. It is not at all probable that two such runners would be used in the same plant, but this example is chosen to give curves of different appearance so that the readings may be readily differentiated.

From the power-discharge curves C_1 and C_2, new curves are plotted of kilowatt per cubic foot per second B_1 and B_2. Then, the first derivative of each power-discharge curve is drawn, this being expressed as

$\frac{\Delta K w}{\Delta Q}$ and defined as the rate of gain in power to

increase in discharge. These curves A_1 and A_2 are actually the tangents of the angles of slope of the power-discharge curves. If a series of horizontal lines is drawn on this diagram, the intersection of each line with the two derivative curves will give the correct division of discharge and load between the two units for best economy.

For example, a horizontal line at 24 on the vertical scale intersects A_1 at 1520 cu. ft. per sec., corresponding to a load of 35,800 kw. and intersects A_2 at 1003 cu. ft. per sec., corresponding to a load of 23,200 kw. This gives the correct division of a total load of 59,000 kw. and a total flow of 2523 cu. ft. per sec. between the two units for best economy.

The correct division of load between two or more units in a station may therefore be stated by the following theorem: *The load should be so divided between two or more units so as to obtain equal values of the first derivatives of the power discharge-curve of each unit.*

This truth may be more clearly understood by reference to the insert curves shown in the upper right hand

corner of Fig. 29. The derivative curves $\frac{\Delta K W}{\Delta Q}$ for

units 1 and 2 are reproduced plotted against the flow Q. The horizontal dash and dot line shows the correct division of load. Assume a change in division of Q so that the discharge of unit 1 increases from Q_1 to Q_1' or ΔQ, and discharge of unit No. 2 decreases the same amount from Q_2 to Q_2' or ΔQ. It is evident that the shaded area under curve 1 between Q_1 and Q_1' is

equal to $\frac{\Delta K W_1}{\Delta Q} \times \Delta Q = \Delta K W_1$, or the gain in

kilowatts for unit No. 1. The area under curve 2 is the loss in kilowatts for unit 2 and it is self-evident that this loss is a greater numerical value than the gain, so that the net loss in power is shown by the difference between the two areas or $\Delta K W_2 - \Delta K W_1$. From the characteristic shape of the derivative curves, this is true for all values of power or discharge chosen, and therefore proves the theorem stated above.

From a series of horizontal lines drawn on this diagram, a table shown below is thus prepared for the operators convenience to show a correct division of load:

TABLE I

Total Kw.	Unit No. 1	Unit No. 2
24,000	2,000	22,000
29,200	7,200	22,000
34,300	12,300	22,000
39,400	17,400	22,000
43,400	21,400	22,000
49,900	27,700	22,200
52,700	30,200	22,500
55,400	32,700	22,700
61,200	37,700	23,500
66,600	42,100	24,500
72,300	45,700	26,600

It is rather interesting to note that for the curves assumed in this case, unit No. 2 must be operated at very nearly constant load, most of the load changes being taken on unit No. 1. This table is based on the assumption that both units must be in operation. For the lighter loads, better economy is obtained by running a single unit. Thus from a study of curves B_1 and B_2, it is evident that the best results will obtain for the following method of operation:

Loads zero to 14,500 kw. operate unit 1.
Loads 14,500 to 25,700 kw. operate unit 2.
Loads 25,700 kw. to 45,000 kw. operate unit 1.

Discussion

PAPERS ON HYDROELECTRIC POWER DEVELOPMENT

(Thurlow and Sirnit, Barfoed, White, Rogers)
Birmingham, Ala., April 7, 1924

W. S. Lee: Mr. Barfoed's paper, like any one touching on hydro-electrical practise and the whole series of operations on the West Coast, could be divided and make good subjects for forty papers.

I am going to take some exceptions to his arch dam in comparison with the ones in Southern use. It is true this type has developed in California on account of the distance which materials have to be hauled as dams of this design have less cement and material to be transported. In the South, I think, the gravity section is the proper one to use.

It is not the practise in the South to use dams of this design, and the reason for it is heavy overflow of water.

I would also take exception to the use of the core-wall in earth dams. A core-wall in an earth dam is of absolutely no use. It is not strong enough to hold anything and with a wet blanket

of earth on one side and a dry blanket of earth on the other it will move, crack, and leak, thereby, destroying its only value.

P. M. Downing: Steam plants in the hydro-electric system have for several recent years been in use on the Coast. The length of the transmission lines in the West is generally quite great, and there can be no question that the steam plant is quite essential as an economical factor in handling peak loads.

I don't want the impression to get out that the people on the Coast have the feeling that multiple arch dams are suitable among all kinds of conditions. There are certain places where one or two-arch dams are much more economical than gravity dams. The kinds of dams used are dependent entirely on the conditions. Very few of the dams of the multiple-arch type are ever used where there is heavy run-off; there the gravity type of dam is certainly more desirable. We don't have the heavy run-offs during the whole year; our maximum flows come along in May, generally, when the snow is melting. Occasionally in winter months, if there is a light snow and a warm rain on top of that snow, there will be quite heavy run-offs; but that is the exception rather than the rule. We do not have the severe conditions to meet there that you have to meet in the streams in the South. So that I say the dams that are selected depend upon the conditions.

Geo. A. Orrok: I am very glad to hear Mr. Downing bring out the fact that where you have a long distance high-tension transmission line it is good practise to run the line at the maximum load all the time.

I have listened to Mr. White and the other gentlemen talk about the pitting. Mr. White pays particular attention to the wearing away of the runner—he calls it pitting; I call it cavitation, but it amounts to the same thing. Cavitation has been one of the most difficult troubles to overcome. I have been told quite frequently that the European manufacturers have learned how to overcome cavitation and that they had no more cavitation. I had occasion last summer to visit Italy and Switzerland, and I was greatly concerned to find in a corner of almost every plant three or four old runners with very marked cavitation. In one plant I found five runners that had been replaced. The old runners had been welded.

It is my own opinion that until a new runner design has been made and tried out in actual service, no one can guarantee that it will not cavitate. In a conversation with Mr. White this morning, he brought out the fact that this might be a chemical action, and that the theory of cavitation which was brought out in connection with the marine propeller is the proper theory. In hydraulic runners it usually is some slight error as malformation or misapplication of the curve of the vane. A vacuum is formed in the wake of the vane where the occluded oxygen of the water may collect. I recollect three runners made from the same set of cores where this cavitation did not occur in the same place. Of the three runners made from one core and put in three separate settings in the same hydro station, one cavitated on the back of the vanes exactly in the center, the second one on the inside of the outside rim, and the third one cavitated near the hub. There have been two other runners made since then from the same box which I understand show signs of cavitation but not in the same place.

When the curve of the vane is changed to meet the condition, the cavitation will cease, and after that you can make any number of runners from that same core and there will be no more trouble.

In making some heat transfer tests, I had occasion to work up a method for testing the amount of the occluded oxygen in water. In this case the water was salt. This method has been adopted as a standard method and I believe it makes a lot of difference whether the water that is flowing through the wheel contains more or less occluded air. In a test on a centrifugal pump several years ago, we got an efficiency of eighty-nine per cent, until we noted a lot of air bubbles in the water and found we had a perfect plant for mixing air with water. The water weighed nearer fifty pounds per cubic foot than sixty-two and a half. That would make some difference in the cavitation as well as efficiency.

P. M. Downing: On many of the plants operating in the West, where we use impulse wheels, we have an action very similar to the cavitation that takes place in the reaction turbines, generally within the buckets on both sides of the splitter. The action there is very similar to the cavitation that takes place in the reaction runner. I would like to ask if there is any close relationship between the causes of pitting in these two different types of wheels?

W. S. Lee: What Mr. White and Mr. Orrok have been discussing takes place on the opposite side of the runner. We have in operation today wheels that have been in operation eighteen years, on which the pitting occurs on the under side of the runner. If it does not cut through, we bore a small hole of ¼ in. in size; this often stops the pitting.

Geo. A. Orrok: Do I understand Mr. Downing to say that the cavitation spots are rough just as though the iron had been dissolved out leaving the graphite of the cast iron showing?

F. M. Nash: I have had to contend with the question of this eating-in or erosion in both impulse and reaction turbines and have found it about as bad in one as in the other. The impulse turbines using a 3 in. nozzle under 1800-ft. head had to have both needle tip and nozzle tip renewed two or three times a year. With the reaction turbines, we had considerable pitting on the back side and near the outer edge of each runner vane, just as Mr. White says, but the worst wear occurred on the clearance rings of a 500-hp. horizontal double-runner reaction turbine under 340-ft. head. This ring was of cast iron and the erosion destroyed the clearance-ring metal for a depth of 1 in. and more in a radial direction. This caused a very ragged and deeply pitted condition that had to be repaired. Repairs were made by dismantling the turbine, cutting back the clearance ring with torch and chisel for a radial depth of 1 in. or more and then welding in by use of torch a ring made up of 1¼-in. x 2-in. iron to give it something near the original setting. This work was all done in the field and no attempt was made to true it in a lathe. The repairs proved to be fairly satisfactory.

All the pitting was considered to be due to chemical action of the particles of air on the iron under a slight vacuum, and not due to the wear of either water or sand and silt. Furthermore, all the pitting of this kind that I have had occasion to observe has always occurred in water wheels or turbines under a relatively high head. Under heads of from 20 to 40 ft. even though the water is heavy with silt the year around, I have never known this pitting to occur.

W. F. Dawson: One would be rash, after noting the serious troubles still experienced with cavitation to claim an immediate remedy, but I am strongly of the opinion that marked improvement could be secured if these parts could be chilled-cast, or at any rate, chilled about those surfaces where electrolysis, due to cavitation, is expected. Many of these runners are cast in manganese "bronze" or more properly manganese brass, which contains approximately 45 per cent of zinc. Zinc has a strong tendency to segregate, particularly when poured in ordinary sand moulds, but if the moulds are lined with chills of thicknesses, say equal to one or two times the thickness of the casting, the segregation is prevented and a clean casting of uniform grain structure is thereby obtained. Chilled castings not only prevent the segregation of the zinc and other materials in the alloy, but also makes a stronger and tougher casting. The elastic limit is frequently raised 30 per cent and I have seen cases where the elongation was increased from 2 to 3 per cent to 10-15 per cent.

While I have not had actual experience with chilled iron castings, I believe that this material can also be chilled to advantage, but in that case the material would have to be carefully annealed after casting.

It is fairly well known, but should be continuously emphasized,

that corrosion occurs due to electro-chemical action between elements separated from each other in the electro-chemical series whenever an electrolyte is present. If the chilled casting or any substitute process maintains a perfect chemical combination of the elements, the tendency to corrode is greatly reduced as compared with those castings in which the elements are segregated.

Geo. A. Orrok: I have never had the opportunity of seeing an impulse turbine bucket that was cavitated. If you take cast iron and put it under a magnifying glass, you can pick out the cast-iron crystals; the carbon standing up by itself, and you can take your knife and pick the graphite out of the cast iron. In cast steel you get that same thing, but certainly the harder crystals of the cast steel stand better while the softer ones are dissolved out by oxygen.

I would like to say one thing with regard to this chilled iron. I have seen chilled iron buckets which cavitated in the same way. I don't know what has been done with manganese bronze, but steel plate buckets cavitate in the same way when the curves are not right.

is available, the thrust bearing in the first unit has been running to date without connection to it. This is possible because of the high efficiency of the water cooling coil. The inevitable agitation of the oil by the thrust-bearing runner, below the top baffle, is utilized to secure this result.

The virtual elimination of loss of oil results from the use of the air-seal ring in conjunction with the baffle plates around the coil. This ring, which is shown in the illustration, keeps air out of the oil bath and films, thus increasing the bearing's factor of safety. The free surface of the oil is protected from all disturbances. Consequently evaporation losses and oxidation of the oil are reduced to a minimum. Their formation being prevented, oil spray and oily mist are kept out of the electrical windings.

With this unit operating normally, an inspection of the bath through the windows provided shows that the oil is clear and solid, holding no air in suspension; also that in spite of the high rim speed at which the bearing operates, the free oil surface is to all appearances as smooth and free from bubbles as during a prolonged shut-down.

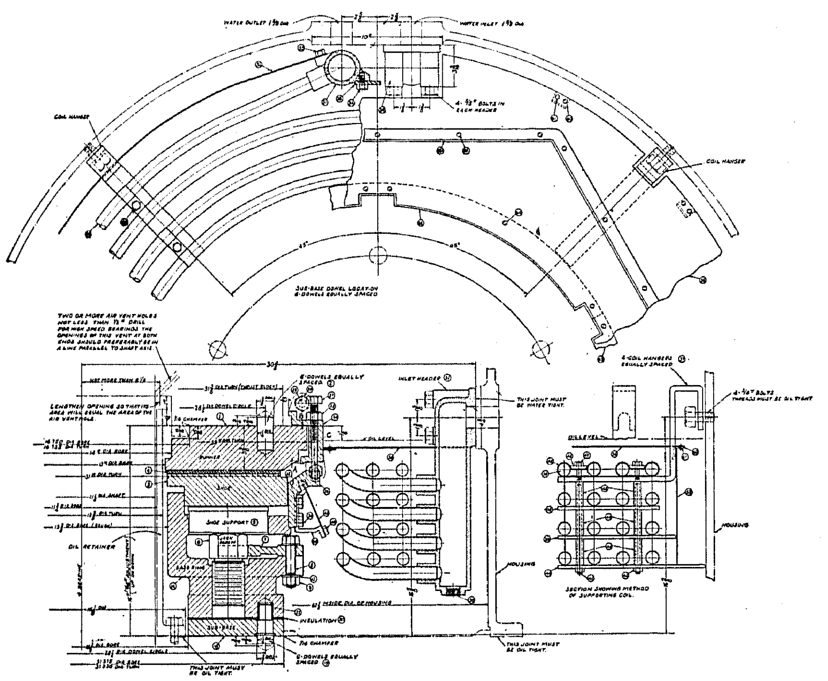

FIG. 30.—THRUST BEARING FOR 70,000-H. P. GENERATORS

Each of the three 70,000-h. p. Units of the Niagara Falls Power Co. uses a 69-in. Kingsbury bearing, illustrated above, which carries 1,250,000 lb. load at 107 rev. per min.

Arthur B. Lakey (by letter): The author has mentioned that the entire rotating weight of his generator, exceeding 700,000 lb., was carried by the Kingsbury thrust bearing. This figure, however, is far short of the total thrust load. When hydraulic load and revolving weights of generator and turbine are all included, the load on each thrust bearing reaches a total of 1,250,000 pounds, the highest bearing load on record.

The first of the three Kingsbury thrust bearings for these 65,000-kv-a. units went into service with the General Electric—I. P. Morris unit on December 18, 1923.

The illustration shows the distinctive features of the bearings which has a diameter of 69 in. across the babbitted faces of the pivoted segments. The unit bearing pressure is 483 lb. per square inch of the net surface of the segments. At the normal speed of operation, 107 rev. per min. the thrust bearing friction loss per unit is about 45 h. p. or 1/16 of 1 per cent of the unit's rated output.

Certain design features of these Niagara thrust bearings are deserving of comment. Although an oil-circulating system

The type of bearing equipment described, with cooling coils and air seals included, is virtually standard on recent important medium-speed and high-speed vertical work. In most of these installations no oil circulation is used for the thrust bearings.

When assembling this 65,000 kv-a. Niagara unit, the jack screws supporting the Kingsbury shoes were utilized to lift the rotor from the blocks and to adjust its height to secure the proper vertical clearance in the turbine. The screws proved much more convenient for this purpose than the station cranes.

The illustration shows the insulation which, also in line with Mr. Kingsbury's recent practise, was included in the Niagara thrust bearings as a protection against possible damage from shaft current.

Later in his paper, Mr. White mentions several other developments using turbines with Francis and high-speed runners. All these units use Kingsbury bearings, mostly fitted with cooling coils and largely employing air-seal rings.

The entirely successful performance of the unit already

operating at Niagara under the previously unheard of load of 1,250,000 lb. has strengthened the conviction that thrust bearings are no longer a limiting factor in hydroelectric design. In fact, a generator has already been projected in which the estimated thrust load is to be 1,600,000 lb. When constructed this giant bearing will not represent any greater relative step in advance than the Niagara bearing which has already proved itself in service.

F. H. Rogers: The various points raised by Mr. Mitchell and others are of considerable interest, as they bring out a method of operation in a hydroelectric station which the writer believes has been in more or less general use, but which unquestionably is in error. That is, in most stations where three or four units are installed, it seems to be the general impression that the most economical method of operating these units is to run as many of the units as possible at their points of best efficiency and to take up the balance of the load by running one or two units at a considerably reduced load.

Without studying this matter carefully, it might appear that this method of operation would be the best as most of the units in the station would be running at their maximum efficiency. However, the fallacy of this is very fully proven and is shown clearly diagrammatically in Fig. 29. The point at issue is that although the majority of units which are run at their best efficiency are certainly developing power in the most economical method, the remaining unit or two, as the case may be, which are running at part load, are running so inefficiently that this loss more than balances the gain in the units operated at their best efficiency, and that the most economical results, taking the plant as a whole, follow when all units are run at the same value of the differential curves showing the rate of gain in power to increase in discharge.

It might be pointed out that the particular examples shown in the paper in Fig. 29 are for units operating under the same head, although these units are of different characteristics and of different size. The general theorem, however, applies to units operating under different heads and in different stations, provided that we are interested in the maximum total output of all the plants in kilowatts for a given total quantity of water discharged through all of the plants.

It might further be pointed out with interest that the curves shown in Fig. 29 are plotted for a constant effective head on the turbine for all flows. In reality, however, in any given station, the effective head on the turbine decreases as the load is increased due to the greater friction loss through the intakes and penstock. If this point were taken care of in plotting the curves in Fig. 29, the power output Curves C_1 and C_2 would bend down more rapidly as the quantity increased and this, of course, would have the effect of bending down the differential Curves A_1 and A_2 more rapidly as the quantity increased. These differential curves show very clearly the inadvisability from an efficiency viewpoint, of running any hydraulic turbine appreciably beyond its best efficiency point, for it can be seen from the differential curves that the gain in power which is equal to the area under the differential curves, rapidly decreases as the load is increased beyond the best efficiency point. In most plants, therefore, when water economy is of importance, it is now considered advisable after making an efficiency test on the unit, to block the turbine gates definitely at a point slightly beyond the maximum efficiency, so as to prevent the operators running the machines beyond this point where the economy is falling off at so rapid a rate.

S. Barfoed: Construction of hydroelectric undertakings is very much influenced by natural conditions. Therefore, structures selected for one location will seldom fit in another. One cannot favor certain types. But it is an engineer's duty to be fully informed about economical methods and structures, so that he can give the public the benefit of saved capital in the use of them. It is obvious that no structure should be chosen for a site where it does not fit or where suitable materials can only be had at great cost.

On southern streams, of which Mr. Lee speaks, no doubt he is right to choose the gravity type. A multiple-arch dam is not an overflow dam, but a single-arch dam properly designed is. Apparently the canyons of southern streams are not of the shape which will at all permit consideration of the single-arch dam. In the west many streams flow in canyons of ideal shape for such dams. A saving in capital expenditure results and the structure has at the same time a much higher factor of safety than a gravity dam.

Earth dams are by no means standardized. With previous foundations of great depth, the corewall is a successful item in their construction.

Tests on 22-Kv. and 4-Kv. Lightning Arresters

BY W. F. YOUNG

Associate, A. I. E. E.

Engineering Department, Duquense Light Company, Pittsburgh, Pa.

Review of the Subject.—*The development, within recent years of high-voltage rectifying tubes has made possible the construction of an apparatus which may be used to produce very high-voltage surges of steep wave front, believed to be comparable in potential and capacity to surges caused by lightning discharges taking place near transmission lines. With such an apparatus it has become possible to conduct tests on lightning arresters which show clearly the kind of performance these arresters are giving in service.*

The Duquesne Light Company has had on its system a great number of lightning arresters of the horn gap and series resistance type. The number of failures on installations these arresters were intended to protect and the number of failures on the arresters themselves have led the engineers of this company to go rather deeply into the lightning-arrester question and into the problem of learning, before an arrester is installed, just what degree of protection it is likely to afford.

To get the information desired it was found necessary to make a series of tests on the various arresters now in the market. In making these tests arbitrary requirements were set up as being necessary in an arrester for satisfactory operation on this system. These requirements were as follows:

1—High speed of discharge

2—Ability to break down dynamic current

3—Ability to operate repeatedly

The protective value of arresters meeting these requirements was felt to be proportional to the discharge capacities of the arresters.

This paper sets forth the results of the tests made on 22-kv. and 4-kv. lightning arresters.

THIS paper is a report of a series of tests on 22-kv. and 4-kv. lightning arresters to determine the relative value of the different types for protection of a power system.

The tests were designed to bring out the following characteristics:

(a) Relative time required to start discharge through gap and arrester.

(b) Relative discharge capacities.

(c) Relative ability to break dynamic current following discharge.

(d) Ability to handle repeated discharges.

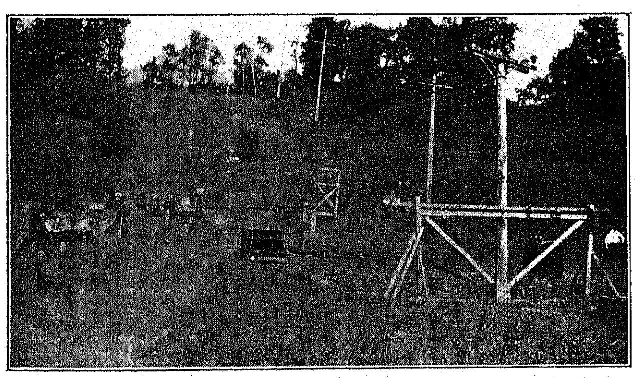

FIG. 1—VIEW OF TEST FIELD SHOWING 22-KV. ARRESTER SET-UP

The first and second groups of tests were made to determine the relative time to discharge and the discharge capacity of the arresters. Fig. 2 shows a diagram of the connections used in this test. A transformer was used to charge a set of condensers of 0.2 μ f. capacity, kenetrons being used to rectify the current. Each lightning arrester in turn was then connected in the test circuit, as shown in the sketch. A resistance shunted by a sphere gap was placed in series with the arrester to measure the discharge currents. One sphere gap was so placed as to measure the voltage of the surge and another placed across the arrester

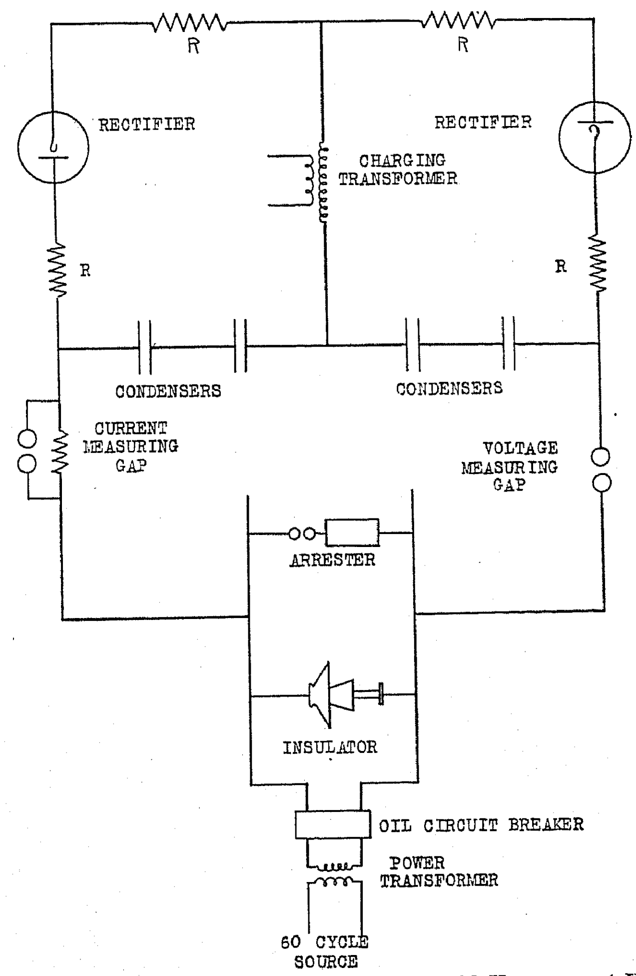

FIG. 2—DIAGRAM OF CONNECTIONS FOR 22-KV. AND 4-KV. LIGHTNING ARRESTER TESTS

itself. In the first group of tests this latter gap replaced the insulator shown in the diagram and was used

to measure voltage across the arrester. The breaker in the circuit from the power transformer was left open. Within this group a separate set of tests was made to determine the effect of resistance in series with the arrester. With the same set up as before, the resistance on several arresters was varied and the voltage across the arrester measured, the surge voltage being made the same, as nearly as possible, on each test. It was found that the voltage across the arrester increased with increase of series resistance.

The results of these tests are shown in Table I.

TABLE I
DISCHARGE CAPACITY OF 22-KV. ARRESTERS

Arr. No.	Surge Kv.	Arrester Kv.	Resistor Kv.	Resistor Ohms	Surge Amps.	Arrester Resist.	Remarks

6	100	99.0	9.0	90	100.0	990.0	
	150	127.0	39.0	270	144.5	879.0	
	150	147.5	19.5	90	216.0	682.0	
	100	111.0	10.0	90	111.0		2 in. gap
7	100	106.5	23.0	270	85.0		
	150	169.0	121.0	90	134.4		
	150	164.0	37.0	270	137.0		
	100	116.0	13.5	90	150.0	771.0	2 in. gap
8	100	109.0	28.0	270	103.7	1050.0	
	150	164.5	22.5	90	250.0	656.0	
	150	150.5	41.0	270	152.0	990.0	

In the second series of tests the pin type insulator shown in Fig. 2 was used in place of the gap across the arrester, in order to demonstrate directly the degree of protection secured. The insulator was a 22-kv. pin type, having a dry flash-over value of about 80,000 volts. Before starting these tests, the surge generator was used to impress high-voltage impulses on the insulator. The insulator flashed-over each time, showing that the voltage was high enough for the test proposed. Each lightning arrester in turn was then connected in parallel with the insulator and the impulses set up as before. A flash-over of the insulator or a flash on the arrester, other than across the gap, was considered a failure of the arrester.

Another set of tests was conducted within this group, also, to determine the effect upon arrester performance of series resistance in the circuit, used to take the place of the surge impedance of the line. In some of the tests on each arrester the surge impedance of the circuit was 224 ohms while in the other tests it was zero. The latter condition was found to be considerably more severe than the former and was thought to be worse than would be met at any time in actual service.

The results of this test were as shown in Table II.

TABLE II
PROTECTIVE VALUE OF 22 KV. LIGHTNING ARRESTERS

Arrester Number	Series Resistance	Insulator Flashovers Per Cent	Remarks
1	224	0

	0	100	Change in series resistance made no difference. Change in gap reduced number of flashovers.
8	224	50	Careful arrangement of resistors was necessary to prevent flashing at resistor.
	0	0	Flashed over insulator on arrester or over arrester resistances.

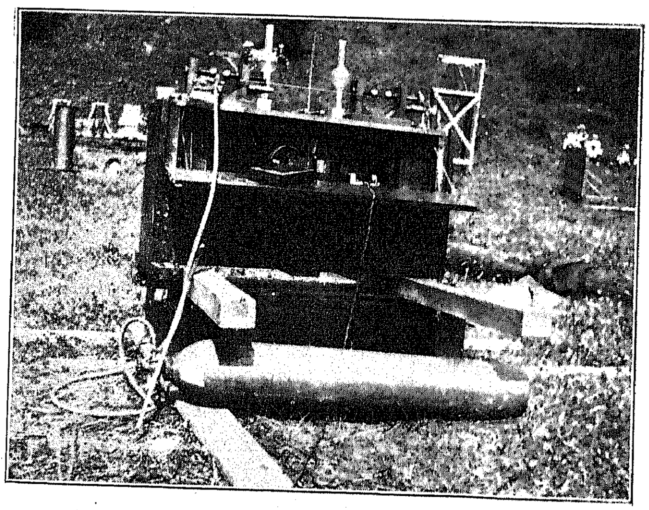

FIG. 3—IMPULSE GENERATOR USED IN FIELD TO MAKE DYNAMIC TESTS

The third group of tests was made to determine the capacity of the lightning arrester to interrupt dynamic current after a static surge had caused an arc across the gap of the arrester when connected to a power line. To make these tests the surge generator was connected to the power line, giving the same effect as closing the breaker in the power circuit as shown in Fig. 2. The connections on the power circuit were as shown in Fig.

4, the 15-ohm resistor in the neutral being in series on the initial test on each arrester. This precaution was taken to limit the short-circuit current in case of failure of the arrester. Each arrester that withstood

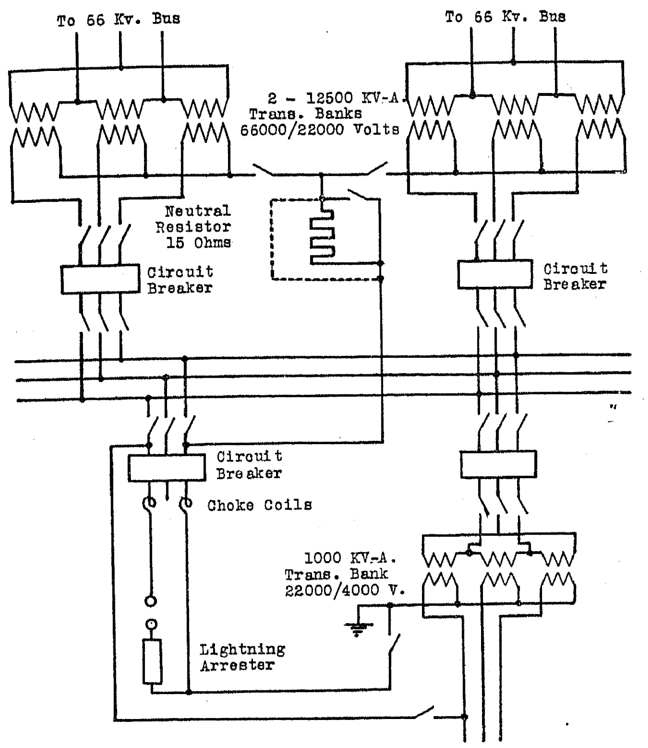

FIG. 4—DIAGRAM OF CONNECTIONS AT SUBSTATION WHERE DYNAMIC TESTS WERE MADE

this test satisfactorily was then tested with the resistor short-circuited to eliminate any effect the resistor might have.

The results of these tests were as shown in Table III.

TABLE III
DYNAMIC TESTS—22-KV. ARRESTERS

DESCRIPTION OF ARRESTERS

The following is a very brief description of the arresters tested.

1—Electrolytic or aluminum cell, 91 trays, laboratory sphere gap.

2—Carbon disc pile, 4 columns of discs, sphere gap.

3—Oxide film; 96 cells; sphere gap.

4—Series water resistance; sphere gap and horn gap.

5—Multiple horn gap with shunt resistance. Fuse ahead of arrester.

6—Multiple gap; series resistance. Circuit-breaking device to increase gap.

7—Horn gap with series resistance, carborundum covered rod to extend arc.

8—Horn gap with series resistance.

RESULTS

Arrester No. 1—showed highest speed and highest discharge capacity, protected insulator and stopped flow of dynamic current.

Arrester No. 2—showed second highest speed and third highest discharge capacity of valve-type arresters. Protected insulator and stopped flow of dynamic current.

Arrester No. 3—showed second highest discharge capacity and third highest speed of valve-type arresters. Stopped dynamic current and protected insulator each time when surge impedance was in circuit but only 50 per cent of time when there was no surge impedance in circuit.

Arrester No. 4—showed slow speed of discharge and intermediate discharge capacity on surges at 100-kv. potential. Interrupted dynamic current. Bushing of arrester flashed over on 150-kv. surges, emphasizing lack of speed in discharging.

Arrester No. 5—showed high discharge capacity and protected insulator perfectly but would not interrupt dynamic current without blowing fuse, thus making it inoperative for further surges. The discharge current went across gaps to ground in the static tests. In the dynamic tests this resulted in short-circuit.

Arrester No. 6—showed intermediate discharge capacity and interrupted dynamic current. Some of the series resistors were wholly or partly flashed over on each test with surge impedance. The insulator was, however, perfectly protected when there was surge impedance in the circuit, but flashed over each time when the surge impedance was removed.

Arrester No. 7—showed low discharge capacity, failed to protect insulator and would not interrupt dynamic current.

Arrester No. 8—showed low discharge capacity, protected insulator part of time but would not interrupt dynamic current.

CONCLUSIONS—22-KV. ARRESTERS

Among the requirements to make an arrester satis-

factory for service, the three following are of major importance.

First, it must operate before the surge voltage impressed on the system can cause a flash over or breakdown of the insulation the arrester is intended to protect.

Second, it must interrupt the dynamic current which will have a tendency to flow through the arc across the arrester gap.

Third, it must be in condition for repeated operations.

If a lightning arrester meets these three requirements, then its value as a protective device will be directly proportional to its discharge capacity. Therefore, using the maximum discharge capacity needed at 100 per cent, the percentage of protection afforded by any arrester may be determined. Thus, since the surge current is equal to the surge voltage, divided by the surge impedance, there is only one unknown in the equation

$$I = \frac{E}{\text{surge impedance}}$$

This unknown is the voltage.

Knowing the surge impedance, we may assume several values of voltage generally agreed to be reasonable. For example, let us assume the voltage to be 150-kv. A series of tests was made on the arresters at this voltage with a surge impedance of 270 ohms.

This value of impedance is low but was so chosen to place rather severe duty on the arresters. The point at which it would be desirable to have the arresters discharge may be taken as 35 kv. maximum. Then the surge will have to be reduced by the arrester from 150 kv. to 35 kv. or 115 kv. Under these conditions the surge current will be

$$\frac{E}{Z} = \frac{115{,}000}{270} = 426 \text{ amperes.}$$

However, as voltage reflection takes place at an open end, current reflection similarly takes place at a short-circuit and, since the discharge of an arrester results in a short-circuit on the line, the current to be discharged by the lightning arrester is twice that shown in the calculation, or 852 amperes. Therefore, a lightning arrester with a discharge capacity of 852 amperes at 150 kv. would be a 100 per cent arrester.

Referring to Table I, we may see that the discharge capacity of the electrolytic or aluminum cell lightning arrester at 150 kv. is 555 amperes. As these tests were single-phase in nature, this arrester may be considered to afford 65.2 per cent protection on single-phase surges. Using this method of calculation and the values of surge current shown in Table I, we find that as to discharge capacity, the lightning arresters tested rank as follows for single-phase surges of 150 kv. and surge impedances of 90 ohms and 270 ohms.

Discharge Capacity—22-Kv. Arresters
150-kv. Surge—High Frequency

Z = 90 ohms	Z = 270 ohms
1—46.5 per cent	1—65.2 per cent
2—17.4 per cent	2—24.7 per cent
3—18.1 per cent	3—31.9 per cent
6— 8.5 per cent	6—17.0 per cent

However, as lightning surges may be considered as occurring simultaneously on all three-phase wires, the true value of an arrester is determined by its operation under such conditions. Arresters No. 1 and No. 3 use a single ground leg for all three-phase legs, while Arrester No. 2 uses a ground leg for each phase leg and the resistance-type arresters have each leg connected directly to ground. Therefore, the discharge capacities of Arresters No. 1 and No. 3 on three-phase surges as compared to the other arresters is 50 per cent of the discharge capacity indicated by the tests. So far as can be seen by the writer, there are no engineering difficulties in the way of connecting Arrester No. 3 in the same way as Arrester No. 2. If this connection were applied to Arrester No. 3 the table above, written for three-phase surges, would be as follows:

Discharge Capacity—22-Kv. Arresters
150-kv. Surge—High Frequency

Z = 90 ohms	Z = 270 ohms
1—23.3 per cent	1—32.6 per cent
2—17.4 per cent	2—24.7 per cent
3—18.0 per cent	3—32.0 per cent
6— 8.5 per cent	6—17.0 per cent

Three-phase tests could not be made with the equipment available, so that these figures could not be verified.

As a result of these tests, conclusions on the different types of arresters as protective devices have been drawn as follows:

Of the lightning arresters tested, Arrester No. 1 is the most satisfactory for removing surges from lines and equipment. It has a very high speed of discharge and a heavy discharge capacity.

Arresters No. 2 and No. 3 are of about equal value as protective devices, No. 2 having a greater speed of discharge and No. 3 having the heavier discharge capacity, provided the same connections are used on both arresters. Neither of these arresters affords the same quality of protection as No. 1.

Arrester No. 6 was the only other one to meet the requirements originally set up. This lightning arrester has a comparatively low discharge capacity with low values of surge impedance and its inability to protect the insulator in some cases was probably due to this characteristic.

Of the other arresters tested, each failed in some respect to meet the requirements set forth. Arrester No. 4 has a low speed of discharge which allows flash-

overs to occur at a weak point in the insulation. This arrester has a fair discharge capacity and would perhaps be satisfactory on surges of sloping wave front. The cause of the slowness of the arrester discharge is thought to be the series resistance. Arrester No. 5 shows very desirable discharge characteristics but cannot be satisfactory so long as the fuse operates to clear the dynamic current, leaving the arrester inoperative on further surges. Arresters No. 7 and No. 8 are felt to be unsatisfactory because of their failure to protect the insulation and to clear dynamic current.

Tests on 4-Kv. Lightning Arresters

The tests on the 4-kv. lightning arresters were similar to those made on the 22-kv. arresters, except that the second group of tests—showing protection to an insulator—was omitted. The results of the discharge capacity tests were as shown in Table IV and the results of the dynamic interrupting capacity tests were as shown in Table V.

TABLE IV
DISCHARGE CAPACITY OF 4-KV. ARRESTERS

Arrester	Surge Kv.	Arrester Kv.	Resistor Kv.	Resistor Ohms	Surge Amperes	Arrester Ohms

TABLE V
DYNAMIC TESTS—4-KV. ARRESTERS

Arrester Number	Number of Tests	External Series Resist.	Surge Voltage	Results
1	3	15 ohms		Cleared
	3	0		Cleared
2	3	15 ohms		Cleared
	3	0		Cleared
3	3	15 ohms		Cleared
	6	0		Cleared
4	3	15 ohms		Cleared
	3	0		Cleared
5	Dynamic tests not completed			
6	1	15 ohms		Failed to clear circuit. Arc held between horns until breaker operated to clear circuit.
7	1	15 ohms		Failed to clear circuit. Arc held between horns until breaker operated to clear circuit.

Description of Arresters. A brief description of the arresters tested follows.

1—Carbon disk pile, single column of disks, enclosed gap.

2—Multiple gap, two shunting resistance rods.

3—Oxide film, twenty cells to ground, sphere gap.

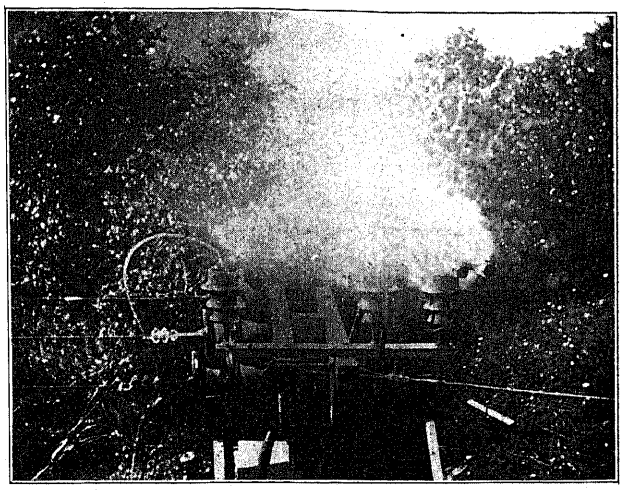

Fig. 5—Failure under Dynamic Test of Horn-Gap Arrester with Series Resistance

4—Multiple gap, series resistance. Whole arrester encased in porcelain.

5—Series water resistance, sphere gap.

6—Porcelain bushing over iron pipe. Horn gap between line and ground, no series resistance.

7—Multiple gap, series resistance, circuit breaking device to increase gap.

8—Multiple gap and series resistance rod encased in porcelain.

Results

The results obtained from the tests on the 4-kv. lightning arresters were as follows:

Arrester No. 1—showed rapid speed and high discharge capacity. This arrester interrupted dynamic current very satisfactorily.

Arrester No. 2—showed high speed of discharge intermediate discharge rate and interrupted dynamic current saitsfactorily.

Arrester No. 3—showed intermediate speed of discharge, a fair capacity of discharge and interrupted dynamic current satisfactorily.

Arrester No. 4—showed low speed and discharge capacity but interrupted dynamic current satisfactorily.

Arrester No. 5—showed low speed and discharge rate. The dynamic tests on this arrester were not completed.

Arrester No. 6—showed high discharge rate but was incapable of interrupting dynamic current.

Arrester No. 7—showed intermediate discharge capacity but was incapable of interrupting dynamic current.

Arrester No. 8—showed intermediate speed and capacity of discharge. The dynamic tests were not completed on this arrester.

Conclusions—4-Kv. Arresters

Ordinarily on 2200-volt and 4000-volt service lightning arresters are spaced rather closely and the lines are placed beneath the higher voltage lines on the poles. Both of these conditions tend to make a very high discharge capacity in the lightning arrester less essential on low-voltage circuits than on high-voltage circuits. The magnitude of the line voltage itself makes it possible to use series resistance in the arrester low enough to give fair discharge capacity and yet high enough to interrupt the dynamic current tending to follow the static discharge across the gap of the arrester when flash-over occurs. In other words, the lightning protection problem becomes much less difficult of solution on low-voltage circuits than is the problem on higher-voltage circuits.

In making the tests on all of the arresters, it was felt that the most accurate results were secured when the resistance in the arrester was of approximately the same value as that of the arrester resistance. However, it was also found that the arresters which operated satisfactorily with low-circuit resistance retained about the same ranking as to discharge capacity under such conditions as when tested with the higher values of circuit resistance. In view of these facts, only one set of discharge-capacity tests was made on the 4-kv. lightning arresters. These tests were made at surge potentials of 40 kv. and 60 kv. No tests were made on the electrolytic or aluminum cell arrester because its principle of operation was found to be satisfactory on the 22-kv. lightning arrester tests and it was felt to be the best surge protective device available in the 4-kv. field.

The dynamic test on the 4-kv. arresters showed very successful operation on most of the types tested. Numerous operations of the arresters were performed very successfully and the manner in which the surge was cleared indicated that satisfactory results would probably be obtained in service with any of the types that withstood the test.

Discussion

E. E. F. Creighton: It seems to me that Mr. Young's tests are in the direction to satisfy the users of lightning arresters. The users have felt for some years the need of tests, aside from those of the manufacturers, developers, and designers of lightning arresters. It is important to recognize the limitations of the tests as carried on outside of a thoroughly equipped laboratory. On one hand, there is the possibility of separating the sheep from the goats. There are on the market types of lightning arresters which are really not dischargers at all and have no particular value. The operator should be able with his tests to separate arresters of good discharge rate from those that have practically no discharge rate.

On the other hand, I hold out no hope at the present time that the operators will so refine their methods of tests as to distinguish between types of lightning arresters all of which have a reasonable discharge rate. It is not yet possible, by any method we know, to distinguish fine differences between lightning arresters. There are no casual tests of a few days' duration that I would accept to take the place of a year of tests involving hundreds of thousands of discharges under as many varied conditions as we can devise. May I repeat that these statements have nothing to do with the work that Mr. Young has done, because the value of his tests is to show whether an arrester has a sufficient discharge rate to take off lightning or not.

K. B. McEachron: For many years the large manufacturing companies have been making tests on lightning arresters of various types in order to ascertain as nearly as possible how the different arresters compare in characteristics. To do this, use has been made of the discharge of condensers through the arresters under test. Different values of capacity and voltage have been used by the different investigators to represent as well as may be, the duty an arrester would be expected to perform in service. Although no agreement has been reached among the several investigators as to the proper values of the constants to be used, all appear to be agreed that the use of a discharge of this general type is proper for the determination of the instantaneous voltage across an arrester. Such a test determines only the peak value of the discharge and does not give any information as to how long such peak voltages continue. Very often lower voltages longer applied will cause more damage than higher peak voltages of much shorter duration. Peak voltages as measured by sphere gaps tell only a part of the story, and thus comparisons based on such tests only partially determine the relative protective values. Of course, the value of the instantaneous voltage with any particular arrester tested will depend not only on the arrester but on the constants of the circuits used. This is true because in general the wave fronts developed by different impulse generators will differ, and as a result the same arrester will discharge at different voltages depending on the speed of operation of the arrester.

With a certain wave front, tests made on different arresters as reported in this paper by Mr. Young are comparable, although it should be remembered that changes in wave front will affect different arresters differently.

To be of greatest value the report of a test of this character should give more details than given, concerning the conduct of the test, and the exact nature of the apparatus used when tested. Such data will aid in making comparisons with other tests made elsewhere.

Since much of the value of the arrester is based on the instantaneous voltage across the arrester when small currents are flowing, and on its ability to discharge large currents without excessive rise in voltage, the measurements given by Mr. Young in Table I are important.

With every arrester tested, except the electrolytic, the voltage across the arrester was found to be nearly equal and in some cases more than the applied voltage. In addition, voltages are also observed across the series resistance which in some instances are also equal to the applied voltage. This is a condition which does not tend to inspire confidence in the test results. By referring to Fig. 2 which is the connection diagram for the impulse test, an explanation for some of the variations in test results may be found. Presumably the gap called the voltage measuring gap was set for either 100 or 150 kv. as the case might be. The actual condenser voltage was higher than the setting of the gap by an unknown amount depending on the arrester in circuit. This is true because the arrester with its gap is in series with the main measuring gap, and the voltage across each gap will depend upon the relative capacity of the two gaps in series. In order that the voltage across the condenser be correct, a high-resistance water tube should have been placed across the arrester and its gap.

There are certain details of test which effect the results considerably, for instance, when reading the gap across the series resistance, the gap in parallel with the arrester should be opened to prevent sparking and vice versa It is assumed that such precautions were taken. The nature of the series resistance is important in that its resistance must be constant at all frequencies. The water tube is the most satisfactory resistance.

It has been my experience in taking a large number of impulse volt-ampere curves with as small a physical circuit as possible, that the sum of the instantaneous voltages across the arrester and the series water tubes was approximately equal to the applied impulse. Cases have arisen due to reflections, oscillations, or other causes, where this approximate equality was not attained.

It is difficult to draw conclusions based on the data given in Table I, because of the apparent lack of agreement in the results. This condition is well illustrated in the case of arrester No. 4. This arrester is a type which should have constant resistance instead of being reduced from 1100 to 520 ohms when the series resistance was reduced from 27 to 90 ohms.

To secure the best comparison it is desirable to make tests on as large a group of arresters as possible to determine the variations between arresters of the same type. Great care should also be taken in making the tests to obtain the most accurate results possible.

The results of tests given in Table II are interesting and are, perhaps, more comparable than those given in Table I. Although the condenser voltage is not given, it is probable, as the author states, that the test made without any series resistance represents a condition more severe than would be met in practise. Such a discharge may well equal 10,000 amperes or more, the actual value, of course, depending on the arrester resistance and the circuit constants.

Table III shows the results of dynamic tests. In a test of this character it is very desirable to take oscillograms so that the exact operation of the arrester may be studied. From the standpoint of the effect of the arrester operation on the system, the valve-type arresters have shown themselves to be superior in that little or no dynamic current flows following the condenser discharge.

The simple calculation made to determine the current to be discharged by the 22-kv. arrester assumes that the arrester resistance during discharge is zero which is, of course, not strictly accurate. This calculation does give a value which indicates the order of magnitude of the maximum current and arrester under the assumed condition should discharge. A more accurate calculation is probably not worth while for the purpose of this paper especially when the actual surge voltage may vary greatly from the assumed value.

It is interesting to note that in spite of differences in detail the conclusions regarding the value of the different types agree in general with tests which we have made. The actual values obtained are in many cases very different, although the agreement is much better for the general tests given in Tables II and III.

The results of the tests on the 4-kv. arresters and the conclusions drawn are interesting. The discussion here given concerning the testing methods applies with equal force to these tests. It should be noted however, that better agreement is found among the results in Table IV than in Table I. Mr. Young concluded that satisfactory protection would be obtained from any of the types which met the test satisfactorily. In general where the density of the arresters is high these conclusions will probably be true. More detailed tests would no doubt have shown more definite differences between various types.

H. G. Brinton (by letter): In Mr. Young's paper, certain calculations of arrester efficiency were made. It was assumed that a surge voltage was applied to two resistances in series. One of these resistances represented the arrester impedance and one represented the surge impedance of the line. The voltage distribution was calculated from Ohm's law. This method is incorrect as the current and voltage relations are not the same as in a circuit involving a true surge impedance which is a factor depending upon the distributed inductance and capacitance of the line. The correct general formulas derived by methods ordinarily used for traveling waves are given in an article by Faccioli and Brinton on "High Frequency Absorbers" in the "*G. E. Review*" for May 1921. The particular formula for each special case can be obtained from the general formula.

In case the arrester is tapped off a line of uniform surge impedance Z and the arrester impedance is practically a pure resistance R, the ratio of arrester voltage to the voltage of the traveling wave or surge voltage is equal to

$$\frac{2\,R}{2\,R + Z}$$

The arrester voltage is 1/5th the surge voltage when the arrester resistance R is 1/8th the surge impedance. Using the above mentioned incorrect method for this same case, the resistance R is found to be 1/4th the surge impedance instead of 1/8th.

In case the arrester is at the end of the line with a transformer, we may assume that the surge impedance of the transformer is about 10 times that of the overhead line and the formula given above is changed to

$$\frac{20\,R}{11\,R + 10\,Z}$$

In this case the arrester voltage is 1/5th the surge voltage when R is one ninth (1/9) the surge impedance of the line.

In the case of the aluminum arrester we have to consider the effect of capacitance as well as resistance in the arrester, although the arrester films puncture and short circuit the capacitance if the voltage rises sufficiently. Taking the simpler case of an arrester tapped off a line of uniform surge impedance the general formula for the ratio of arrester voltage to surge voltage (assuming film has not yet punctured) reduces to

$$1 - \frac{Z}{2\,R + Z}\,\epsilon^{-\frac{t}{c(R + Z/2)}}$$

Assuming that $Z = 300$ and $R = Z/8 = 37.5$ and $C = .033$ m. f. = capacitance of 75 cells in series and further assuming that $t = 1$ micro-second with a wave 1000 feet in length, the magnitude of the above voltage ratio is 0.32. Thus, the arrester voltage is about ⅓ instead of $^1/_5$ the surge voltage, as it would be if the arrester were a pure resistance. This assumes that the arrester voltage is not high enough to puncture the film. From the formula for condenser voltage it can be calculated that the voltage on the films is about ½ the arrester voltage under the above conditions. After the films puncture the action is that of a pure resistance.

W. F. Young: To the writer's mind, the four characteristics of lightning arresters which are of most interest to operators are those named at the beginning of the paper. A statement in absolute terms of the manner in which any arrester meets these conditions is of academic interest to any one buying or selling arresters, but to the operator the thing of practical interest is a comparison of the arresters that are available with respect to these various characteristics. It was to get this comparison that the tests described were made. It is felt that the result desired has been secured.

Because of the wide divergence in design of equipment to bring about the same result and the obvious conclusion which is to be drawn therefrom that somebody is wrong, some hesitancy was felt by the Duquesne Light Company management concerning the publication of the results obtained. However, it was finally agreed that the results might be made known, along with an easy way of interpreting them, provided conclusions drawn were based upon arbitrary requirements. A considerable

amount of protest was expected from the manufacturers of lightning arresters. Some of this protest has been forthcoming. It is possible that certain of the manufacturers have been silent for the reason that the conclusions have been agreeable to them either as the type of arrester made by them stands high on the list or because they do not pretend that their equipment gives maximum protection, but rather that it gives a degree of protection for a comparatively low price.

The real purpose of the paper has been to accomplish what Mr. Creighton indicates has been accomplished, namely, to separate the sheep from the goats. No pretense is made that the method of calculation is exact. Neither is any pretense made that the characteristics of any arrester tested are exactly the same as the characteristics of other arresters of a similar type. It is maintained, however, that the analysis proposed, when applied to any set of arresters subjected to complete comparative tests, will result in a classification of the arresters which will be correct.

It is recognized that such a classification of arresters is not sufficient information upon which to condemn any of two or three types of arresters of similar characteristics. It is felt, however, that the results obtained in these tests now shifts the problem from a study of the arrester itself, to a study of the requirements of an arrester, *i. e.*, to a study of the nature and magnitude of the surges which the arrester may be required to discharge.

Mr. McEachron's discussion has brought out several points of error which it is absolutely essential to guard against if correct results are to be obtained in a test of this sort. It is necessary for instance that a surge of uniform shape be applied to the various arresters to secure comparative results. Several different types of surge, however, may be applied to all of the arresters to eliminate, as far as possible, error due to lack of knowledge of the form of wave imposed upon lines by lightning discharges. It is interesting to note that while such changes in wave form will give considerably different results, the same general classification of arresters usually prevails when any surge, which may be considered an imitation of that imposed by lightning, is used. It is also interesting, but not surprising, to note that the general results obtained agree with those obtained in other tests although there was no connection between the persons making the tests.

In this paper effort was made to avoid detail as much as possible as it was felt that the thing of real interest was the general classification of arresters obtained in tests made by an operating company. It may be stated here, however, that the test circuit differed from that shown in Fig. 2 in that the arrester under test was shunted by a very high resistance leak.

Lightning Arrester Application from the Economic Standpoint

BY A. L. ATHERTON
Member A. I. E. E.
Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

FOR a good many years, it has been recognized that practise in application of lightning arresters varies and that different engineers determine their choice and use of arresters on widely different base lines. While this may be partly explained by differences in climatic conditions, the variation is without question largely due to the fact that a clear relation has not been established between cost of and benefit from arresters.

Such a relation is difficult to determine because the wide variation in conditions, even in a single locality, makes necessary the consideration of a large number of installations as a unit. Mr. D. W. Roper's extended experience and close analysis of results over many years with thousands of installations shows that even several hundred arrester-years experience cannot be depended upon to give closely accurate results.*

However, the fact that the acquiescence to this lack of a basis for arrester application is an untenable position for arrester manufacturers has been brought definitely to our attention, as a result of the bringing out in 1922 of the two parallel lines of autovalve arresters. Previous to this time, valve type arresters had been made only in the large capacities, intended for protection of important installations, and too expensive or otherwise unsuited for use at the smaller and less important installations. Arresters, designed with the particular object of being low enough in cost to be suitable for use where the valve types were prohibitive, were of so greatly reduced protective value as to be naturally and logically considered as of an entirely different order, just as a fuse is a different order of overload protector from an oil circuit breaker. A comparison between an electrolytic arrester and a former distribution arrester, both for 6600-volt service, will illustrate this.

The electrolytic arrester has a relief voltage at steep wave front of approximately 18 kv., instantaneous value (11.5 kv. for the "AL" type arrester), a resistance of approximately 19 ohms, at ordinary summer temperatures, and a counter voltage of 9.3 kv. The distribution arrester had a relief voltage of approximately 28 kv. and a resistance of approximately 400 ohms. Since this arrester was not of the valve type, it, of course, had no counter voltage. The comparison is well shown by curves 1 and 2 of Fig. 1. For higher voltages the difference is still greater and for this reason we have never felt justified in making the distribution-type arrester for higher voltages.

With the autovalve arresters, the case is quite different. The station type is designed to duplicate the electrolytic arrester in protection. The relief voltage is approximately 21 kv., instantaneous value, the resistance approximately 15 ohms, though this varies with voltage, decreasing as the voltage increases, and the counter voltage is approximately 13 kv. The distribution type is exactly the same as the station type, except that the electrode area is one-fourth as great and therefore the resistance, at the same overvoltage value, is four times as great. The comparison is shown by curves 1 and 3 of Fig. 1, no curve being given for the station-type autovalve arrester, since this closely parallels the electrolytic.

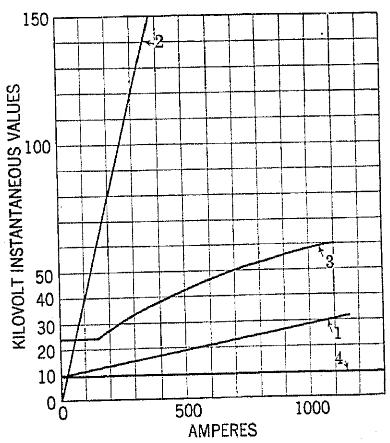

FIG. 1—VOLT-AMPERE RELATIONS SHOWING COMPARATIVE PERFORMANCE CHARACTERISTICS OF SEVERAL ARRESTER TYPES

Curve 1—Standard 6.6-kv. Electrolytic Arrester
Curve 2—Former standard 6.6-kv. Distribution Arrester of the Gap and Resistance Type
Curve 3—Standard 7.5-kv. Distribution Autovalve Arrester
Curve 4—Line Voltage

It is impossible at the present time to express the comparison shown by these curves in terms of directly comparative protective values, but since the object of an arrester is to hold surge voltages down to a safe value, and since this can only be done by permitting surge current to flow through the arrester without excessive rise in voltage, it is obvious that the arrester with the lowest voltage value in the volt-ampere curve is the best one.

It is known that injury by surge voltages begins at some overvoltage value such as 2.5 to 3 times line voltage, and that it increases with increase in voltage, probably faster than in direct proportion to the excess over the minimum injury voltage. It is probable

*TRANSACTIONS A. I. E. E., 1916, Vol. XXXV, p. 655.
*TRANSACTIONS A. I. E. E., 1920, Vol. XXXIX, p. 1895.

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-10, 1924.

that arresters may need to carry surge currents as high as 1000 amperes completely to prevent injury, but that such severe conditions occur only a few times per season, while the less severe surges, requiring the arrester to carry 100 amperes or so, are far more frequent. True relative values cannot be established without more complete data than we now have as to the effect of the surge voltages on insulation and as to the frequency with which surges of different magnitudes occur. For use in applying arresters, however, it may be assumed without fear of very great error that, presuming on the fulfillment of the intention of complete elimination of injury from surge voltages by use of the electrolytic arrester or of the station type autovalve arrester, the distribution autovalve arrester will do one-half as well, that is, in the long-run, eliminate one-half the failures which would occur if no arresters were used. No attempt is made to place a value on the relatively small protection given by the old distribution type, since it is no longer made.

As soon as the changed conditions brought about by the autovalve development were recognized, the need for better general application data was made apparent by a diversity of inquiries, indicating such a wide range of conceptions as to make a logical recommendation seem worthwhile even if it must be based on estimates.

The following attempt to reduce the problem wholly to an economic basis resulted.

General Considerations

The general approach to the problem was an attempt to evaluate the extent and cost of failures to the average system, if entirely unprotected, with the assumption that the yearly expense so incurred may justifiably be spent for lightning arresters. This assumes that the proper application and use of autovalve lightning arresters will reduce the trouble from surge voltages to a negligible quantity. As stated above, it is thought that this is a reasonable assumption, in case the type "SV" station arresters are used. When the type "LV" arresters are applied, as a compromise of protection for the sake of reduced cost, the assumption is that the damage due to surge voltages will be reduced to 50 per cent of the unprotected value instead of practically to zero as with the type "SV" arresters.

Based on records of experience, it is assumed that on an unprotected system in territories of average lightning conditions, 7½ per cent of the transformers installed will be injured by surge voltages each year. Put in another way, each transformer will be injured by surge voltages on the average of once in 13 years.

In calculating the cost of such injuries, two major points were given consideration, namely, the actual cost of restoring service and repairing the injured transformers, and the estimated valuation of the loss of service.

The cost of restoring service and repairing the injured transformer consists in locating the trouble, replacing the injured transformer with a spare unit from stock held for this purpose, transporting the spare transformer to the point of installation and the injured transformer back to the repair shop, and examining, testing and repairing the transformer. Estimates of these expenses are divided into two parts, a more or less fixed charge to cover all except the actual repairs, and the cost of repairs, which is assumed to be equal to 7½ per cent of the initial cost of the transformers.

The evaluation of the cost of loss of service is based on the supposition that cost to the power user must be given the same weight as cost to the power suppliers. It has been many times demonstrated that this idea of determining business policies from the standpoint of the customer is sound. As an average, the cost of power is approximately 5 per cent of the total cost of manufacturing process.

For short time interruptions, the power user's expenses continue without decrease and he thus loses 20 times as much as the power supplier.

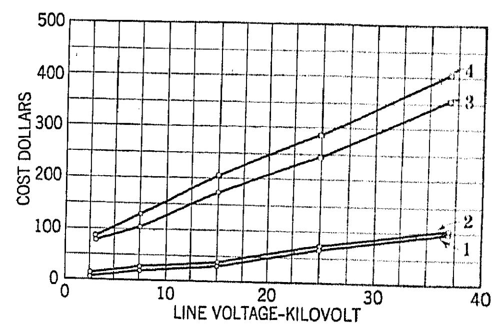

Fig. 2—Arrester Costs
Curve 1—Type *L V* Arrester—First Cost
" 2— " " " —Installed
" 3— " *S V* " —First Cost (Per Phase)
" 4— " " " —Installed (" ")

Based on these two points, the cost of loss of service is taken as 20 times the value of the revenue loss, due to the interruption.

To determine the value of lost revenue, it is assumed that the average duration of a service interruption is 5 working hours, that is, 5 hours always taken from the normal revenue producing period. Average loads are taken to be for lighting service, full load four hours per day and for power service full load eight hours per day and six days per week. The average cost of power to the user is assumed to be 6 cents per kw-hr. for lighting and 2 cents per kw-hr. for power.

As a matter of interest, to check the results of the analysis, the following data are also of interest. Of the total operating company expense, approximately 35 per cent may be taken as interest on the investment and 65 per cent as "operating cost," which includes all other items. Of the total investment 38 per cent may be taken to be in generating station, 18 per cent in transmission lines and substation and 44 per cent in the distribution system. Approximately one half of

the investment in the distribution system may be considered to be in distribution transformers. This means that 7.7 per cent of the gross revenue may legitimately be credited to the initial investment in the distribution transformers.

The cost of arresters used is the installed cost, consisting of initial cost plus an assumed average cost of installation.

Data and results are given below:

Normal Lightning Arrester Costs

Type "LV" Arresters		Type "SV" Arresters	
Rating kv.	Cost Dollars	Cost Dollars	Cost per Phase Dollars
2.5	\$5.67	\$230	76.5
7.5	17.81	310	103.
15.0	30.00	520	173.
25.0	65.00	735	245.
37.0	97.50	1065	355.

Values for cost per phase are given in order that the values for the arresters may match up with the values for single-phase transformers.

Cost of Installation

Type "LV,"a ll voltages, \$7.50 per arrester
Type "SV"

Rating kv.	Cost	Cost per Phase
2.5	\$25.00	\$8.50
7.5	75.00	25.00
15.0	100.00	33.00
25.0	125.00	41.00
37.0	150.00	50.00

Cost of Arresters Installed

Rating kv.	Type "LV" Cost	Type "SV" Cost per Phase
2.5	\$13.17	\$85.00
7.5	25.31	128.00
15.0	37.50	206.00
25.0	72.50	286.00
37.0	105.00	405.00

These costs are shown on curve Fig. 2.

Transformer Costs

Trans. Rating kv-a.	2,300-220 Volts	6,900-2,300 Volts	12,300-2,300 Volts	22,000-2,300 Volts	33,000-2,300 Volts
1½	33	63			
5	64	97	154	266

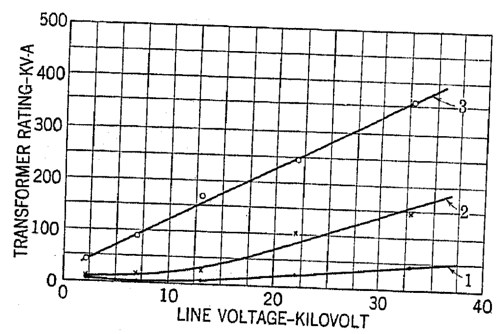

FIG. 3—TRANSFORMER SIZES FOR ECONOMIC BALANCE OF ARRESTER COST AND BENEFIT
Curve 1—Type *L V* Arrester—Grouped Installation
" 2— " " " —Isolated "
" 3— " *S V* "

MINIMUM TRANSFORMER SIZE FOR WHICH PROTECTION IS WARRANTED

The last column in the tables immediately preceding is the capitalized value of the pro rata average yearly cost of failure. This is equal to the maximum permissible cost for an arrester to give complete protection on the basis of an exact economic balance between cost of arrester and savings by use of an arrester. From these values and the figures for the cost of Type "SV" arresters per phase, a determination is made for the minimum size of transformer with which it is justifiable to use type "SV" arresters.

In the same way, the minimum-size transformer, which it is economically justifiable to protect with type "LV" arresters, is determined from the cost of the "LV" arresters and from values equal to ½ the value in the last columns of the tables, showing capitalized value of pro rata average yearly cost of failures.

In the case of network systems in which type "LV" arresters are installed, close enough together so that each transformer is virtually protected by four "LV" arresters, as later discussed under "EXCEPTIONS," complete protection is afforded and the minimum-size transformer which it is economically justifiable to protect with type "LV" arresters is determined from the full values in the last column of the tables, showing capitalized value of pro rata average yearly cost of failure.

Transformer sizes so determined are given in Table I and curve Fig. 3.

Voltage	Transformer Size for Economic Balance: Type "SV" Arrester	Type "LV" Arrester Isolated Installation	Type "LV" Arrester Grouped Installation
2,300	41.5	10	4.0
6,900	90.0	16	1.5
13,200	170.0	27	6.0
22,000	247.0	105	23.0
33,000	363.0	148	45.0

Similar calculations for 25-cycle transformers show that the sizes for economic balance are from 5 per cent to 10 per cent smaller than in the corresponding cases with 60-cycle transformers.

DISCUSSION

To get an idea of the meaning of these transformer sizes and the arrester cost, the following further calculations are made.

On the assumptions made, the average yearly loss per transformer is $\frac{5 \times 20}{2000} \times 0.075 = 0.00375$ times the gross yearly revenue.

Crediting 7.5 per cent of the gross yearly revenue to the distribution transformer, this means that the average yearly loss represents 5 per cent of the income which may justly be credited to that transformer. This in turn means that 5 per cent of the revenue, which may justly be credited to an individual distribution transformer, should be spent for lightning protection.

From the foregoing data, a determination is made as to the percentage which the first cost of the lightning arrester is of the first cost of the transformer of a size for economic balance of cost of arrester and benefits from arresters. The percentage figures are given below.

Voltage	Type "SV" Arrester Percentage	Type "LV" Arrester Isolated Installation Percentage	Type "LV" Arrester Grouped Installation Percentage
2,300	27.2	5.6	10.3
6,900	19.7	9.4	28.3
13,200	21.4	9.8	18.7
22,000	21.9	8.6	17.1
33,000	24.2	10.4	18.3

This means that it is justifiable to spend for lightning arresters for complete protection something like 25 per cent of the initial cost of the transformers to be protected and that in the case of type "LV" arresters, it is permissible to spend from 10 per cent to 25 per cent of the initial cost of the transformers to be protected, depending on installation conditions.

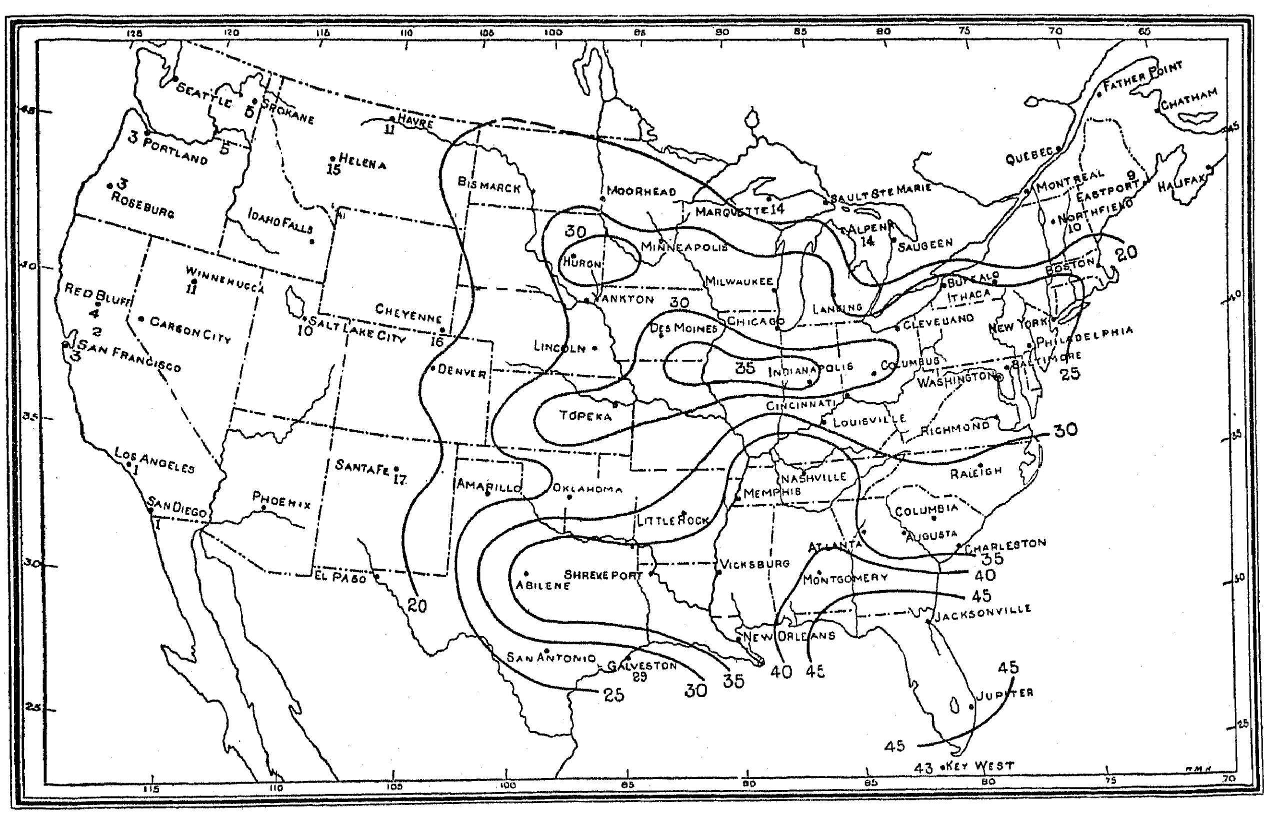
Exceptions

It will, of course, be realized that the conclusions reached in this analysis are only applicable to average cases, and that particular conditions in individual installations will make wide departure from these conclusions permissible. Several of the major exceptions are discussed below.

Although an individual transformer is best protected when the lightning arrester is connected to the system directly at the transformer, considerable benefit is derived from additional arresters, connected to the same circuit, if they are not too far distant. Thus, where the density of installation is sufficiently high, a network can be completely protected by the use of type "LV" arresters.

There are many cases of industrial load in which the actual damage, resulting from loss of service, is not adequately represented by 20 times the cost of the loss of revenue. Examples of this are the kind of processes in which a failure of power supply results in loss of valuable material in process, as for example, in a steel mill, a foundry, and a bakery. Under such conditions, it is not justifiable to omit the best available type of lightning arrester under any circumstances. Type "SV" arrester should always be used regardless of other considerations.

There is a tendency in many systems to safeguard loads where continuity of service is vital, by the use of inter-connections which provide for supply to these loads from more than one source. Wherever a transformer failure does not involve a shut-down and is less than that necessary for re-placement of the transformer, the justifiable expenditure for lightning arresters is reduced, the amount of reduction depending on local conditions, as for example, load requirements and the time for restoring service.



Reprinted from U. S. Weather Bureau, Bulletin No. 30.

FIG. 4

The intensity of lightning conditions varies very widely over the country. Ordinarily, for any particular location, a general idea of the intensity of these conditions is in the mind of the operating engineer. An interesting supplement to this direct information is given by the map, Fig. 4, which shows the distribution of thunder storms throughout the United States over a long period of years. Some comparisons between different sections of the country can be made with this map.

Appreciation is expressed of valuable assistance rendered during this study by Mr. E. C. Stone.

Discussion

K. B. McEachron: In the fourth paragraph in the first page, the statement is made that the relief voltage of the aluminum arrester for 6.6-kv. service is 18 kv., and for a certain distribution arrester is 28 kv. In the next paragraph is stated that the station type auto-valve has a relief voltage of 21 kv. instantaneous value. It is also stated that the comparison is well shown by the curves in Fig. 1. If the relief voltage is taken as that at which current first begins to flow then, according to the figure referred to, the distribution type (Curve 2) has a relief value of zero volts and the type *S V* and *L V*, 10 and 24 kv. respectively. From an examination of the curves, is it not true that these curves do not represent test results, but rather calculated curves based on theoretical considerations It is stated that the station type "closely parallels the electrolytic and therefore no curve is shown." As shown, however, this cannot be the case, since as stated in Mr. Atherton's paper before the Institute in 1923, the arrester is designed for a so-called counter voltage of 25 per cent above the crest value of the rated voltage of the arrester. In this case, this gives about 13,000 volts, which is the value given in the paper. It should be remembered that this critical voltage is without the series line gap which adds materially to the voltage at which discharge begins.

At 60 cycles this increase may amount to 25 per cent or more, while with a steep wave front a still larger multiplying factor is usually required. In this connection, I would like to have Mr. Atherton explain how the value of 21 kv. is obtained.

Curves, such as shown in Fig. 1, are misleading unless it is stated that the values are based on assumed theoretical conditions, and that they cannot represent operating results because the series gap—always used—has been omitted.

It is desirable to correct an erroneous impression as to the characteristics of the multigap arrester, which may be inferred by a study of Fig. 1. Curve 2 represents the volt-ampere characteristics of a 400-ohm fixed resistance. In practise the resistance used in many thousands of arresters is not constant as assumed by Mr. Atherton, but is reduced to a fraction of its 110-volt resistance when subjected to high-voltage steep-wave-front impulses. This means that in actual operation the instantaneous voltage at the higher currents will be very much less than indicated and is not correctly represented by a straight line. Well designed arresters of this type compare very favorably with the valve type of arresters when compared on the basis of instantaneous voltages during discharge. There are other features of the gap-resistance type which make it inferior to the valve types.

In making this study of the economics of lightning-arrester application Mr. Atherton finds it necessary to make certain assumptions. Among other things he states that the type *S V* arrester may be considered as giving perfect protection. For the purpose of this paper any other arrester might have been used or perhaps better yet a hypothetical arrester which might be called arrester No. 1 and the arrester giving half protection designated as arrester No. 2. It has not been established that any type affords the assumed protection, nor do I believe that the art has yet been developed to such a point that no failures in service can occur.

The experience of Mr. Roper in Chicago, referred to in the paper, shows that increasing density of the arresters results in decreased losses of apparatus. In general until the number of arresters exceed the number of transformers the best results will be secured by placing an arrester at each transformer. If additional arresters are required it is probable that the greatest benefit will be obtained by placing the additional protection along the line rather than placing several arresters in parallel at one transformer installation.

In making tests using impulse voltages to determine arrester characteristics, it is well to bear in mind, that laboratory tests will, in general, give varying results, and to be directly compared, all the tests should be made on the same impulse generator. Tests made by different investigators, should be compared with caution.

It is also true that although a line is drawn as the volt-ampere characteristic of an arrester, as a matter of fact, with present-day testing methods, the curve is a broad band whose width is determined by two factors. The first is the inherent variation between arresters and the second is the range of division of sparking on the measuring spheres. These variations do, in some cases, produce a deviation of as much as 10 per cent above and below the average curve.

A. L. Atherton: Mr. McEachron's comments and questions in regard to Fig. 1, "Volt-ampere relations showing comparative performance characteristics of several arrester types," merely point out that such a characteristic does not indicate the relief voltage, or voltage at which the discharge starts, and to this extent such curves fail to give a complete indication of protection value. Since the lightning-arrester performance is discontinuous, the relief voltage cannot be shown on the curve of operating characteristics, but must be covered by a separate statement, as I have done.

The value of 21 kv. cited, is merely the crest value of double-line voltage which is fairly representative of this type arrester. This value is secured by test and, since the time lag is very small, it is not very greatly different for power frequencies and for steep wave fronts.

Volt-ampere characteristic curves of lightning arresters as determined by present-day testing practice will not be precise, but will, as Mr. McEachron has stated, cover a band of considerable width, due not only to variations in the testing procedure and measurements, but also to variations in the product. A central line, however, clearer to use, and, if the limitations are recognized, just as dependable.

Operating Experiences with the Relaying of the Duquesne Ring

BY H. P. SLEEPER

Associate, A. I. E. E.

Duquesne Light Company

Review of the Subject.—*A paper was presented by the writer at the A. I. E. E. Spring Convention, held at Pittsburgh, April 24 to 26, 1923, and was published in the July 1923 issue of the Institute Journal, on the subject: "Selective Relay System of the 66,000 Volt Ring of the Duquesne Light Company." That paper described in detail the systems of relaying which are used to protect the Duquesne Ring for both short circuit and ground faults. That paper also described the service tests which were made on the ring to test the relay protection.*

Nearly a year has passed since the ring was put into operation with the protection described, and ample opportunity has been given to study the protective schemes under actual service conditions and to prove their practicability. This period of service has included one of the worst, if not the very worst, lightning seasons that has ever been experienced in the history of the Duquesne Light Company. Electrical storms in the Pittsburgh District, are unusually severe, both as to intensity and duration, due probably to the geographical location of the district, situated as it is at the junction of two rivers. Storms in this vicinity almost invariably seek the Ohio River Valley and follow it up to the point of junction of the Allegheny and Monongahela Rivers, after which they will continue up one of these streams. Storms of several hours duration are not at all uncommon during the height of the lightning season. These have resulted in many insulator flashovers during the past season, and the ground relays have given an excellent account of themselves. Several line short circuits have occurred, and the proper relays functioned correctly in every case.

This paper gives a log of all relay operations on the ring for the first eleven months' service, and it will be noted that every case of trouble on lines has been cleared by the proper relays. A study of all operations leads to certain conclusions, as to the proper means of improving the present protection, and these are described in detail. All troubles and difficulties have been frankly described and nothing withheld. It is hoped that other operating companies, which are using, or contemplate using similar types of protection may derive some value from the discussion and data presented.

THE Duquesne Ring consists essentially of a double-circuit 66,000-volt loop surrounding the City of Pittsburgh. (See Fig. 1). Its circumferential length is approximately eighty miles, and the two circuits are paralleled and sectionalized at six step-down sub-stations, and two generating stations. Power is fed into the ring at opposite ends by the Colfax and Brunot Island power plants, the capacity of each plant being 120,000 kw.

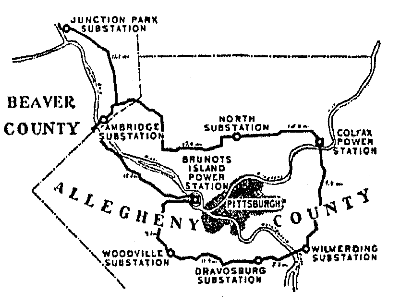


FIG. 1—MAP OF THE DUQUESNE RING

The short-circuit protection of the lines is secured by the use of cross-connected reverse-power Westinghouse Type "CR" relays. The ground protection is effected by means of balanced-current Westinghouse Type "CD" relays connected in the neutral of the balancde lines. These lines are balanced in pairs in every case, except at Junction Park, where no balance is made, and where straight reverse power protection with interlocked overload relays for directional ground protection is used.

The busses and transformer banks at each station are protected by differentially-connected overload relays. The low-tension busses are protected by means of overload relays only on the low-tension transformer breakers.

The line protection is shown diagrammatically in Fig. 2; a relay diagram of the system is shown in Fig. 3;

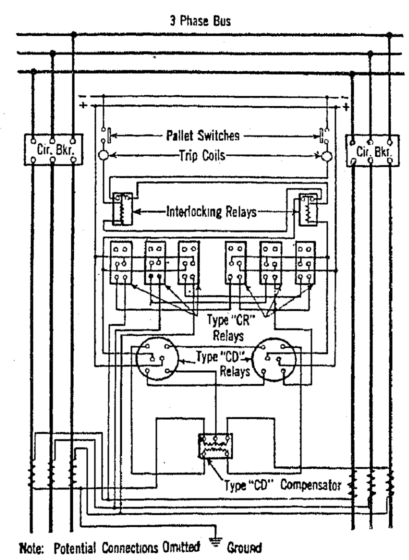

FIG. 2—DIAGRAM OF CONNECTIONS OF LINE RELAYS

and a schematic diagram of the relay protection of a typical station is shown in Fig. 4.

The relay settings used during the past year were as follows: Line short-circuit relays, 7-ampere current tap; 0.4 second definite minimum time; current transformer ratio 400/5. Since each 4/0 circuit is rated at 30,000 kw., this current allows each circuit to carry 200 per cent load before tripping, and hence

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-10, 1924.

requires an unbalance of 560 amperes between balanced phases to operate the relays. As the minimum short-circuit current on the system is approximately 3000 amperes, this leaves an ample margin of safety.

The line ground relays are set to operate on an unbalance of 40 amperes. As the minimum ground current is approximately 600 amperes, positive operation of these relays is assured. The ground current on the 66,000-volt system is limited by the 63-ohm ground resistor at each of the two generating stations.

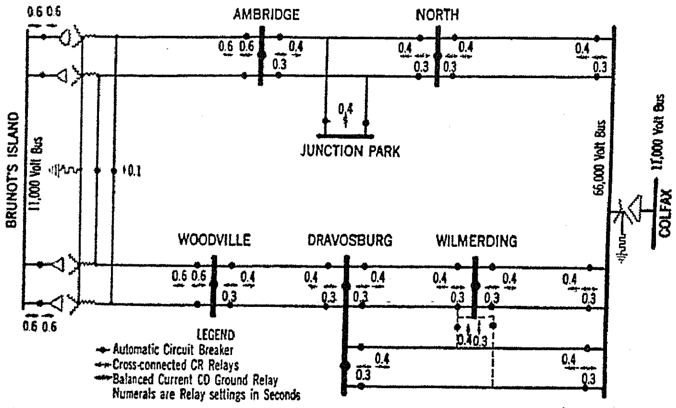

Fig. 3—Schematic Diagram of 66-Kv. Ring System, Showing Relay Protection of Lines

The high-tension bus differential relays are set to operate on 0.7 ampere current tap, 0.75 second. With 400/5 current transformer ratio, this causes these relays to operate on a minimum of 56 amperes, which allows the same relays to give short circuit and ground protection on the busses. The value of the time setting for the differential relays was arrived at after several incorrect operations of bus differential relays had occurred. It was observed at certain stations that the bus relays would operate each time that a line fault occurred adjacent to that particular bus. The line relays would first operate correctly to open the line breaker. Immediately, as soon as the line breaker opened, the bus differential relays, which were then set at 0.1 second, would close contacts and isolate the bus. The cause was readily surmised and proved by test to be due to the action of the pallet switch of the breaker. This is a heel and toe switch, the function of which is to operate mechanically when the breaker is opened, to short circuit the current transformers in the breaker and to open the parallel circuit of these current transformers with the transformers in the breakers remaining in circuit on the bus, thus leaving a true balance on the bus differential relays. Thus, when the breaker opens under load or short circuit, it is necessary that the arc on the breaker contacts be broken simultaneously with the operation of the pallet switch contacts. Any time difference which may exist will create an unbalance in the bus differential relay circuits, and if the time of duration of this unbalanced condition is equal to or greater than that of the time setting of those relays, it is obvious that they will close contacts. As the time of duration of the arc in the breaker is problematical, and will vary somewhat with faults of different characteristics; and moreover as the heel and toe pallet switch has a brief period, during which the blade is closed on

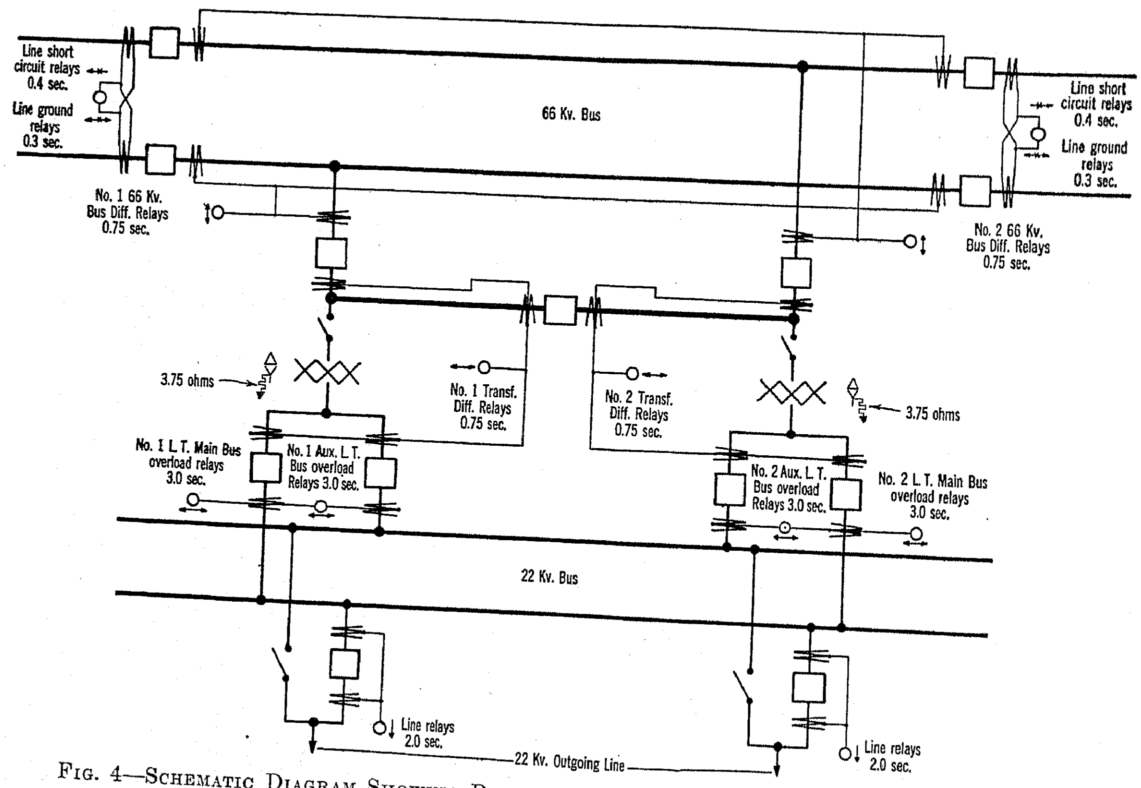

Fig. 4—Schematic Diagram Showing Relaying of Typical Substation-Present Layout

TABLE I

LOG OF 66-KV. RELAY OPERATIONS

Case No.	Date	Cause	Breaker Openings	Relays Operated	Correct Relay Operations	Incorrect or Unaccountable Relay Operations	Total Relay Operations	Remarks
1	3-23-23	22-kv. bus short on bank tapped to North - Colfax No. 2	North-Colfax No. 2 at Colfax North-Colfax No. 2 at North 2 remaining No. 2 differential breakers at North	CR CR Bus diff. Grand Totals 47	3-15-23 to 3-15-24				87	21	108	

*One failure.

both sets of contacts to avoid open circuiting the current transformers; it is obvious that some period of current unbalance will exist each time a breaker opens. It is, therefore, necessary to set the time of the bus relays in excess of any such possible discrepancy. The maximum time difference found was between 0.2 and 0.3 seconds. The setting of 0.75 second therefore has a considerable factor of safety.

The transformer differential relays are set at 0.7 ampere current tap, and 0.75 second definite minimum time. The same condition of unbalanced currents will exist on these relays when one of the breakers in this differential opens, as in the case of the bus differential relays, discussed above.

The low-tension bus overload relays are set for a current tap which will allow the bank to carry 200 per cent load without tripping; and a time setting of three seconds. This time setting is used to be selective

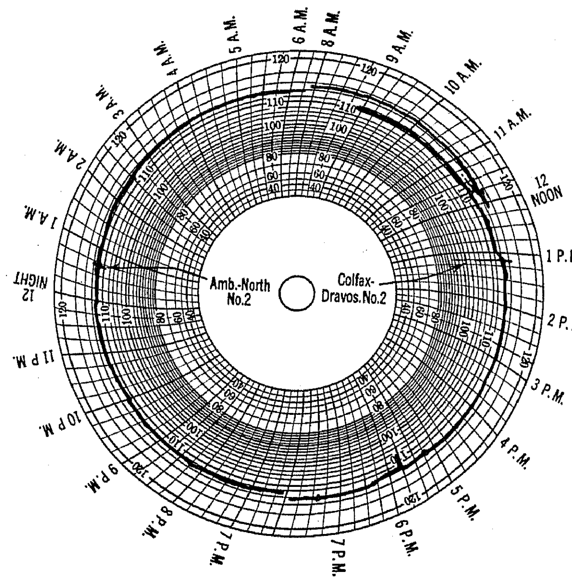

FIG. 5—VOLTAGE CHARTS SHOWING DISTURBANCES RESULTING FROM NORMAL OPERATIONS OF 66-KV. RELAYS GROUND RECORD AT LEFT—SHORT CIRCUIT RECORD AT RIGHT

with the two-second settings on the outgoing feeders from the low-tension bus.

Table I gives a log of total relay operations on the ring for the eleven months period March 15, 1923 to February 15, 1924. During that time a total of 39 line faults occurred, all of which were successfully sectionalized by the relays. Of these 39 faults, it is interesting to note that 12 were short circuit and 27 were ground faults. This division is not strictly accurate, as operation indicators were not installed on all relays during the entire period. However, it is believed to be substantially correct, and was determined by checking such indicators as were installed, and by a study of the phenomena observed at the locations of the faults, and also by the observed and recorded disturbances on the system. The latter is a very dependable factor, as was demonstrated when the initial service tests were made. A ground fault on the 66-kv. ring, which exists as a ground only, does not give a noticeable voltage disturbance on the low-tension busses, and a maximum voltage variation of the system voltage of four volts has been recorded on a 110-volt meter, which is fed from the 11-kv. bus in the center of the high-tension transmission network. The disturbance is usually less than four volts, varying from two to three volts on a normal operation of the ground relays. Fig. 5 shows a voltage chart, recording a ground fault on the ring which was sectionalized by the ground relays without any noticeable voltage fluctuation, giving a drop of about three volts with arise of one volt. The same chart shows a record of a 66-kv. line short circuit which was sectionalized by the short-circuit relays. This shows a voltage drop of twenty volts, followed by a rise of three volts. It is probable that the actual drop was less than this value, as the meter has considerable overtravel. Hence the voltage variation which occurs at the opening of any section of the ring has been found to be a very dependable criterion as to the nature of the fault.

In every case of line fault the trouble was successfully sectionalized by the ring relays, and the ring was left intact. The ring was opened at one point several times, but the other side remained closed and the power plants were not separated by the action of the automatic relays. Some of the cases, however, involved operations which were unnecessary, and some which were not entirely accountable. One failure was experienced.

The following general divisions may be made of the total number of cases of trouble which occurred on the ring:

Total faults on the ring	43
Faults giving 100% correct relay operation	36
Faults involving incorrect or unnecessary relay operations	6
Other incorrect operations	11
Faults involving relay failures	1

An analysis of the above leads to some interesting conclusions. First, of a total of 43 faults which have occurred on the ring, all but one have been successfully cleared by the relays. This gives an overall efficiency for relay operation of 97.7 per cent. It is also interesting to note five of these faults were double circuit faults. That is, the trouble which occurred involved both of the balanced circuits, either simultaneously or nearly so. It is obvious that this is the worst type of fault to encounter with a system of balanced protection, which depends inherently upon the inequality in fault energy in the balanced circuits. Yet, in each of these cases, both defective units were removed successfully from the system. Three correct operations have occurred on transformer differential protection. On the basis of relay operations, a total of 108 have occurred, of which 87 were correct and 21 incorrect or unaccountable.

The matter of unnecessary breaker openings is one of the utmost importance, particularly on a double-circuit system like the Duquesne Ring, where two

important factors enter. First, if any breaker opens unnecessarily, it leaves its mate (the line against which it is balanced) in a precarious condition unnecessarily. Second, if any section of the lines is operating singly (only one line in service, its mate being defective or out of service) and it opens unnecessarily when a fault occurs on the opposite side of the ring, it may separate the two power plants, situated as they are at the opposite ends of the ring. It is therefore obvious that it is of utmost importance to prevent such incorrect operations, which may endanger the unity of the system. Exactly how many of the operations listed as unnecessary were correct or incorrect is impossible to determine definitely. Several operations occurred, such as Cases 10, 15 and 39, where only one breaker opened on a section of line, and then went back into service when closed and carried load. This of itself gives no definite indication, since in every case where insulator flashovers occurred and the line was sectionalized by the ground relays, the lines went back into service immediately and carried load in a rain storm. Usually an inspection of the line would find a small part of one insulator petticoat slightly chipped. Therefore, the fact that the lines which opened at one end only, went back into service immediately is not an indication that no fault existed. In fact, all indications point to the fact that a ground fault did exist. This gives rise to the point that a flashover was apparently extinguished by the opening of one end of the circuit, potential being continuously supplied from the other end.

The hazard of unnecessary breaker openings on a system of this kind is very clearly shown in Cases 13 and 37. In each of these cases one line of a balanced pair had been automatically opened at both ends, due to a line fault, or else the one line was out of service for repairs. Under these conditions, a fault occurred on another section of line, and this caused the good section of line, operating singly, to open at the feeding end, as all relays are set to operate in a given time, which is, of course, the same for either single or double-line operation. These operations resulted in splitting the ring open on one side, which, however, did no harm, since the ring was closed on the other side. If, however, the ring had been operating with a single-line section on both sides, and a fault had occurred, it would have opened both single-line sections and separated the power plants. Obviously, the lesson to be learned from these cases is that single-line operation must be automatically rendered selective with the remaining balanced sections. This may be called Modification No. 1 and is referred to later.

Two other cases of trouble have been experienced which may prove of particular interest to users of balanced protection, and which have led to Modification No. 2. These cases both have to do with the use of interlocking relays. These relays, which are shown in Fig. 2, are connected in the conventional manner, so that the automatic tripping of breaker No. 1 on a pair of balanced lines operates the direct-current interlocking relay on line No. 2. The contacts of this relay open instantaneously, and lock out the tripping circuit of its breaker until a definite time interval has elapsed, when it is restored. This time interval is sufficient to allow the faulty line to clear at the opposite end and thus remove the fault from the system. If some such precaution is not taken, it is obvious that the good line of the pair will open at No. 1 end simultaneously with the opening of the bad line on No. 2 end. It is evident that the success of this scheme depends entirely upon the proper functioning of the interlocking relay. If this relay fails to trip, the good line of the pair will be incorrectly opened. If this relay trips but fails to reset, the second line is left without protection at that end. Both of these conditions have been found to exist, although fortunately under test and not service conditions. At best, a direct-current time relay requires considerable maintenance, and the timing feature is not accurate. For the latter reason it is desirable to set them for a liberal time interval, so as to assure the positive clearing of the bad line at both ends to hold the good line in service. For this reason, and because the particular type of interlocking relays supplied were especially accurate and dependable at that point, these relays, as used in 1923, were set for a re-setting time delay of eight seconds. Under these conditions, two cases occurred involving the operation of the relays.

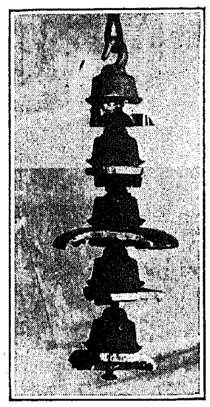

Fig. 6—Line Suspension Insulator Subjected to Short Circuit by a Direct Stroke of Lightning

Case 13 occurred during a severe electrical storm in July. A stroke of lightning hit at or very near one of the 66-kv. double-circuit steel towers about one-half mile from the North Substation on the North-Colfax lines. The severity of the discharge is shown by the fact that on the following day it was found necessary to replace 20 suspension insulator strings on this line in the vicinity of the stroke. (See Fig. 6.) At the tower struck, all three insulators flashed over on No. 1 circuit, and at least one insulator string on No. 2 circuit. This action presumably was simultaneous. The operators at both North and Colfax

report that both lines opened simultaneously. This is, of course, theoretically possible, assuming a three-phase short circuit on one line and a single-phase ground circuit on the other line, in which case the short-circuit relays on one line and the ground relays on the other line would be unbalanced and operate simultaneously. To do so, it would be necessary for both sets of relays to close before the interlocking relay had operated to render one line temporarily non-automatic. Moreover, it will be noted that there is a difference of 0.1 second in the time settings of the short-circuit and the ground relays. Hence, it is highly probable, that the short-circuited line opened first and the ground circuit remained on No. 2 line during the 8.0 second period, that this line was rendered non-automatic, due to the proper functioning of the interlocking relays, and that this line was tripped as soon as the trip circuits were restored. No distress, however, was apparent on the system, except a severe voltage dip when the initial short circuit occurred.

The next cast was not so fortunate. This is recorded as Case 29. The initial fault was occasioned by a lightning-arrester lead coming loose at the Woodville Substation platform and swinging into an adjacent phase of the Brunot Island-Woodville No. 1 line. The short-circuit relays functioned properly, and the line was cleared at both ends. However, almost simultaneously with the short circuit on No. 1 line, a fault developed on a strain insulator at Woodville on Brunot Island-Woodville No. 2 line. This line was then non-automatic by the action of the interlocking relays, resulting from the opening of No. 1 line. The fault on No. 2 line developed almst immediately into a short circuit and for eight or nine seconds the system was in distress. The voltage dropped to a low value and the two power plants hunted, resulting in considerable surging. At the end of the eight second period, the interlocking relays restored the trip circuits of the line and it was tripped automatically at both ends. All synchronous load was dropped, but no other damage resulted, nor did any simultaneous failures develop. As a consequence of this breakdown, resulting as it did in sustained distress, it was decided to reduce the time delay on the interlocking relays from eight seconds to four seconds, Since that time, two similar cases of trouble have developed. Cases 34 and 44, and no particular distress has occurred on the system, while only a small part of synchronous load was lost, and that only in the immediate vicinity of the trouble. As previously stated, these two occurrences resulted in the adoption of Modification No. 2.

A third and fourth modification have been made as a result of Case 40. This resulted in the only failure to date of any of the 66-kv. relaying, and it is interesting to note that the failure occurred on differential apparatus protection rather than on the balanced line protection, where perhaps the probability might be considered greater, particularly considering the larger number of operations which occur on the line relays. This failure was the result of a rather extraordinary sequence of events which could hardly be foreseen. A 22-kv. line breaker was closed on a fault to test the line, after the breaker had opened once automatically. The breaker apparently cleared the fault at the contacts, but threw fire and oil from the vent in the case. This caused a short circuit on the bus side of the breaker bushings, and the overload relays on the low-tension bank breaker operated to trip the breaker. The 22-kv. bus was split at the time. This breaker failed in opening, blowing off two tanks and short circuiting the low-tension side of the transformer bank. This placed the fault within the bank differential protection, which failed to operate. The fault was cleared when the operator stripped the board, opening all high-tension switches. An investigation later showed the transformer differential protection to be in perfect condition. A very thorough investigation brought forth the following explanation, which, however, could not be definitely substantiated, since the evidence was destroyed. It seems probable that when the transformer breaker was tripped, the breaker did not fully open, with the result that the heel and toe pallet switch remained in the neutral position. This left the differential relays short circuited and hence inoperative, thus accounting for their failure to close contacts.

As a result of the experiences to date with this relay system, certain conclusions have been reached as follows:

1. It must be possible to operate the ring with one or more single-line sections in circuit, without danger of dropping these sections when faults occur on other sections. (See Modification No. 1).
2. Some system of interlocking must be used which will be capable of more accurate time settings than the present, and especially one whose failure to function properly cannot leave any lines without protection. (See Modification No. 2).
3. Every system of primary relaying must be provided with a system of back-up protection which will act if the first system fails, a "second line of defence," as it were.

These features are now being applied to the ring, and are described in the following, under Modification No. 3.

4. Means must be provided to give protection for faults occurring inside the tanks of circuit breakers. (See Modification No. 4).
5. It must be possible to automatically remove any single unit from service at a station without killing this station. (See Modification No. 5).

Modification No. 1 consists of the addition of a set of overload relays, which are automatically thrown into service when one line of a pair is removed from circuit. These relays then give overload protection on the remaining line, and their time is set high enough to be selective with the remaining fast-time balanced relays. This will prevent the unnecessary opening of all good single-line sections when faults occur on the other paired sections. At the same time, the single-

line sections are left with ample protection for themselves. The modified protection is shown schematically in Fig. 7. The balanced line protection is the same as before, shown in Fig. 2, except that the direct-current time delay closing interlocking relay has been eliminated. This relay has been replaced by an instantaneous direct-current multicontact relay, the function of which is to shunt out of the tripping circuit the contacts of either the fast-time balanced relays, or those of the long-time overload relays according as the station is working with one or two lines in service. The action of the direct-current relay is controlled by the position of the breaker. If the breaker is closed, the pallet switch to this relay is open, and the back contacts of the relay shunt the tripping contacts of the long-time

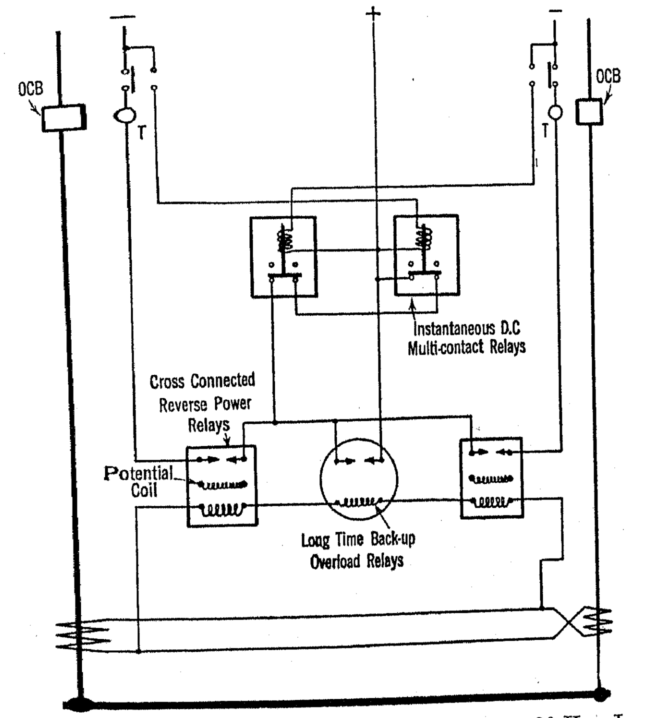

FIG. 7—SCHEMATIC DIAGRAM OF IMPROVED 66-KV. LINE PROTECTION

overload relays, provided the direct-current relay on the other line is in the closed position. This leaves in circuit the contacts of the balanced relays only. But if the one line is open and the other line closed, the pallet switch in the former is closed, thus energizing the direct-current relay, which takes the shunt off the trip contacts of the long-time overload relays, and shunts out the trip contacts of the balanced relays. This places the desired long-time setting on the relays of the single line, and gives it selective operation for subsequent faults on balanced sections.

Modification No. 2 follows as a consequence of Modification No. 1, and secures the employment of accurate and dependable interlocking relays. This is accomplished by the same relays as were added in the preceding modification to secure selective single-line operation. The time delay is secured through the action of the long-time back-up alternating-current overload induction relay, which is automatically thrown into service when one of the balanced lines is tripped out, either automatically or otherwise. This relay starts to trip out the good line, but the bad line clears at the other end before the long-time overload relay can close contacts. This scheme has the additional features:

1. That the good line is never rendered non-automatic;
2. That the failure of the direct-current relay, either to close or open, does not cripple any protection, but merely destroys the selectivity;
3. That all units in the interlocking scheme are very positive in their operation;
4. That very accurate time-setting of the interlocking feature is accomplished.

Modification No. 3 has been adopted to secure a second line of defense to two different systems of relaying: the line relays and the station protection. This is shown in Fig. 8, and consists of reverse-power relays on each 66-kv. transformer breaker, set to trip for power flowing from the ring to the station bus. The trip circuits of these two sets of relays, however, are crossed, that is, the relays on No. 5 transformer breaker trip breaker No. 6, and the relays on No. 6 transformer breaker trip breaker No. 5. This is done to secure back-up protection for the line circuit breakers, and is accomplished as follows. Referring to Fig. 8, let us assume that a fault has developed on the upper right hand line. The breaker at the other end has opened correctly but breaker No. 1 at this station has for some reason failed to open automatically. This places a balanced fault on the ring, which cannot be detected by any of the remaining balanced types of protection. Such an occurrence would shut down the system, unless special means were provided to relieve it. This is accomplished by the No. 1 66-kv. bus-splitting reverse-power relays which respond to the power which will pass over the bus tie feeding into the fault through line breaker No. 1. These relays will trip breaker No. 6, which leaves all the station load on the good line, and by splitting the bus, has taken the balance off the lines. This passes the trouble back to the next adjacent station, where the line relays will operate to clear the fault from the system. The second function of these bus-splitting relays is to act as back-up protection for any faults which may occur at the station. Thus, if any of the bus or transformer differentials fail to function properly when in trouble, these relays will act as overload protection to take the trouble off the ring.

Modification No. 4 has been adopted to take care of faults inside breaker tanks. It is done, as shown in Fig. 8, by overlapping the protection around each circuit breaker. Thus, on a line breaker, the relays are connected to the current transformers on the bus side of the breaker, and the bus differential relays are connected to the current transformers on the line side of the breaker. Thus, a ground circuit inside a

tank will operate both the line and bus relays, and thus clear both sources of feed to the fault.

Modification No. 5. The purpose of this modification is to prevent a 22-kv. bus short circuit from killing the station. It consists of the installation of a bus tie breaker in the main 22-kv. bus, and the protection of each section of this bus by means of bus-differential relays. (See Fig. 8). An additional set of over-load relays is inserted between these busses to act as bus-splitting protection. The purpose of this is to complete a second line of defense for the 22-kv. outgoing line breakers. Thus, if line breaker No. 14 fails to open for a fault on its line, this will put the trouble on No. 2 section of the 22-kv. bus, which will then be cleared by the operation of the bus-splitting overload relays opening bus tie breaker No. 12 and the operation of No. 2 main bus overload relays opening breaker No. 11. This will clear the fault from the system and leave the station hot on the No. 1 section of the low-tension bus. If the fault had been on the bus itself, such as by the failure of a line breaker No. 14, this would have operated the No. 2 22-kv. bus differential relays and opened breakers 11, 12, 14 and the breakers of any other outgoing lines from this section of bus.

All of the improvements described above are now in the process of being installed at the ring stations. It is not assumed that this will mean that perfect operation may be expected hereafter, but it is believed that these improvements are a big step in the right direction and, that the improved performance derived will amply justify the added investment.

As a whole, the performance of the ring relaying during the past eleven months is considered extremely successful. Of a total of 43 major faults which developed, 42 were successfully sectionalized and only on two occasions was a major outage permitted to result. The single failure which occurred was the result of defective apparatus which could not be controlled. This contingency will be eliminated in the future by the safety valves which are being added. The action of the balanced line relays has been very pleasing. All cases of line trouble have been relieved with a very small amount of damage and disturbance. This is, of course, due to the sensitivity of the relays and their rapidity of action. Every case of insulator flashover during the past season has been disconnected so quickly that a negligible amount of injury has resulted at the fault and the lines were returned to service in every case under adverse conditions. This even includes the case of the direct lightning stroke of Case 14, where, although considerable damage was done to the porcelain, it was nevertheless possible to put the lines back into service immediately as the copper was practically undamaged.

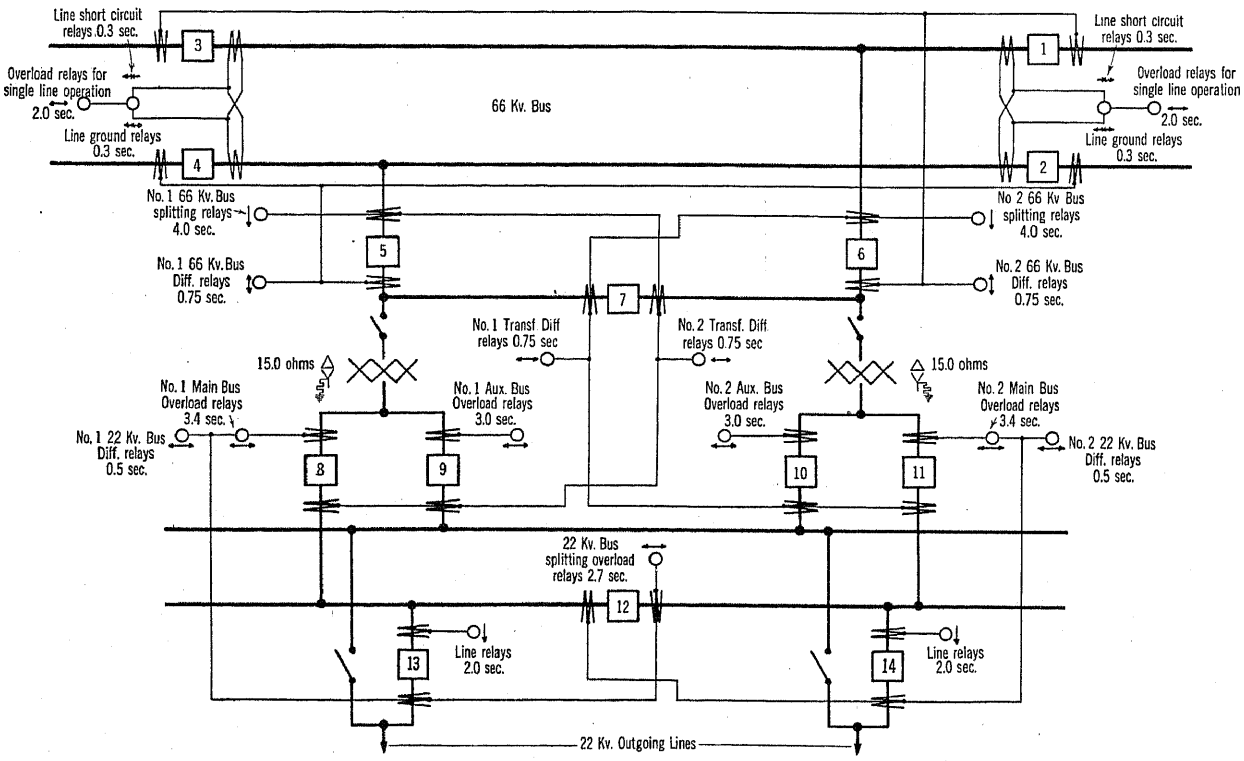

FIG. 8—SCHEMATIC DIAGRAM SHOWING RELAYING OF TYPICAL SUBSTATION—ULTIMATE LAYOUT

As a result of the past eleven months' experience, many valuable lessons have been learned. These have been carefully weighed and acted upon. Systems of this kind, with this type of protection, are still young and present many problems which are novel and interesting. It is, nevertheless, confidently believed that the performance to date will compare extremely favorably with any equivalent system during the same time. It is further believed that with the additional safety features added, as described in this paper, the coming year will considerably better the record to date.

New Type of High-Tension Network

An Interconnecting System for the Supply of Electric Power over Large Areas

BY PERCY H. THOMAS
Fellow, A. I. E. E.
Consulting Engineer, New York, N. Y.

Review of the Subject:—*The purpose of the paper is to present for consideration a new method of interconnecting sources of power and load centers in a large district with a well developed and well distributed load. The central idea is the superposition of a high tension network of single-circuit lines over the whole district for the purpose of supplying a medium in which current may flow in any general direction as changing conditions may dictate. This is similar to the underground network of the Edison Companies in the large cities.*

With such a layout available, power anywhere in the district may be fed into the network and it may be taken out at any other point without serious loss of energy.

The network is connected directly to load centers as well as to existing generating centers and thus greatly assists the present distribution lines distributing power and also stabilizes the potential at each load center reached.

The charging current of the network may largely neutralize the lagging component of the load with favorable design.

A concrete illustrative network is worked out in considerable detail, covering the present load with an equal amount of new future load in the interconnected systems of Alabama, the Carolinas, Georgia and Tennessee, with a branch to the Appalachian Power Company in Virginia. The result shows a very effective, efficient and low cost system for this territory.

The plan is applicable to other districts as well.

Details are given as to the layout taken and the operating characteristics of the system.

INTRODUCTION

THE purpose of the present paper is to propose a new type of inter-connection for high-tension networks for the economic supply of electric power over large areas having an already well developed load. No judgment can be formed on such a proposal without considering all pertinent factors, such as feasibility, cost, economy operating quality, technical design, etc.

There is a natural evolution in the development of the supply of power to any growing industrial district. In the beginning, supply centers start at favorable points, either sites for cheap power or favorable for advantageous load, and grow and spread until the district is fairly well covered with power systems, at least where the active industries exist. As these systems come in contact at their extreme points, they make connections and exchange power to their mutual advantage. In fact, one system may to a material extent depend on power from another system for supplying increments of its load as well as for emergency power.

There comes a point, however, as the load of the district grows, where the favorable sites for local power plants, especially water power, are exhausted in much of the district and resort must be had to local steam plants or more distant water power.

It will usually be the case that within any one such large district some few points will be much more favorable for the development of power in large blocks than other points, calling for the transmission and distribution of this power over the district. When this point is reached, a radical change in the nature of the interconnection and the general supply system is required. To propose a suitable system for such a situation is the object of this paper.

Up to the present time no true general high-tension supply network has been installed. The report of the U. S. Geological Survey, 1921, entitled "A Super-power System for the Region between Boston and Washington," by W. S. Murray and others, Professional Paper 123, proposes an interconnection for the Northern Atlantic States, but the present system differs materially therefrom and is believed to have some marked advantages for many districts.

The point of view taken in the layout of the type of network proposed herein, is to utilize the transmission lines made necessary by the transmission of power from the most favorable sources of water or steam power in bulk, to serve at the same time to distribute this power over the district as widely as possible and to gain such other advantages as can be secured at the same time at small cost, for example, the improvement of voltage regulation and power factor.

The total advantage that can be gained over the trunk-line conception of interconnection, *i. e.*, using heavy lines between large power centers, is surprisingly great and can be realized only by studying concrete examples. In the paper following, these matters are gone into in some detail and a concrete example worked out to permit intelligent judgment to be made.

Part I

SPECIAL FEATURES OF THE NEW NETWORK

The underlying features of the new type of high-tension network, which is predicated on the combination of the supply of power from large central stations, located at the most favorable generating points, with the ready delivery of power at all points in the district where it may be needed, are the following:

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924, also presented at the Northeastern District Regional meeting, Worcester, Mass., June 4-5, 1924.

Laying out the high-tension lines to reach as many substations at load centers as possible and using single circuit lines for this purpose, thus securing a true network.

Increasing the capacity of the distribution lines to deliver power in their own territory by feeding power back along these existing distribution lines from the various points of connection to the network, thus shortening the average local transmission and increasing the available feeds.

Establishing each point at which the high-tension network is connected to the existing distribution lines as a point of constant voltage, as well as a new center of distribution of high-tension power.

Utilizing favorably situated local power stations to stabilize the network voltage and to hold the established voltages fixed, regardless of the amount of or distribution of the flow of power and taking advantage of the slope of potential along a line with the prevailing direction of the flow of power to improve the line-power factor.

Co-ordinating the network voltage and charging current for any particular network to improve the power factor in the distribution lines and providing for control of line power factor at individual substations.

The result of the application of these principles is a network covering a district in all directions by many individual circuits and touching all the important sources of power and load centers;—a network of such a nature that any power available at any point may be freely drawn at any other, so that the most advantageous sources of power may be developed, regardless of their location and load centers be established, regardless of their relation to the location of the generating plants;—such a system that the capacity of the existing distribution circuits is very greatly increased and their power factor improved without additional expense and the voltage regulation of local distribution lines is stabilized at many new points.

This high tension network has the advantages of the low voltage underground net works of the Edison Companies in large cities as far as efficient transmission and flexible distribution of power is concerned.

Aside from the North Atlantic district, of which so much has been written, there are several districts in this country where some such high-tension network as here described will be of great advantage. The Southeastern States with their well-known combination of systems and the States south of the Great Lakes from Buffalo to Chicago, and as far South as the Ohio River and others may be cited.

Typical Network

In order to make the value of this type of network more evident and to give a concrete example of how an actual installation would work out, a layout suitable for the Southeastern States, including Southern Virginia, North and South Carolina, Georgia, Alabama and Tennessee, has been worked out in some detail, but based on more or less arbitrary assumptions of load.

This network transmits new power, generated largely by hydro-electric plants, located in Alabama and Tennessee, to the amount of nearly 1,000,000 horse power, including 350,000 horse power from Muscle Shoals, and distributes it over the whole district, wherever it can be best used, this all being in addition to the present 800,000 or 900,000 horse power now generated. A large part of this load is located in the States of North and South Carolina, while the bulk of the power is generated far west of this.

To cover periods when water is low and steam must be used, a large steam plant is taken at the center of the system of the Appalachian Power Company in Virginia and another near Knoxville, where steam plant conditions are favorable. Furthermore, it is assumed that some power will be taken for general use from seasonal-storage reservoirs in a dry time.

It is expected that this amount of new power will be required by the growth of the district in from seven to ten years.

This network which operates on an average voltage of 190 kv. has a total line loss at peak load of about 11 per cent and also has satisfactory voltage regulation. The average $C^2 R$ line loss may be less than half of this, on account of the large portion of time when the load is light. Furthermore, the power factor in the distribution lines is raised to about 95 per cent on the average. As it happens, no synchronous condenser need be added in this layout. The capital cost, including transmission lines, high-tension oil breakers and step-down transformers, will be from $30,000,000. to $40,000,000 or or from $45. to $60. per kw, delivered to the local distribution lines.

The actual locations of the high tension lines, the load carried by each, and the new power taken from the net work at each substation and generating point are shown in the accompanying map. The details of the layouts, will be found described at length in Part III.

Before discussing more in detail the advantages and economies gained for this district by this network, a brief discussion of some of the considerations underlying an organization to handle such an installation will be appropriate.

Obviously, to secure the greatest benefit from the layout under consideration, its operation and control must be under one authority. This suggests a *Network Organization* of some sort. It is further necessary that the savings and advantages be divided equitably among the several constituent companies and that the relationships be such that the most economical use of the water power and of the installation may be made without its being to the advantage of one system over another; also that new developments shall be made at the most favorable points and in the most economi-

cal manner, without unfairness to any particular company.

While it would not be appropriate in this paper to prescribe any definite corporate organization for this situation, for this would necessarily be an evolution after much consideration of all the special factors existing in this as in any district, it may be of some value to discuss briefly one possible plan.

Controlling Organization

It may be taken that the *Network Organization* sells, buys, generates power, constructs and owns or leases the new power stations. The Network Organization is controlled by the constituent companies, the equity of each being proportional to the maximum load taken from the network, plus its agreed capacity to supply power to the network on demand. These quantities are kept independent of such power as is generated and consumed by any one local company without regard to the network as at present. As the system grows, a new apportionment of equity will be made yearly among the constituent companies, adjusting for any increase in load or supply capacity. This keeps the interests of the several companies proportional to the part they play in the network operations, as well as their shares in the profits.

The Network Organization should be able to finance improvements, credits for which might be guaranteed by that company in whose territory the improvements lie, so that the best possible rate of interest might be obtained.

In negotiating contracts with constituent companies for the delivery of power, the Network Organization would have to offer a price lower than that at which the local company could generate its own power, which would give a more or less practicable method of arriving at an equitable selling price for power and one in line with market conditions, which is desirable. Such a contract could be of any suitable form for the service.

Contracts for the sale of power might well be made also with outside consumers.

Contracts by the Network Organization to buy power or to buy water-power sites should be based on maximum power for which the Network Organization may call and not for the amount of power that may actually be delivered in any particular. This is so that the network load dispatcher may be able to draw power from the most economical source without regard to the monetary interests of any of the particular companies. The competition among the various constituent companies should enable the Network Organization to buy the cheapest power or develop the most favorable sites. It should be the policy to make the operations of the Network Organization profitable, so that its credit would be of the best. The constituent companies would get the net proceeds in any case.

Part II

Advantages and Economies

In this section the advantages and economies of the 190 kv. network, shown on the map and described in detail in Part III, are discussed:

1. All the advantages of diversity, as applying to any interconnection, are obtained, such as daily-load-curve diversity, reduction of spare capacity, divergence between the differing periods of activity of different industries, either seasonal or due to swings of "boom-times" and "hard-times," railroad electrification, etc., also diversity due to difference in the dry periods of water power at different parts of the district. While it is beyond the scope of this paper to study this particular matter in a numerical sense, it may be pointed out that with a diversity gain of 10 per cent on the total peak output, here taken as 1,250,000 kw. on the 100 kv. lines, the additional power that might be sold would be 125,000 kw., with no additions to the general installation.

When the opportunity to reduce spare capacity is considered, it may well be that 10 to 15 per cent in the capital cost of generating units, power house, etc., may also be saved, at least in all new work. This may well amount to two to three million dollars in the final installations. This is in addition to the value of the above 125,000 kw. which may be worth from $2,500,000 to $3,500,000 a year; an amount sufficient alone to cover fixed charges on the cost of the network, transformers and high-tension breakers.

2. The fact that power generated at any point may be used at any other, without material loss and within any reasonable limit, with the advantage of unitary control for the system, would permit power to be sold considerably nearer the total water power available than with the component systems all operating separately. With this factor may be taken the material reduction in the continuous discrepancy between the growth of the load and the new generating capacity installed, which is a material factor, getting greater as larger units must be installed. If these two factors aggregate 10 per cent it means another 125,000 kw.;—if 15 per cent, 187,500 kw., which at $25.00 a kw. year and 10 per cent fixed charges, would cover to a capitalization of $30,000,000 to $45,000,000.

The advantage of the factors so far considered might be appraised also by considering that a plant of 75 to 80 per cent of the size otherwise necessary would be sufficient for carrying any definite load.

3. If the same quantity of power be transmitted by direct trunk lines from the same water powers and steam plants to selected single points at the centers of the chief loads, about three quarters of the same mileage will be required for the actual transmission, but when the necessity for spare lines for individual trunk units is taken into account, it is doubtful if the trunk lines

would not require more total length of circuit. This is because in the network properly laid out, very few links are long enough or important enough to require a spare. The delivery of this power to 35 step-down stations by the network system will thus cost no more for the high-tension lines than trunk-line distribution to a half dozen points. It should perhaps be stated that there may be all gradations between the two types of interconnections and that probably there is little likelihood that a trunk-line type pure and simple would be installed in this region.

To distribute the amount of power assumed to the 35 substations from the delivery points of the trunk lines would require perhaps 25 to 30—No. 0000 cable—100 kv. circuits, 50 miles long, aggregating with spares, 1500 to 2000 miles and costing $10,000,000 to $15,000,000. The necessity for this expenditure is largely avoided by the network and the delivery of power is made in a much more satisfactory and reliable manner. The statement here made must, of course, be based on averages and is largely of the nature of an estimate.

4. In the matter of voltage regulation, a very great advantage is secured by the network. In the first place, the voltage is stabilized at 35 load points, largely at points of distribution lines remote from their supply, and consequently with a naturally variable voltage. This means that the voltage at intermediate points on the distribution lines will be very materially steadied. Furthermore, with the power factor raised to 95 per cent in the distribution lines, the drop will be cut nearly in half. This improvement in the regulation is a major factor, but no effort is here made to give it a money value.

5. Perhaps the most important advantage of the network, shared only to a less degree by the trunk line transmission, is the opportunity to develop the most favorable power station projects to the exclusion of less favorable ones, which may happen to be nearer the load. If it be assumed that the large favorable sites may be developed for $30.00 a horse power less than local ones, this would mean for one half of the 1,000,000 new horse-power $15,000,000. This advantage may amount to a very much larger sum of money. As no such amount of local water power as 1,000,000 horse power is available, the absence of interconnection would mean local steam plants, adding 0.5 cents more or less to the cost of the power or the building of both steam power plants and part-time water-power plants, a still more expensive plan.

6. If the separate development of local companies means the addition of enough steam power with its higher cost to force an increase in power rates, with all the dissatisfaction that follows, and this can be avoided by the development of the distant water power, this factor alone would be of very great moment—as a matter of fact, this seems to be not an improbable contingency.

7. It is possible to concentrate a load of 100,000 or 200,000 kw. at almost any point in this system with only a small and local addition to the network. In case of war, this power could be secured by curtailing other uses, if necessary, at almost any desired points. This would be of extreme value in case of a war, since large amounts of power could be obtained at specific points and at very short notice, this power being drawn from any available supply at any point in the network. This would be useful in such work as the making of nitrates, poison gases or other special chemicals that might be required. During the late war the lack of any such quickly available large blocks of power greatly impeded the quick development of our war activities. In time of peace, the same thing could be accomplished, for example, by using secondary power, by power from the large Tennessee or Alabama storages, by operating steam plants or by adding additional generating capacity in small amounts wherever advantageous opportunities offer, such as completing plants in which provision has been made for future extension. 200,000 kw. of concentrated secondary power at $10.00 a year would be worth $2,000,000 a year, which would pay interest on the full cost of the network and step-down transformers and breakers.

It may be that a much larger amount of secondary power might be used.

8. An examination of the map will show that the flow of power can be in almost any direction in the district over favorable routes. The power from eastern Tennessee may go to the neighborhood of Charlotte, Virginia, Birmingham, or Atlanta. Muscle Shoals may send power to Charlotte, Virginia, Atlanta or Birmingham and similarly with the steam plants. This facility of the network is of a fundamental importance as it is not necessary to predetermine before installing a new station where the block of new power is to be used, as is the case with the trunk line system. If the center of load shifts greatly, no material disadvantage results.

9. The unitary control and the ability to distribute large blocks of power in any direction over the network are of the greatest advantage. Where it is necessary to pass water over a dam when the local companies' load does not call for it, either at night or in the day time, the power of all such water can be absorbed in the larger system and the various reservoirs and pondages may be used to store water at other points. It may well be that new reservoirs could be added at favorable points for the specific purpose of saving energy in this manner. As far as the usefulness of the reservoir is concerned, it may be located at any point in the system without material disadvantage.

If it be determined to equalize the flow of the Tennessee River up to a certain point for purpose of navigation, this need cause no loss, since the power may be absorbed elsewhere as just stated.

10. With the trunk-line type of transmission, the steam plant must be at the receiving ends of the trunk lines, or if placed at favorable points for the generation

of steam, additional and often long transmission lines must be installed. This is a most serious factor.

11. The supply of energy to new districts, which may be a little remote from existing lines, is easily provided, for the voltage here chosen is low enough so that step-down transformers and switches will be of reasonable expense, even for capacities as small as a very few thousand kw. The cost of tap high-tension lines, if layed out with this in view, can be made very reasonable. The network is so complete that for the district covered and a fringe of 50 miles wide on each side, the high-tension supply can be economically brought to any point.

General Conclusion

A great deal of ground is covered in this paper and the importance and far reaching character of many of the considerations pointed out have not been adequately emphasized, on account of the limitations of space. It seems clear to the author that the interests of the power companies, the power users, and the community as a whole, require that the applicability of such a network as here proposed be carefully studied in all those districts where the industrial load has reached the proper development.

If important new lines are installed in such a manner as not to fit the plan of this type of network, a great future advantage may be lost. It would not be for the interest of the community as a whole, for development to start along lines which might sacrifice great future advantage, merely because it might be of a temporary advantage to some particular company.

The principal idea to be here emphasized is the importance of an early and fundamental study of the best ultimate method of interconnection, before inadvertantly a district is committed to some disadvantageous plan. If the study here made be a proper criterion, the advantage to be gained by the use of the best suited system, as distinguished from the mere enlargement of existing systems along conventional lines, is very great, affecting the cost of power, the reliability of operation and the conservation of our coal, in addition to the freedom with which power-using communities can be located at most favorable points without regard to the location of power stations.

Part III

Technical Basis of Network Performance

The discussion above has been based in part upon a definite performance of an assumed high-tension network, covering the Southeastern States. A statement will now be given of the basis on which this performance has been determined.

High-Tension Lines

The high-voltage circuits are single circuit steel tower lines. The line conductor for each phase is composed of two or three cables strung side by side and electrically in parallel. Either two No. 0000 or three No. 00 aluminum cables, steel reinforced, can be made, if properly spaced, to give substantially the actual electrical line constants assumed. The limits of the present paper will not permit a discussion of the mechanical characteristics of such a line, interesting and important as they are. This is the resistance equivalent of about a 400,000 cm. aluminum steel cable or 85 per cent of the resistance of No. 0000 copper. The outside diameter of the equivalent cross section of two No. 0000 aluminum steel in one cable would be about 0.83 inch and the maximum voltage permissible for this single cable would be about 190 kv. However, the dividing of the conductor will raise the corona limit so that it will be well over 200,000 volts. This statement of the raising of the corona limit by the dividing of the conductor has both a theoretical and experimental basis. It will not be further discussed here. The line spacing is taken as 15 ft. average. While this is less than is sometimes proposed, this value is considered ample. One of the factors justifying the lesser spacing is the relatively tight stringing appropriate to the steel cove lines.

The electrical line constants used are as follows:

R = 0.23 ohms per mile equivalent conductor, of two No. 0000 aluminum cables.

Reactance = 1.59 ohms per mile x $\frac{2}{3}$ = 1.06, this being for one mile of two double cables, single phase.

(Allowing for a reduction of $\frac{1}{3}$ from the divided conductor).

Charging current = 0.267 x 3/2 amps. per mile = 0.4 per 100,000 volts for two double cables, single phase.

(Allowing for an increase of 50 per cent for the divided conductor).

Neutral dead grounded at each station.

Assumed Loading

As a starting point, loads were more or less arbitrarily assigned to about 35 substations in the territory covered and aggregating approximately the sum of the present peak loads of the companies now serving the district to represent the existing loads;—this total comes to 632,000 kw. The list of stations and the load assigned to each is shown in Column 1 of the table. Capacities were then arbitrarily assigned to the principal *existing* generating stations, more or less representing their maximum outputs, in the aggregate appropriate for carrying the assumed loads. Capacity taken for the steam units is shown for the several stations in Column 2 and capacity for hydraulic stations in Column 3.

For the purpose of this study, it was then assumed that at the time supposed to be appropriate to the full use of the network, an additional or new load equal to the present would have developed at each substation, these new loads being shown in Column 4 in the table.

TABLE I—DATA FOR STATIONS IN THE NETWORK

$C^2 R$ Line loss 711.800 − 632.500 = 79.300 Kw.
As per cent of power generated 12.5 per cent
As per cent of power delivered 11.1 per cent

To supply the new load and transmission-line losses, it was assumed that new hydro stations would have been developed in the most favorable locations, these being shown in Column 5. The principal new plants are at or near Cherokee Bluffs on the Tallapoosa River and the big storage powers of the Upper Tennessee, together with Muscle Shoals and also Coosawattee. The general condition with the present power, carried by the present units in the present manner, together with the new 632,000 kw. carried by the new hydro-electric plants, but all connected with the same system, is called Case A.

As an alternative, to show a typical low water con-

dition, with 238,000 kw. of the new load carried by steam plants, the conditions of Case B are set up, the locations and loads of the steam plants being shown in Column 8. These conditions are the same as Case A, except that the water power in certain of the new stations is assumed to be short in the aggregate amount of 238,000 kw., corresponding to the amount of steam power generated. The actual locations and amounts of water shortage assumed are shown in Column 9 in the table.

It is assumed that the simultaneous water shortage in the *present* plants is cared for at the same time by the *present* steam plants. It is believed that Case B here assumed is more exacting on the network than the situation that would occur in actual service.

It is assumed that a certain amount of hydraulic power, taken above the normal high water requirements, will be drawn from two or three of the best seasonal storages, in lieu of an equal amount of steam power and this storage-water power is shown in Column 7 of the table.

New 100,000 kw. steam power plants are located at Glenlyn near the center of the Appalachian Power Company territory and near Knoxville in Tennessee.

The points at which the equivalent of steam power is taken from the storage are the following:

Bridge water	10,000 kw.	N. C.
Tallulah Falls	15,000	Ga.
Dam No. 1	23,000	Tenn.
Dam No. 21	5,000	Tenn.
Hales Bar	5,000	Tenn.

It is assumed that a 100,000 kw. steam plant is located near Dam No. 3 on the Clinch River.

Voltage Control

It has been further assumed that the high-tension voltage at all regulating points; that is, all points where synchronous apparatus of important capacity and under control of the system operator is located, will be points of fixed voltage, regardless of load conditions and for dry or wet seasons, but that the particular voltage at any particular point may be chosen at any suitable value within certain limits, here between 180,000 and 200,000 volts, as may best fit the power-factor conditions in the line. While these limits were set up for the layout of this case, it was found as the calculations progressed that the voltage slightly exceeded the upper limit at certain points, but it was not considered worth while to recalculate the system to bring down these high voltages within the limit, as might readily have been done by slightly changing the power-factor assumptions at certain regulating stations.

The control of voltage at load points between the regulating stations may be handled in two ways. First, it may be assumed that the variations in voltage at these intermediate-load points, which will be probably on the average a fraction of one per cent and only rarely and at a very few points over 1 per cent, are negligible and no provision made to correct for the variation. Second, an automatic variable ratio device may be used at each station, such as an induction regulator. With the small variations of the voltage to be expected, only a very small capacity regulator will be required, well within the limits of present regulators. As in favor of the use of automatic regulation at all points, it should be noted that while the high-tension voltage will vary very little, the drop in the step-down transformer which carries a lagging load may be several per cent.

The tendency of variations in load, or in the distribution of load, to change the voltage at various points is corrected by changing the power factor at which power passes from one regulating station to another. For example, if the voltage at station A is 190 kv. and at B 187 kv. with a load of 50,000 kw. passing at 99 per cent power factor, the same drop of 3000 volts will exist when only 25,000 kw. is passing, if the power factor be right, in this case say 80 per cent. To control this power factor, there must be an appropriate out-of-phase current flow from synchronous apparatus in A to that in B as is well known. This function will be automatically attended to by voltage regulators.

In the table the out-of-phase kv-a. required of each regulating station for Case A is shown in Column 6. It will be found that no machine is called on to operate when well loaded at any power factor less than 0.85 lagging. Leading-power factors are all much higher.

Power Factor of System

For the purpose of making a numerical calculation certain further assumptions were made.

1st. That the *new* load taken by the *new* network is at 80 per cent power factor, high tension.

2nd. That a lagging load will be taken at the load points, in addition to the above, sufficient to raise the power factor of the *present* load fed by the present distributing lines to 95 per cent.

As a matter of fact the charging current to the 190 kv. line will in the aggregate nearly neutralize the total lagging kv-a. of the load and transformers, but as the distribution of the lagging kv-a. and the leading kv-a. is different, the neutralization is far from complete.

Exception to the above assumptions was made in the case of Method and Glenlyn Stations where the lagging kv-a., taken by the high tension, was slightly less than the amount above specified.

Calculations of Performance

On the basis of the above assumptions, the actual voltage, current, kw. and kv-a. values were calculated for the whole system for Case A. The formula used for this purpose was the so-called "Split Capacity" formula, described by the author in a paper presented before the Institute on June 29th, 1909, entitled "Calculations of the High-Tension Line." Any suitable formula, taking into account the capacity of the

line, may be used. Of course, it was necessary to obtain an approximately correct distribution of currents between the various parallels of the network. For the purpose of clearness and convenience the following statements are made.

In using the split capacity formula, any out-of-phase kv-a. at the starting point of the calculation (normally the receiving end of the line) of such a direction as to cause a slope of potential going-up from the starting point is to be marked + and vice versa. Also any energy delivered to the starting point of the calculation is to be marked + and vice versa. By observing this rule and remembering that the quantities $C^2 R$ and $C^2 p L$ are always positive and added to the appropriate quantities at the starting point to find the totals at the finish point, a line may be calculated from either end with identical results.

When a synchronous machine is connected to a transmission line, containing a material amount of capacity, we have the following:

a. Current, flowing from the machine (whether a motor or a generator), to the line and tending to cause a slope of potential upward from the point of connection of the machine, is such as to strengthen the field of the machine and may be called "field boosting" current similarly with kv-a., and

b. Current or kv-a. flowing from the machine into the line tending to cause a slope down in the line away from the machine, tends to weaken the field and may be called "field bucking" current or kv-a. This current is called leading if the machine is a generator, but must be called lagging if the machine is a motor or synchronous condenser, because the positive direction of current flow in these motors and condensers is taken as *into* the machine, not *from* the machine, as with generators.

If another synchronous machine is connected to the other end of the line, then:—

c. Cutting resistance out of the field-exciting circuit raises the potential of the machine, but reduces the amount of out-of-phase "field boosting" kv-a. flowing to the line, throwing it into the other machine, thus tending to bring the power factor of the first machine nearer unity and vice versa. If, however, the field has already been raised so high that "bucking kv-a." is flowing to the line, this field-bucking current will be increased by further raising of the field, and vice versa.

It would not be feasible to secure scientific accuracy in such a calculation as this with a reasonable amount of labor, but the voltages here given are believed to be correct within less than 1 per cent, except for two or three points where numerical mistakes have been found too late for correction. There errors are, however, not sufficiently important to materially effect any of the station quantities. The power actually flowing in the several lines is indicated in the transmission lines on the face of the map and are marked "*A*".

This calculation permits a determination of the total $C^2 R$ losses in the new network for this maximum load condition. The losses exclusive of corona or transformers are 79,300 kw. or about 12 ½ per cent of the delivered power and 11.1 per cent of the generated power for the maximum condition. The average year around losses would be probably about 35,000 kw. In this calculation no allowance is made for the saving in line losses in cases like the line from Atlanta to Tallulah Falls, where the current will tend to flow one way over a given route in the network and is now the other way in the present parallel distribution line. In such a case, of course, the oppositely flowing currents cancel, leaving only the difference flowing partly in one line and partly in the other. This will affect a large local saving in line loss on both lines.

Case B—The Station voltages and power factors of the system as a whole were not calculated in detail for Case B on account of the amount of labor involved. To give an approximate idea of the effect of the change in the location of the sources of the power on the energy flow in various lines, a determination was made of the change in amount of *power flow* for each line—neglecting $C^2 R$ line losses, however. The resultant energy flow values are shown on the map in the appropriate transmission lines, marked with the prefix "*B*". Since line $C^2 R$ losses are neglected in the *B* values, these amounts will not be as accurate as the *A* figures.

An examination of the values on the map will show that in many lines as compared with case *A* the current is reduced in Case *B*—in some reversed and in a few increased. The net result will be to slightly reduce the $C^2 R$ losses.

The effect of these changes in current flow on the *voltages* at the various stations should be further discussed.

Consider, for example, the lines between the new steam plant of the Appalachian Power Company, assumed to be installed at Glenlyn for new reserve power and Mt. Holley on the Southern Power Company's system, both regulating stations. In Case *A*, 81,000 kw. is delivery to Glenlyn—in Case *B*—9,000 kw. is sent south from Glenlyn. Considering the branch line from Glenlyn to Grayson, Lookout Shoals, Salisbury, Concord and Mt. Holley, the effect of starting up the steam plant is to superimpose upon the Case *A* flow of 40,500 kw. north, a 45,000-kw. flow south, giving a net flow of 4500 kw. south. This 45,000-kw. counter flow varies a little in the several sections of the branch line on account of the side circuits, as will be seen from the map, but this 45,000 will be about right to represent the average flow. This will tend to reduce the average current and the slope of voltage appropriate to Case A, which is from Mt. Holley down toward Glenlyn.

Suppose now that this 45,000 kw. energy current be sent at 80 per cent power factor, so that the out-of-phase component tends to increase the slope of the potential from Mt. Holley toward Glenlyn. This will then tend to balance the change in the potential slope

caused by the 45,000 kw. load counter current and leave the voltage slope unchanged.

However, since in this case some of the line sections carry cross currents toward the Tennessee powers, the effect of these various corrective currents will be different in different line sections and while the terminal voltages may be unchanged, the intermediate voltages will be affected, as is shown by the following table, in which the second column shows the voltages appropriate to the special assumptions under Case B just described.

	Case A	Case B Special
Glenlyn	188.0 kw.	188.0
Grayson	190.3	190.6
Lookout Shoals	190.3	194.3
Salisbury	188.4	186.7
Concord	187.8	187.7
Mt. Holley	190.9	190.9

Here it is seen that the maximum departure from Case A voltage is at Lookout Shoals. If, however, an out-of-phase kv-a. of 12,500 lagging is taken locally at Look-out Shoals this will drop its voltage to approximately the Case A voltage without disturbing the Mt. Holley or Glenlyn voltages. This will, however, lower the voltage at Salisbury until it is much below the case A voltage. But by taking an out-of-phase current of the proper amount locally at Greensboro, the voltage at Salisbury can be raised without affecting the voltage at Lookout Shoals or Mt. Holley. In this case, the out-of-phase current from Greensboro must go in proper proportions to Lookout Shoals and Mt. Holley and then be absorbed by the synchronous apparatus at these stations. This will correct all the voltages and be close enough for all practicable purposes. A similar analysis may be made for the other branch line via Bridgewater or for other lines, such for example, as the line from Dam No. 3 to Cleveland and Anniston where a heavy reversal of flow occurs over a long distance. This line can be more easily controlled than the line just discussed, because there is less cross current flow and the generating stations at the ends are of larger capacity and will handle larger out-of-phase currents.

While the numerical verification has not been made for Case *B* as a whole, on this particular point, there is no doubt that by properly controlling the power factors at the control stations, all the various station voltages can be kept constant within 1 per cent or less, without calling for any generator to carry full load at less than 85 per cent power factor lagging. In this case it should be remembered that when the steam plants are operating, there will be a largely increase electrical capacity available, and that an underloaded generator can carry a much lower-power-factor current than a fully loaded one.

In general, the use of synchronous condensers would greatly broaden the range of control of voltage and they may be necessary in some networks. In the present case, however, it is apparently possible to operate with constant voltages and reasonable power factors without condensers.

Again, in a network there is always a tendency for the currents to so distribute themselves as to have the least possible loss of voltage.

These operations here described are automatic if the voltages are kept constant at the regulating points by adjusting the field strengths of the synchronous apparatus and require no intelligent intervention.

The change in conditions here assumed between Case A and Case B is the extreme and occurs only once a year and comes on gradually, giving opportunity for adjustment by changing taps, if necessary, as the change develops.

The effect of light load will be less difficult to handle than Case B for their out-of-phase currents are more effective, ampere for ampere, in correcting voltage slopes and there is ample machine capacity to handle them.

A high-power-factor load, having the characteristics of decreasing to a lower-power-factor load, as with induction motors, when off the peak, tends to hold the potential slope along the line relatively constant.

Relation of Network and Distributing Lines

Since the plan here proposed throws the generators, distributing lines and the low-tension network in parallel with the high-tension network between stations common to both networks, the method of control of the division of current between the high tension network and the distribution lines, *e. g.*, the present 100-kv. lines, should receive some consideration.

Assume that a present power house is located at *P*, Fig. 1, feeding loads at *M* and *N*. If the line voltage be taken as 110 kv. and it be assumed that a load of 30,000 kw., 80 per cent power factor, is carried at *N* and an additional load of 20,000 kw., 80 per cent power factor, be carried at *M*, a voltage of 117 kv. will be required to maintain 100 kv. at the load. If, now, a connection be made at *N* to a constant potential network, the 30,000 kw. load is taken from the transmission line by the network, relieving the distribution line, provided suitable voltage adjustments are made as will be later explained. Furthermore, since the point *N* is now a source of energy, the load at *M* will be carried jointly by the network and the generator at *P*. Suppose, now, that we increase the load at *M* until the voltage at *M* is the same as that originally existing at *N*. This will require a load of approximately 160,000 kw. at *M* which, together with the original 30,000 at *N*, makes 190,000 kw., not including a possible increase at *N* above 30,000, showing an enormous increase in the effectiveness of the 110 kv. line for distribution purposes, by connection to the network at the point *N* instead of at *P*, as is ordinarily proposed. This extreme case is taken to bring out the principle

involved, that is, the great advantage in delivering new power at the load ends of the distributing lines.

As already stated, in the layout here proposed, the present distributing lines are frequently in parallel with the high-tension network for certain sections. It is proposed to control the power factor of the current passing over the distribution lines. In the case where the distribution line is connected to the network only at the other end than the generator end, the true power passing over the line can also be controlled by adjusting the governor of the generator prime mover. If there are several distributing lines thus connected to the same generator and to the network, it will be possible to control only the total power sent to the network, but the division of this power over the several distribution lines will be determined by the electrical constants of the lines and the network and the power-factor adjustments at the various points. The distribution of the true power and the power factors at various points cannot be separately controlled in the system proposed without special devices, when the generator is connected to the high-tension network as well as the load stations.

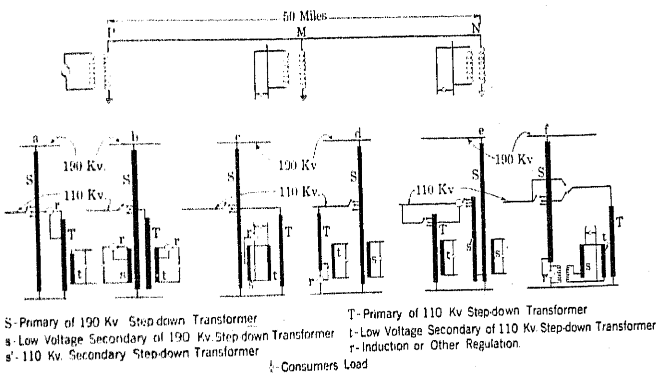

Fig. 1

Returning to the control of the power factor in the distribution lines, it will be noted that if a loaded distribution line be connected at its terminal to the step-down network transformer on a voltage tap giving exactly the same voltage as the line terminal, no current will flow to or from the network. Suppose now that the line has a change of load or change of power factor so that its terminal voltage is different. If the line now be connected to a second voltage tap in the step-down transformer, corresponding to the 2nd terminal voltage, no current will flow. If, however, the line carrying the second load be connected to the first tap, the potential of the line terminal will be changed and current will flow to or from the network until the line load is the same as in the first case; for the line, with the generator voltage fixed, can have this definite terminal voltage only with this particular line condition.

The above explanation ignores the effect of differences in power factor between the line terminal and the tap. It is the interplay of the reactance and resistance of the 110 kv. line with the tap voltage of the step-down transformer that really determines the division of true power between the 110 kv. and the 190 kv. lines. Similarly, whenever the line terminal is connected to a different voltage tap in the step-down transformer, current will flow into or out of the network until the current in the distribution line is of such a power factor, when carrying the appropriate amount of true power, that the terminal voltage of the line naturally is that of the tap, and so in general. Since the line must carry an appropriate amount of load the power factor of this load at the terminal point will be determined by the particular voltage point at which it is connected to the network. Once this power factor is determined at the terminal, the power factor will also be determined at the other points in the distribution line. When load is connected to intermediate points in the distribution line, the power factor that is controlled by the tap voltage is the mean or equivalent power factor. If, as will theoretically always be the case, the voltage of the step down transformer, fed by the network, is changed by the flow of current into the line where it is connected, the power factor of the current in the distribution line will be that corresponding to the terminal voltage at which the system finally settles down.

To put it another way, since the object of controlling the power factor of the 110 kv. is to improve the voltage regulation of this line, it is merely necessary to connect the line terminal to the proper tap and its voltage is fixed and the power factor will take care of itself.

Clearly, changes of low-tension voltage, due to changes of load and load power factor at the line terminal point, can be compensated for by changing the taps on the high-voltage winding of the low-voltage step-down transformer; so can changes be made in the voltage of the network—or correction of voltage may be made on the low-tension side of the step-down transformers or individually on important feeders.

If we assume that the network voltage is constant and that the distribution line terminal is connected to a particular tap in the step-down transformer, the voltage of the line terminal is fixed and hence the load at that point will be determined by the power factor of the line current and vice versa and the power factor of the current flowing into the network will vary with changes of load.

With the 110-kv. line terminal connected to some definite tap in the step-down transformer, if the network voltage does not vary greatly, nor the range of power factor become too wide with the actual load changes found in service, a very simple and practicable operating arrangement results, in which the *average* power factor can be controlled by choosing once for all a suitable tap on the step-down transformer. Means should be provided to then adjust the low tension bus-bar potential to the value desired when the tap has been chosen to secure the proper power factor.

The transformer ratio, represented by the tap under discussion, has to do with the *relative* potential of the

generator and that of the step-down transformer tap. Thus the adjustment of voltage may be made, where other conditions permit, either at the generator end of the line, in the step-up transformers or on the generator bus, or at any other point in the line.

If, on the other hand, the network voltage varies too widely or the range of power factor with a fixed voltage tap is too great, a more sensitive and very flexible system may be secured by providing means for automatically changing the tap during operation in response to a suitable regulator, set to maintain constant potential or constant power factor, as may be desired, for the action of the regulator is here equivalent to a change in tap.

With the tap changing device, which might well be an induction regulator, connected between the distribution line terminal and the step-down transformer tap, automatic control from a voltmeter would maintain constant voltage on the line terminal or control from a power-factor meter would maintain constant power factor. In either case, the quantity not controlled by the regulator could be controlled *on the average* by properly selecting the power factor or the voltage which the regulator should maintain constant.

Both power factor and voltage could be simultaneously controlled by having two independently controlled regulators.

In all these cases where there is a change in taps to control both power factor and voltage, means should be provided for correcting the effect of a change in the taps on the low tension service busbar.

A number of connections may be used for this control, for example, diagrams *a*, *b*, *c*, *d*, *e*, and *f* in Fig. 1, which are largely self-explanatory. In all cases the automatic regulator can be controlled to give constant voltage, preferably on the low-tension bus to which local feeders are connected. In case *e* the regulation can be controlled by the power factor at any suitable place to give constant power factor on the 110 kv. line. Where automatic control is provided for one factor, manual adjustment should be provided for the other.

In all cases except *e*, Fig. 1, an auto transformer is used for stepping down from the 190 kv. to the 110 kv. and an auto connection might just as well be used here. Regulators are just as effective in the low tension circuits where they are more readily installed, except that for automatic-power-factor adjustment there must be a change in ratio between the 190 kv. and the 110 kv. lines.

In cases *d* and *f*, the regulator is on the ground connection of the high tension windings, thus relieving insulation strains. In case *f*, a small balancing transformer is used with its high-tension winding connected around the regulator and its low-tension winding in series with the low-tension winding of the 190-kv. transformer to equalize its voltage with that of the low-tension winding of the 110 kv. step-down transformer. A special winding on the regulator or a tap on the regulator winding would accomplish the same thing.

While all windings have been shown star, delta windings may be used in many cases. In cases *d*, *e* and *f* the 110 kv. transformer can operate without the 190 kv. transformer. Case *f* is the most flexible.

As a matter of convenience the variations in power factor, required for various loads in a typical 50 mile 110 kv. transmission with No. 0000 conductor, are shown in Fig. 2, in which lines of constant power factor are shown connecting terminal voltage with load. It is assumed that the line voltage at the generator is maintained constant at 110 kv.

From these curves it can be seen how much the 110 kv. line voltage at the terminal must vary with the power factor fixed as the load changes; or by following the horizontal line corresponding to any voltage, it may be seen how much the power factor will change for any range of load. This is rather an extreme case and no doubt an actual installation would show much less variation. The case where load is carried at intermediate points is more complex but will involve no serious practical difficulties.

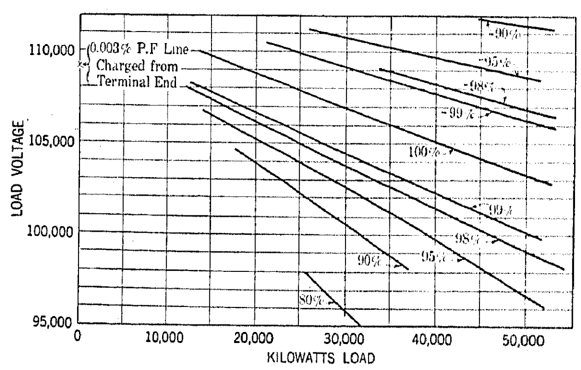

Fig. 2

Many other matters of interest connected with this use of regulators and method of voltage and power-factor control might be touched upon, but the most essential factors have been discussed and space will not permit more.

Part IV

Operating Features

The operating requirements of this system as they involve new or difficult features may be considered as follows:

Control

It is obvious that from a technical point of view and as far as day to day operating is concerned, the system must be under the absolute control of one dispatcher, at least as far as generators connected, field charge and governor adjustments, load carried, operation of all high tension connections, etc., are concerned. The maximum use of facilities further demand that control of water in rivers and reservoirs, the taking on of load

and dropping of load where necessary should be under single control.

Power Distribution

The distribution of power among the several generating stations is a fundamentally important one, for not only must the frequency be rigidly maintained but the dispatcher must be able to say how much load should be taken by particular machines so that water may be properly conserved.

Theoretically, the best results will be obtained from the point of view of the maintenance of frequency, by having a single station do all the regulating and setting all the others on a fixed gate and it may be that, as a matter of fact, one station may be able to regulate the frequency in this system. This will result, if the changes in load on the system as a whole occur so slowly that the load on the fixed gate machines can be adjusted rapidly enough to keep the proper margin for regulation at the regulating station. There are perhaps three or four stations or local groups of stations that could supply a regulating margin of 5 per cent which might be sufficient. This would mean, however, a large amount of idle apparatus at one point which would be undesirable, especially where there is no pondage to save water.

Furthermore, since governors of individual units must in any case be arranged so as to perform in consonance with others in a similar manner on load variations, they may about as well be in different stations. From these and other considerations, it is probable that the best plan is to have a single regulating station in each of the major systems, all with their governors carefully designed to be adjustable as to sensitiveness to changes (that is quickness of action); as to range of load change with change of speed; and as to normal speed. They may then be so adjusted that under operating conditions they will operate as nearly alike as possible. The setting of governors can be adjusted from time to time during operation, so that very close frequency regulation can be obtained. These regulating points should preferably be at the large storage reservoirs, so as to conserve water and to have water always available for regulating purposes. It is not likely that there will be any serious trouble on the distribution of load.

In this, account must be taken of the penstocks and water columns feeding the regulating generators but fortunately in this district there will probably be available in each system generators supplied directly from reservoirs and dams with very short water columns. It will do no harm to have a certain amount of variation in the sensitiveness of quickness of action of the governors, since the momentary overload capacity of the quickest acting will hold the frequency until the others catch up.

Instead of setting the machines which are not expected to govern on a fixed gate, their governors may be adjusted to have a wide range of speed with small changes in load. Then by changing the "normal" speed setting of the governor at the switchboard from time to time as conditions change, the load may be maintained at the prescribed value substantially as though with a fixed cut-off.

By this arrangement the following advantages are obtained—

a—Frequency will be maintained by a few specially sensitive governors, operating in stations selected as the most favorable.

b—Should anything happen to break apart the network, each sectional system would have its own system-regulating station and furthermore other local machines will come to the rescue of the regulating station on account of their wide speed range governors, above described, though with a slight drop in frequency, if the disturbance is very serious. In the case of a plant "importing" a large amount of power, it would be necessary to drop some load, if disconnected from the network at all points.

c—Regulation would be obtained without disturbing the economical use of stored water, for the *average* rate at which water is passed through the regulating station can be controlled at will by the load settings of the fixed-gate machines.

d—No very heavy blocks of power would have to be passed backward and forward over the network, as with change in load with regulation concentrated at one point system.

Favorable regulating points would seem to be
Bridgewater (with generating capacity enlarged)
Tallulah Falls,
Cherokee Bluffs (with the large storage developed)
Dam No. 3 including the large storage.

Voltage Regulation

A plan for making every station on the network a voltage stabilizing point is covered in Part III above and need not be further discussed here.

Power Factor Control

In Part III above is described a plant for controlling the *average* power factor of any network station, although the power factor must be allowed to vary within certain limits to secure voltage control.

Reliability

Any general scheme of transmission and distribution must offer a high order of reliability of service. This proposed scheme is exceptionally favorable from this point of view. In the first place, a breakdown in any one transmission line link will affect only stations on this particular link, for no single link is essential to the network as a whole. The segregation of a single link is simplified because with the wide separation of power houses and the absence of large concentrated loads, no short circuit can occur in the network of a magnitude

to exceed the safe capacity of oil breakers. The single-circuit lines contribute to this result.

In the second place, since it is usually considered that with two circuits feeding a station, either circuit being able to carry the whole load, a reasonable degree of reliability is secured. Even if these circuits are on one tower, the network plan is especially well guarded, since any station is fed from two or more directions so that no cause affecting one supply line would also affect the other. In addition, most substations are connected to other stations by the low-tension distribution lines giving still another source of emergency power. With the trunk-line type of circuit a break in the line will affect a large amount of power and a number of stations.

Protective Relay System

At first thought the securing of a satisfactory relay layout for protection against disturbances may seem difficult, but this is not likely to be the case.

When once a satisfactory means is found to properly disconnect a bad circuit at one station, the same means may be used for most stations regardless of their number. Special stations, however, would require special treatment. Considering one of the long single lines of the proposed system, containing several intermediate stations, a line short circuit or ground will ordinarily cause a great fall in the potential at the point of the trouble and the potential of the line will slope up in both directions to nearly normal at points at some distance. Suppose now that inverse-time-limit-overload relays of the normal type be used, and that a device be added for rendering the devices inoperative for a certain period more or less proportional to the momentary line voltage. Then, upon the occurence of a ground the inverse-time-limit relays will all start to run, but the one nearest the ground will be rendered operative first on account of its lower line voltage. If it be assumed that the time of action of the retarding device be 0.2 sec. for 30 per cent voltage at the relay and 2.0 sec. at 90 per cent voltage, a difference in perhaps 20 per cent in the momentary voltage between two consecutive stations would permit time enough to cause selective opening of circuits.

At points where the voltage is over 90 per cent, normal selective action comes only from the difference in the inverse-time-limit relays, but this is not important for a short circuit or ground in which the voltage drops only 10 per cent at the nearest station is very rare. It should be remembered that at each branch line and at each station there will be a dividing of the short circuit current so that there will be a marked difference in line current at points only one or two stations from the short circuit permitting selective action.

In addition to the above, a directional relay should be placed in each line at each station so that when power is flowing in *excess* away *from* the station in one line, it will open the tripping circuits of the breakers in the other lines. This will prevent any good line being cut off on the wrong side of any station.

When a high tension short circuit occurs at a station inside the breakers, the last mentioned power relay will not operate and all the breakers will open quickly on account of the low line of voltage.

When a low tension short circuit occurs the reactance of the transformer will prevent its pulling very heavily on the high tension so that any desired local form of low tension protection may be used, except that inverse time overload relays should be used, set to act quickly to clear a heavy short circuit such as would occur only at or near the buses.

The above scheme of relay protection is suggested as one feasible method. It is, of course, to be understood that the best scheme for this network should be the subject of long and careful study and many alternative schemes can no doubt be devised.

Metering

The metering of power should not be very difficult or expensive, although it involves a number of problems of some interest.

Power should preferably be measured at the step-down side of the network transformers both for load power and for generator power;—also the maximum demand kw. and reactive kv-a., on graphic meters, set with accurate timing. By summing up these kw. and reactive kv-a. for all the stations in a particular system, taking account of positive and negative values, the total net *power* supplied the system from the network will be obtained and its equivalent power factor.

This plan means that in cases where the network carries a certain amount of power from a local generator to a local load, formerly carried by the local distribution circuits and in the same direction as the main flow of through power in the network, the network is charged for the increase in the $C^2 R$ line losses, while with the through power flowing in the opposite direction to the local flow, the network gains the decrease in $C^2 R$ line losses.

If an accounting of this variation in line loss is desirable, in place of taking the numerical sum of all the kw. in or out at the several stations, the values of the several kw. *loads* may be separately combined and the total value of the kw. generated obtained and a slightly higher rate per kw-hr. set on the load kw. than on the generated kw.

In addition, there should be taken the readings of kw. and reactive kv-a. in the high tension line at the incoming side of those stations located nearest the boundary line of the district on all through lines passing from one local system to the next. The best readings that can be obtained from bushing-type transformers, two to each phase of each breaker, (taking advantage of calibration curves obtained in place, if necessary) should be sufficient. These readings will not be usually as good for determining the charges for power to any system as the

readings recommended above, since where there is much through power, the power supplied to the local company, as measured on incoming and outgoing lines, will be a relatively small difference of two large quantities and hence relatively inaccurately measured.

Part V

Costs

Only the briefest estimates of costs can be here made, but some idea of the magnitude of the expenditure involved is important. The elements of most interest in this study are the transmission network, the step-down transformers, the oil breakers for substations and other high-tension gear. These costs may be approximated as follows:

2500 miles single circuit, 190 kv. transmission line @ $8000. Exclusive right of way...........	$20,000,000.
2/3 x 1,250,000 kv-a., 190 kv. auto transformers @ $3.00 in place..........................	2,500,000.
200 oil breakers 190 kv. with dead grounded neutral and miscellaneous switchgear, outdoor stations, etc. in place..............................	4,500,000.
500 miles additional 190-kv. line @ $8,000.........	4,000,000.
If straight transformers instead of auto transformers be used add........................	1,500,000.

All for the delivery at 110 kv. or low-tension feeder voltages of 632,000 new kw.

Discussion

Robert Treat: Those who have had occasion to try to calculate the division of current in parallel high-voltage and low-voltage lines, will have great admiration for Mr. Thomas' courage in undertaking the solution of a problem of the magnitude of this one. Those who have not been brought in contact with such computations, probably have very little conception of the difficulty of the task.

Some time ago, in our office, we were faced with a similar problem, except that it was very simple compared with the one which Mr. Thomas has undertaken to solve. A brief description of the problem and some of the important things we learned in working it out, will be of interest.

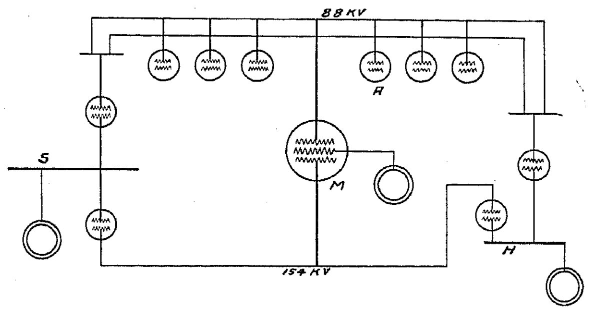
Referring to cut herewith a large source of power S, supplies a double-circuit 88,000-volt transmission line from which are distributed a number of variable loads. At the far end of the line, there is connected a hydro-station H, whose available capacity varies from full load to nothing. In parallel with the 88-kv. lines, is a 154-kv. transmission line running from H to S. There is one other connection between the 154 kv. and the 88-kv. systems at a point M near the middle of the transmission, which is made through a three-winding transformer bank.

It was required to determine under certain limiting conditions of load and with different amounts of power available from H, the variation in voltage on each of the substation buses. In order to calculate this voltage variation, it was first necessary to know the division of the power and wattless current in the system. The manner of procedure was as follows. An assumption was made that the load at a certain substation A came partly from M and partly from H. Calculations were then made step-by-step on the 88-kv. system from A to H; and then through the three-winding transformers, and the 154-kv. line to H, to see whether the voltages on the low-tension bus at H arrived at by the two calculations were the same.

It was soon apparent that mere equality of the magnitude of these voltages was not sufficient, that they must also be in phase, naturally, because they were the same bus voltage. So it was necessary to keep track of the phase angles of the voltages during each step of the computation, *i. e.*, we assumed a certain load on the lines adjacent to A toward H, and calculated the drop to the next substation. At this substation it was necessary not only to determine the amount and power factor of the current transmitted toward A, but also to know the phase angle of its bus voltage with reference to the voltage on the bus at A. This process had to be carried out through each step of the way to the low-voltage bus at H; then similar calculations were carried out through the other portion of the loop, A-M-H. Obviously, the criterion of the correct assumption as to the distribution of load and wattless in the two systems, was that the voltage on the low-tension bus at H when calculated over the two sides of the loop, came out the same both in magnitude and in phase.

It was also necessary to carry out the same process in the loop formed by Stations M and S, and sometimes, it was found that assumptions which appeared to give satisfactory results in one of the loops, were not right when we considered the other. This was because the two loops had one part in common, the three-winding transformers at M. Sometimes it was necessary to make the computations for one set of conditions several times, before arriving at an estimate of load division sufficiently close for the purpose.

One of the interesting things which we found out from these calculations was that the 88-kv. line from H was carrying about



Transmission Network

154,000 and 88,000 volt systems constituting two loops having one part in common.

twice as much load as the 154-kv. line. This was undoubtedly because of the higher reactance in the 154-kv. transformers at H and M as compared with the lower voltage single transformation in the bank at H. The losses in the 154-kv. line were low, it is true, but there was some question as to whether, with the very small load which it was carrying, its investment was justified; whether it also might not properly be an 88-kv. line, and, therefore, less expensive, and for the particular conditions which we were investigating, carry more power. In the example investigated, the justification for the higher voltage line is found in future conditions which operate to increase its loading.

It was also found that with no regulators or tap-changing equipment in the system, it was impossible to change the distribution of power current and wattless current over the two circuits of different voltage; they were fixed, once and for all, by the circuit constants. In order to get more wattless current to flow in either system, it was necessary to be able in some manner, to secure the effect of changing a transformer tap, thus changing the apparent voltages of the two systems which are tied together through the transformer, thereby shifting the wattless. A shift in the wattless also changes the angle of the voltage drop in the two circuits; thereby the actual load in the two circuits is also changed somewhat, but the two components, power and wattless, are both changed with only that means of adjustment, *i. e.*, by transformer taps there is no independent control of power and wattless.

In order to get more power current to flow in the 150-kv. line, it would be necessary in some way to introduce a phase shift in the voltage similar to the phase shift which is inherent in a three-phase regulator. That would shift the distribution of power current between the two circuits, which in turn, would change the voltage drops, thus affecting the distribution of wattless current to some extent. Here, again, it is seen that it is impossible to change the power current without, at the same time, changing the wattless current.

Complete control over the division of power current between the two circuits, and the independent control of the division of wattless current, demands some means of independently varying both the magnitude and the vector angles of the voltages applied to the two circuits; *i. e.*, it is necessary to secure independently, the effect of a phase shift, as by a three-phase regulator, and the effect of changing transformer taps.

This whole question, of course, has very many factors, and as Mr. Thomas suggests in his paper, it requires much further study. I agree with him that it should be fully analyzed from all possible angles, in order that as much as possible may be learned about the problem before attempts are made to carry out the program which he suggests.

W. S. Lee: Mr. Thomas deserves the appreciation of transmission engineers and the power companies at large for this study. It is impossible for Mr. Thomas or any other man to take a system or a group of transmission systems and lay down on a sheet of paper, transmission lines that will fit all the conditions. That can't be done. Unfortunately, load will come at some unexpected place; power plants may be developed at one point or another, and they, of course, must be coordinated in his system of transmission lines. His paper does give us a great deal of food for thought, in that we should continually study the possibilities of connecting all these companies together.

H. Cole: I think there are a number of important problems which have to be worked out in connection with the tying together of large transmission systems. It has seemed to me that some sort of tap-changing transformer or other device which would allow different voltages to be carried on either side of the point of interconnection would be very useful.

H. L. Wills: What is the use of considering these interconnected networks as individual propositions? The only reason we use a synchronous condenser or some method of that kind for holding down the voltage rise is because we haven't enough of that system. If we had that system so big that it was practically one plate, it wouldn't matter where we put our power into it; we would have the same thing as one plate of a condenser—and that is what you are working towards, according to my notion.

W. E. Mitchell: From an operating standpoint this problem is not quite as simple—while it works and we have been working it very satisfactory for the past two years—as it might appear to be. The problem of regulation, to push the power whichever way you want it to go, is not so difficult. We had a good deal of trouble in the beginning getting the governors in the different systems to a speed of control that was more or less similar for the load changes in each system, so that with a swing in load, no particular system would try to pick it all up. The result was, from that standpoint, that we were able to carry through from our system over to the east of us, and they were able to pass on farther to the east, loads of 30,000 to 35,000 kw. without any serious trouble. Strangely enough, our troubles all came at night-time when the loads became lighter and when we were trying to keep steam plants here loaded up and the hydraulic plants just floating in for regulation purposes. Under those conditions, we found that the swings were very much greater and that unless the governors had been carefully set and readjusted at night-time the swings of load instead of going 20,000 eastward, we would find were coming 10,000 westward when we didn't want it at all.

But that isn't as bad as the other problem, the problem of voltage regulation and the loading of the wattless current onto the one who is trying to give the power. You come in to help a gentleman out of his troubles, and he promptly doubles the burden on you and doesn't take anything away from you at the same time. Now that, we have found, is serious, and that is a question entirely of voltage.

That can't be controlled, so far as I can see, at the generating plants alone. It has to be controlled at the load centers, and, as far as we can see on our system today, that necessitates condensers.

We are studying our system; Mr. Lee is studying his system; Mr. Edgar is studying his system, looking forward ten years, and when we look forward ten years, we double our present loads. So there is nothing extravagant in Mr. Thomas' suggestion here. If anything, it is too conservative in the quantities considered.

H. S. Fitch: It is not at all simple to adjust plant frequencies so that the load may be distributed as desired. The first point is to adjust the settings of all governors repeatedly until there is obtained an easy fluctuation of load on the least efficient plant, and base load which is constant probably throughout the whole twenty-four hours in the day on the most efficient plant.

The next thing to solve is the wattless current. On our system, by means of penalizing the consumer, forcing him to pay a higher rate for poor power factor, we do obtain some help by having him install synchronous apparatus, but our problem has been met more generally by spotting synchronous condensers at the low-voltage points on the system. We have had to come to the point at the less efficient power stations of disconnecting the turbines from the generators, to take care of this wattless.

The third point is the relay problem. Any interconnected system on which there is a great amount of network must have a relay system which will function so that if one plant is shut down, the load is transferred from that section; in other words, if line trouble occurs between plants and they separate one from another, are the plants unequally loaded so that you are forced to transfer loads by dropping them? Or, again, if you are forced to shut down during the hours of the night or on Sunday, will a condition be created whereby the load must be interrupted again to transfer it to the plants which are running? These problems on relays are large ones and require a great deal of thought on the subject of interconnected networks.

F. M. Nash: I think I can give an illustration of what sometimes happens when you have a long line and try to get two hydro-electric generating stations on the opposite ends of the line to parallel successfully. The bigger station of 10,000 kw. in this particular instance, after a case of trouble, was allowed to charge the line. Then the smaller station at the extreme opposite end of the system was synchronized before any load was taken on anywhere. This was done two or three different times, and in each instance when the lower station had synchronized there began, very shortly afterwards a slow oscillation on the meters that gradually increased to such a point that the two stations would go out of step. It was an urgent condition and the only way we got the plants operating again in parallel was to get the large plant to charge the line, then pick up a large synchronous motor load near the center of the line, and then synchronize the smaller plant.

As the present-day tendency is in the direction of still longer lines and higher voltages, this particular incident is to my mind splendid evidence of the necessity of using synchronous motors or synchronous machines of some kind to hold the high-tension net works together and maintain satisfactory operating conditions in the generating stations.

Howard A. Stanley: There has been one point made which, I think, perhaps needs a little attention. On Page 12 of Mr. Thomas' paper, he says: "The segregation of a single link is simplified because with the wide separation of power houses and the absence of large concentrated loads, no short circuit can occur in the network of a magnitude to exceed the safe

capacity of oil breakers." That is about all there is, I think, in the paper on the question of short circuits.

I wonder if in this network we are not trying to accomplish two mutually conflicting objects. No matter how much reactance you may have, it is entirely possible to have a greater concentration of kv-a. in a short circuit a hundred miles from the generating station than at the station itself.

We have, in Fall River, a network which compared with what we are talking of here is something in the nature of a toy, 23,000 volts—serving approximately 30,000 kv-a. at the present time. It actually works out, in our network, that short circuits remote from the stations are more severe than those at the station.

W. A. Moore: I am speaking from the viewpoint of a manufacturer taking a large block of power.

You said that you would regulate the voltage at a substation by changing the fields possibly in the nearest generating station. That is a problem we are struggling with today on a smaller scale. We are trying to hold a certain voltage condition. I am wondering just how often you would have to change the fields, that is, would you change them at seven o'clock in the morning, at noon time and at night? Or do you find that for actual operation you would have to keep a man on the board, varying the fields every five or ten minutes just to compensate as people 'phone in and tell you that the load at a certain place has changed?

P. H. Thomas: Use an automatic voltage regulator at the generating station. The nearest power house would be the place to do it.

I would like to say here that the advantage that is gained by this particular scheme is that the total transmission, the total amount of power handled by the high tension is overwhelmingly large with regard to any particular station. You have a 220-kv. line 100 miles long between two stations. No local load you can take off the middle of that will affect that voltage so you will notice it. By having a big thing dominate the whole, the variation produced by the local users doesn't amount to anything. If the voltage of this system is regulated every 100 or 150 miles, that is all that is necessary. It wouldn't vary more than half a per cent. from any load you take off in between. The voltage control should be automatic. If the voltage is maintained constant by voltage regulators in the general stations, the regulation generator takes care of itself.

Mr. Moore: That leads to another question. Suppose this sub-station is big enough to have some regulating equipment. Then you would, at times of light load, lower the power factor purposely so as to get the voltage drop.

At the present time here in New England some of the power contracts call for a certain average power factor, and you get a bonus or get penalized, depending on that average. At the time of low load and you lower the power factor purposely, then where the wattless energy is read on a reactor meter, a large reading of wattless power is recorded, and this in turn penalizes you.

C. R. Oliver: It depends upon whether you are trying to maintain the voltage or improve your power factor. If you have a contract like that, let the power company regulate the voltage.

L. W. W. Morrow: The big question in regard to the scheme proposed by Mr. Thomas is "Will it increase service reliability and decrease the cost of installation?"

The long-line bulk-power transmission line has been installed in several instances and its problems have been solved very successfully by using synchronous condensers. But instead of this method Mr. Thomas makes a proposed equivalent to taking power from Niagara Falls and sending it through an interconnected network in multiple to the loads in the New York district. It is a question as to whether this proposal is a better economic and operating proposition than the heretofore used bulk power line having no intervening loads. Under abnormal conditions for example a short circuit on one of the light load taps of the network system might interrupt service to heavy load points and introduce more chances for service trouble than occur on the long line system having no intervening taps between the source and the load.

Then as regards the cost of installation it would seem that the use of single circuit multiple link lines would result in a cost comparable to that incurred in building bulk power double circuit lines because greater mileage is involved in the network system. And, although power factor and regulation are worked out satisfactorily on the network proposed by Mr. Thomas without using synchronous condensers it is a question as to whether this investment could be avoided in the general case.

Another element involves the question of voltage regulation under abnormal and normal conditions of load in a large territory. Mr. Thomas has several fixed but different values of voltage at several locations in the network which retain practically constant values for changing loads under the conditions he assumes. But experience with large networks indicates a continual shifting of loads on the system, the necessity to change the sources of power to conform to water, fuel, and load conditions and the necessity to handle troubled parts of the system quickly and easily. Under these conditions it would seem difficult if not impossible to retain constant voltage values at the different load points on the system. Apparatus are not yet developed to automatically give a wide range of voltage at a substation nor have operating facilities been developed to a degree which will permit a load dispatcher to control excitation, governing and transformer ratios at multiple points on a system in a very short time.

Then again experience indicates that the satisfactory operation of an interconnected system requires that each system in the network have the same standards of construction, service and insulation. This condition is seldom found and there would seem to be difficulties in instituting the type of system proposed in territories now occupied unless this condition was fulfilled.

These points are brought up in connection with this notable paper only as points apt to be raised by engineers more accustomed to the old methods and I am sure Mr. Thomas can answer them.

J. C. Damon: Mr. Thomas presents a pioneer system as regards voltage and extent, but some of the advantages of this network over a trunk line system have been practised.

The West Penn Power Company has a 22,000-volt distribution network which if mapped to an enlarged scale would be similar to that presented and the experience of this system largely bears out what Mr. Thomas expects in economy of lines to reach customers and the ability to feed in both directions to the customer. Relaying such a network has been very difficult but recent developments are solving the problem.

Another question discussed is being demonstrated right on the systems shown on Mr. Thomas' map. The ring of transmission lines shown on the southern portion of the map has been closed within the last few weeks by a new connection between the Alabama Power Company, and the Columbus Electric & Power Company, and the existing connections between the Columbus Electric & Power Company, Georgia Railway & Power Company and the Alabama Power Company. Before the closing connection was made, an investigation showed that the power stations around that ring could control the voltage, as well as the flow of power and wattless current between companies, within commercial limits without any new synchronous condensers. One assumption differed from those made by Mr. Thomas. That assumption is that, knowing beforehand when the light-load periods come, the station voltages can be lowered somewhat to avoid the necessity of drawing heavy lagging current to hold down the voltage over these lightload periods.

F. L. Hunt: The problem that Mr. Thomas has worked out, is, of course, one that we must all solve. We are facing it now, and we have attempted, to some extent, to solve it along

the line of economics. It seems to me the solution must be economically sound.

I noticed in one place Mr. Thomas suggested that the system of operation must be worked out only with regard to the whole, regardless of how it might effect one company. Such a plan would be difficult to work out in practise.

Mr. Thomas, in the case which he has assumed, has allowed 100 per cent growth on each sub-station, and, states that the network should be laid out with that assumption to take care of the future conditions. It seems to me that is a little optimistic. They don't always grow so evenly as that, and if you map out a big network on that basis and then the growth is entirely different, the result is not so good as pictured.

C. E. Skinner: Mr. Thomas' scheme presents one rather serious objection from the standpoint of the manufacturers of transformers. This is on account of the very large number of voltages varying by small steps from 190 kv. to over 200 kv. Either the transformers must be provided with a considerable number of taps or transformers in the different stations will not be interchangeable. Interchangeability of transformers is, of course, very desirable for such a system.

C. R. Oliver: Looking at the paper purely from an operating man's standpoint, it struck me as unique and radical in some parts, because of the results on our system; a small interconnected one in this paper. Before I take up the points brought out in the paper, I would like to mention one or two things that Mr. Thomas discussed outside of his paper this morning. One was that by running the generators on the system—it would be possible to eliminate any synchronous condenser apparatus.

Now, our experience here in New England has been probably the same as that of most of the other companies similarly connected. We have a peak load of 140,000 kv-a., and it has been necessary for us to install 47,000-kv-a. of synchronous condensers. That was after we had used all the correcting capacity of the generators, and we had a hard time convincing our financial people that we needed those condensers. And since we have had them running we have had an awful time to get one out of service for ordinary repairs, because the operating people are using them all the time.

I am wondering on this larger system, using the old stations and the old generators designed for probably only 80 per cent factor, how Mr. Thomas was arranging to keep the power factor constant regardless of the flow of current and regardless of the direction and the amount of current. It is something we haven't been able to do on our system in New England.

P. H. Thomas: The power factor wasn't kept constant.

C. R. Oliver: One other point Mr. Thomas mentioned was that the advantage of the loop over the double-line transmission was that the loop would give so much more capacity because of being fed in by both routes. It seems to me as though the loops must be designed of unlimited capacity. A case I had in mind that particularly illustrates the point I want to make is that on your map at Muscle Shoals, where there is 243,000 kv-a. capacity, with a line running east towards Huntsville and a line running south towards Birmingham, Alabama. Now, in case of trouble on the 65-mile line between Muscle Shoals and Huntsville, that single-circuit line would be called on to transmit 226,000 kv-a. 204 miles to get it back up around Chattanooga.

Now, the General Electric and Westinghouse Company, to date, haven't even been able to figure a double line able to carry that power. I am wondering how that would be taken care of unless that water is wasted and the load is supplied from some other station.

I am particularly interested in how Mr. Thomas is going to maintain these various voltages that he has laid out, all the way from 185,000 up to 195,000, with a generating voltage of 220,000. We have light-load conditions; Saturday afternoon conditions; Sunday conditions and night conditions, and I am very curious to find out how that voltage would be maintained unless we had an extensive amount of tap changes on the transformers. I don't see how the system can be worked unless we use synchronous condensers and hold the voltage flat.

The other point that our company is particularly interested in, is his suggestion of multiple conductors. We have been doing quite a lot of studying on the super power transmission line, and our engineers have not been able, to date, to solve this problem, which is the problem of suitably mounting and handling multiple conductors on transmission lines.

In your design of towers, you claim that a 15-foot spacing is ample between conductors. Now, the insulator manufacturers tell us that the length of insulators on 220,000 volts will be at least six feet. With a 15-foot spacing between wires we will have 7½ feet between the wire and steel. The conductor, under extreme wind conditions, will swing out to a 45-degree angle. The clearance then will be less than two feet between the 220,000-volt conductor and the steel. We felt that was too close.

With regard to the method of regulating the voltage all over this loop, particularly the transfer of power, in case of power shortage from the extreme southern portion to the extreme northern portion—I am anxious to find out how you are going to do it. Apparently, it is not going to be so simple, with all of the various power companies connected, to transfer power back and forth unless you have unlimited capacity of line and unlimited capacity of transformers.

The other point I am particularly interested in is regarding the question of costs. You have outlined 2500 miles of single-circuit line at a cost of \$8000 per mile, exclusive of right of way. A line which we finished a month ago, which is a super power line, cost us more than \$8000 a mile for material alone, regardless of any labor or right-of-way or anything else.

Your 200 oil circuit breakers, at \$4,500,000 would come to \$22,000 apiece. The latest quotation we had from the manufacturer, was \$30,000. And your figure not only included the oil circuit breakers, but miscellaneous switchgear, outdoor stations, etc. On a recent estimate we made, this came to \$75,000 per breaker.

Farley Osgood: Mr. Thomas has shown us, theoretically, what we would like to do. He has heard practical criticisms from the operating men which may alter the results as he shows them in his paper. I do not think this casts any discredit upon the paper, nor do I think we owe any the less to Mr. Thomas for having developed it in the way in which he has, because if he can point out to us the ideal, with our practical field operation we can lead ourselves into the avenues of finding out how the ideal scheme will have to be modified, so Mr. Thomas' work for us, as operators, is truly accomplished.

I think that I can appreciate his paper as much as anybody, because in New Jersey we are working on this same problem ourselves. Fortunately, it does not have to be decided tomorrow, but with this basic information which Mr. Thomas has prepared for us, we are able to save a great deal of time and to point out to ourselves the difficulties that we are likely to get into.

The practical criticisms which you have heard, I would like to concur in, because our experience matches up with the statements which have been made.

There has been some reference made to the voltage regulation and control, and we in our system get a good deal of help, particularly in power factor improvement, by using, whenever it is possible to do so, our idle generators as synchronous condensers. We have developed a fairly quick coupling arrangement, by which the generators can be disconnected from their turbines, and it is our practise to throw our generators on to the line as synchronous condensers whenever the steam end of the unit is to be taken out for repairs for any extended period, say even for longer than a day or two. We have been doing this for a number of years and, if I am not mistaken, we were the first group to establish this as a universal standard practise of operation.

In our northern network of several hundred thousand kilowatts, we have many prime-mover elements, the generator ends of which are used as synchronous condensers whenever they can be released for such service, and the improvement in the load carrying capacity of the system will vary from 25 per cent to 50 per cent of the kv-a. rating of any generator thrown on as a synchronous condenser.

There is no reason, where a generator is driven by a water wheel, particularly if it is a horizontal unit and easily uncoupled, why it could not be used in this manner. In a system as outlined by Mr. Thomas this same scheme could be applied, and all the free generators that would naturally be shut down on account of high cost of driving them, could come on the line as synchronous condensers, and the result to the network must be a very considerable benefit.

You men here in New England are studying your problems as they relate to power obtained from the St. Lawrence, and we in New Jersey are most interested in your study, as it is not beyond the possibility that we might participate in that same development should it be carried through the Metropolitan section, including New Jersey, and on through to Philadelphia.

In the matter of fear of coordination of operation, we must not forget that the people who are going to make these interconnections, while they are not all controlled by one holding outfit, at least, are neighbors, and neighbors are supposed to be friendly, and in the electrical fraternity I am glad to say that is very largely true. And if a network can be devised which will give a group lower costs, the fellows who are operating that group are going to go along with the combination and play the game in the best arrangement of load dispatching that may be worked out mutually.

No engineer ever went into a conference at which some fellow in the group did not say something that he did not believe or that he did not like, but generally the conference comes through with a unaminous opinion, and I have not the slightest doubt that that will be the practical outcome of the conferences which will bring about this network operation on an economical basis as soon as it can be set forth properly, physically, to warrant the money that it will cost.

The thing that I fear most is that, as engineers born full of enthusiasm and who seem to develop more each year, we might be too hasty in recommending to our financial people the accomplishment of this problem outlined. So—not in the way of any disparagement, but rather in the way of a note of warning—let us be sure in making our recommendations to our financial people, first, that we are sound and positive in the engineering accomplishment which we are going to get, and second, that we do not make the recommendation before it will pay.

Long transmission lines are all right, but they should not be built before they will pay their way. We have had many discussions on the cost of transmission lines versus cost of transportation of coal, and in most of the studies in our section of the country one hand about washes the other—in fact, it is mostly in favor of the transportation of the coal by freight.

If we have a large investment for a long period, not earning its way, we are going to get into discredit with the people who back us in these schemes. Our duty is to convince the financiers that they must furnish us money far enough ahead of the load to make us sure that we will be ready to take care of it when it comes. Let them figure the cost of carrying the financial burden meanwhile. We, on our part, will be prepared to show them accurately when the load is expected, and that when connected it will pay.

Otherwise, we shall get into ill repute and we shall have difficulty in getting money for the most excellent engineering enterprises which are in front of us, which are the most costly of any which have come before our electrical body thus far, and which are the most important to the industrial and operating men, and which should be gone into carefully, co-operatively, with our financial backers.

P. H. Thomas: Mr. Mitchell has asked why I have been able to secure stabilization of voltage without the use of synchronous condensers.

There were three reasons. The first and most important one is this: I have taken the liberty of establishing the voltage at each point at the value which will be most favorable for this purpose. I have not taken a level-voltage system. There has been a great deal of talk lately about the constant-voltage system, meaning the level-voltage; that is to say, a system in which the voltage is the same at all points. When you have established such a condition,you have committed yourself to a large and unnecessary expense, at least, in any case where the flow of power is predominantly in one direction. In the transfer of 100,000 kw. for 100 mi., there is a natural drop of voltage along that line for that power. If you establish the voltages at the two ends as normal which gives this natural slope of voltage, you don't need any synchronous condensers; but if you undertake to maintain the voltage at both ends at the same value, you must have synchronous condensers at one end, the receiving end. You notice in my set up I have freely adjusted the voltages to the flow of the load. That is the biggest factor in eliminating the necessity for synchronous condensers, and it is a very powerful one.

In the second place, there is no distinction between leading current which you get from a condenser and what you get from a generator. By taking lagging current on the generator stations, we reduce the natural voltage drop produced by power coming from the line. I have used the present generators up to 85 per cent lagging factor, where that was necessary to make a favorable power factor for having the power flow across the system. The conditions of this set-up come very close to requiring some synchronous condensers. A worse power factor load would call for some synchronous condensers, but their capacity would be very much less than you would expect.

As the third feature, I have worked in the new idea of "divided conductors". It isn't entirely new; I proposed the scheme either in 1911 or 1912, but it is new so far as most of you are concerned, I think. Here is a case where that idea is of extreme importance. Instead of using a conductor ⅞ in. in diameter, I use three conductors in parallel of the same total cross-sections, spaced 12 or 15 in. apart to increase the electro static capacity of the line and reduce its reactance. At the limit, I think, you can get about double the electrostatic capacity with the three conductors that you get in the one, and about half the inductance. The power in this set-up is taken as flowing over a line where the inductance is two-thirds of normal and at the same time the discharging current is 150 per cent of the normal. The result is obviously to reduce greatly the line drop and to help the power factor.

Those three points, taken in this case, eliminate the synchronous condenser. That is the answer to that particular question.

W. S. Lee: What are you going to do with a voltage regulator on one system which tries to halt the whole load?

Mr. Thomas: The voltage regulator only controls the voltage; it won't affect the distribution of load very much. Give a definite case, Mr. Lee.

Mr. Lee: A power station situated 50 or 60 mi. from a load center, with a capacity of 80,000 kw. in the station, with a voltage regulator on it. When it boosts that load and another load is perhaps 80 miles on the other side, and it is lagging, what is going to happen?

Mr. Thomas: The generator must be big enough to stand the maximum that can come on, that is all. I don't see any complication there. It seems to me the flow of lagging current automatically takes care of itself.

Mr. Lee: Regulation in putting the voltage up means a bigger flow of current, that opens the governor wide. Then that plant goes out of regulation.

Mr. Thomas: A raise in the voltage doesn't change the load on an induction motor materially. The load is the mill.

Mr. Lee: It does on all we handle.

Mr. Thomas: If the voltage regulator keeps the voltage constant, there shouldn't be any change in the load.

Mr. Lee: Certainly; but if the voltage regulation can have this effect I think the regulation does more harm than good.

Mr. Thomas: That is the problem of the governor, I should say.

Mr. Lee. We would take the governors off, to run your system better.

Mr. Thomas: I will venture to say this type of network will work in much better shape than any other form of a regulator system that you can get. I think the problem you speak of is primarily a governor problem.

Mr. Lee: I think it is a governor problem, and I think you want a rather slow-acting governor.

Mr. Thomas: I am not saying it ought to be slow or fast, but that should be decided by whatever governor you use. That doesn't hinge on the character of the network. The governor should not be too sensitive. But the point I would make is that all the governors should be alike, equally sensitive.

With regard to the calculation of the line—there are 62 different transmission lines. The way I got at it was this. I took the map and drew the lines, noted their lengths, and assumed that the drop in any particular line was proportionate to the power that would flow over it. That is not strictly correct, because the power factor is not exactly the same all over the system. However, it varies only a few per cent., and for the purpose of this discussion, it was legitimate to assume, I think, that the drop in any line was proportionate to the length and the power flowing over it.

These lines are all of the same conductor. The size of this conductor was determined by corona and it happened to come out about right for the energy losses.

After establishing the load taken at each station and the power to be supplied from each generator, I made a trial distribution of the current through the network, to see whether the drop in each branch was the same as in other parallel branches. Of course, it wasn't, at the first trial.

Then I shifted the values and finally succeeded in getting, by trial, a series of values within about one per cent. checking up, so that the drop between any two points was the same by different routes, taking the drop as the product of the length times the power.

Then I started at the load end, with the known power at any one particular station, and made a guess at what the proper power factor would be, that is, at what field strength the local generator would be operated. That enabled me to calculate the voltage at the other end of that local line. If that were a generating station I would add in the power or subtract the load, make a guess at the right amount of wattless power and work back over the arrangement.

I had to make one or two tries at that, but finally a satisfactory set of values was found. It was, I might say, a case of shrewd guessing. However, each particular line was calculated exactly when the original assumption was made.

In regard to the distribution of power between the steam and hydraulic stations, I would like to say this. It no doubt strikes you all as a tremendously complicated system to operate, but as I have thought it over and as it has grown in my mind—and it is of two or three years' growth—I don't look upon it as a complicated system. It may be a difficult thing to get started, but picture, in your minds, the ordinary Edison direct-current network in a large city like New York or Boston. In many ways those are the simplest things to operate. They are networks. The power distributes as it likes. If they find the cables are getting too heavily loaded at one point they put in another cable, either parallel or feeding to some other substation, and they keep the voltages about right.

Now, as regards the operation of the distribution of power. Supposing we are starting at a time when water is high and hydraulic plants can carry all the load. The water wheels will have automatic governors. Now, if the water goes down, pretty soon there comes a point where there isn't quite enough water to produce a sufficient backing for regulation. You see that the water is perhaps drawing down in the different ponds, and the load dispatcher tells the steam plant to start up and put a machine on the line. A machine is put on the line and probably that machine begins to govern then, and as the water still drops, or the load becomes higher—the governor on the steam machine will open up and take more steam—and as the water drops off more and more they will take off a water wheel, put on a steam machine, and as any interconnected system now distributes the power by the automatic control of the prime-mover governors, so would this system.

As far as any practical interchange of power for synchronizing purposes or distribution of load, is concerned, this network is a perfect connection; that is, the drops are so small they wouldn't prevent interchange of power or prevent the developing of a large synchronizing power.

This ideal is theoretical, but it is the basis on which successful operation rests in all of our systems today; and I don't see any reason why it shouldn't work out in the same way here.

Now, I would like to make this distinction. At the present time there are interconnections in the South. Most of the companies touch one another. But that is, in no sense, comparable with this network. Each one of these systems is a self-sustaining system, or almost self-sustaining. One company may have an outlying sub-station on one side, which touches a line on another system. They make a connection between. If there is a little surplus power in one or the other, they can pass the power backwards and forwards. But it is limited by the capacity of the individual circuits with which the systems connect and by the fact that those systems are operated for the local power and not for the sake of supplying power to one another. It is like trying to pull a heavy load with a small string. If, however, they are connected firmly together, then the automatic interchange will be complete and it won't be so delicate and won't be so likely to fall apart at any time.

In regard to that voltage regulation, it looks very complicated, but it isn't. Supposing the system is running and we have our power houses; each power house has its power factor; each load has its power factor. We will say the peak of the load is on. The load drops off, and perhaps around Charlotte, Concord, Gastonia, Mount Holly, the voltage will begin to creep up because the load is creeping off and the generators, we will say, are maintaining the same voltage.

As that happens, the voltage regulator, when it feels the voltage rising, will change the field, until it makes a little difference in the power factor, and then your voltage goes back to where it was. Nobody worries about it.

Now, if at midnight you find that these machines are drawing a big lagging load to keep the power factor down at Mount Holly when at Tallulah Falls it is very high, there is no objection to the man at Tallulah Falls lowering his field. It will change his voltage locally, but that won't bother him. Then the voltage regulators at Mount Holly will reverse and change the power factor back to whatever is necessary to keep that voltage.

The control of power factors at all of these stations is absolutely in the hands of the load dispatcher, if he is willing to change the generator field settings in the different places. Any time you lower the voltage at the station, you change the power factor.

I assumed fixed voltages here to convince you that if you wanted to have constant voltage you could do it—that the system permits it—that the theory provides that you can control your voltage. As a matter of fact, if I were operating the system, I wouldn't have exactly constant voltages. I would adjust them. The main load centers I wouldn't allow to shift

very much, but in the distant power houses, I would have the voltage shift up and down somewhat, and by such a method as that, you can eliminate such objections raised as to running many light generators at night, etc.

Mr. Osgood made an excellent point with regard to the use of generators as synchronous condensers by cutting off the prime mover. That is really economy. You are getting something for nothing when you do that. The only thing I will say is that in this case you will get an added advantage from that sort of thing where the generators lie in the sub-stations because you correct the power factor at the sub-station and the lower power factor doesn't have to be taken over the high-tension line. In a remote generating station, if that is where your synchronous condenser is located, that merely relieves your other generators of the bad power factor load.

I didn't intend to say very much about the costs, in this paper, and Mr. Oliver isn't the first one to criticize the $8000 per mile as the cost of these circuits. I feel very confident that if Mr. Oliver were given the task of building 2500 mi. of single-circuit line in Alabama and Tennessee, and he had five or ten years in which to do it, and if those lines merely had to do what these lines have to do, he could do it for that price. Remember that conditions will be very, very different. I have taken some actual figures for the cost of towers, etc., and I feel confident that can be done.

Now, of course, there are all kinds of conditions in which work is done. Where conditions are favorable, in foreign countries with better labor conditions, and that sort of thing, that $8000 cost could be bettered. But conditions around here are very different. A man doesn't have a free hand—he can't do as well as he might in other places.

The question was raised at the beginning of the discussion as to how it happened that we could have such large amounts of power transmitted such long distances and when it came to a short circuit not have much, if any, power to handle. Mr. Stanley, I believe, pointed out that it wasn't the case down at Fall River. This is the reason. We are working on a larger scale. We have longer distances here. We have high voltages. Now, you who have studied high-voltages lines, know that a 220-Kv. line will transmit a very large amount of power a long distance if the voltage is maintained. As a result of the reactance of the line, you can get a high degree of efficiency because the charging current in that high-voltage line neutralizes the effect of the reactance, and as long as the charging current will neutralize the effect of reactance in that long line, you will get efficient transmission.

But should you get a short circuit so that the voltage is killed at that point, then the reactance is no longer neutralized by the capacity effect, and you are working with a reactance, pure and simple, at least on one end, but the net result is that you are working through a large reactance and the amount of power taken is very small.

Take, for example, a case which I have in mind of a 500-mile transmission at 220-kv.—a very large circuit. You short circuit one end of that with full voltage on the other end and the amount of power from the generator is about 7000 kw., on a circuit which has between 140,000 and 150,000 kw. as a maximum load.

Most of the jumps between stations in this set-up are 20, 30, 40 and 50 mi. If you get a short circuit, a ground, there, you will find, by actual calculation, that the amount of power that will flow is small and is below the minimum limits of a 190,000-kv. circuit breaker.

That is a hard idea to get through at first, but you will realize it as you go into it. But that comes from the fact that we have a very high voltage and far distances. It is not true with our present installations. Conditions are not the same as they are in normal networks. These long-distance networks have a radically different character, and the great difficulty is to get enough synchronizing power between stations, and not too much.

The question of reliability is another very important one. It was in my mind, as it is in yours. But I feel pretty well satisfied, from what thinking I have done, that this network is far more reliable than the so-called trunk-line type of transmission. The principal reason is this. Supposing you have a receiving end here and a sending end here, with a transmission line between. If something happens to the center of that line, or any part of it, and you get a ground, you lose the voltage—there is practically no flow of power between one end and the other. You have lost your chance for holding synchronism.

On the other hand, where you have a scheme like this, where there are two or three different routes, you may get just as heavy a short circuit as you want on one route and there may be no interchange of synchronizing currents across that link; but the other link holds them in synchronism. And after a while, whenever you are ready and a good circuit comes back, they are still in synchronism.

That isn't the only thing to consider, but that is one of the essential points in keeping continuity of service in a network, and that, it seems to me, is pretty nearly enough to throw the balance in favor of the double link connection—seperate link sections between stations.

I maintain, also, that a single circuit, feeding a station from both directions, is safer than two circuits coming from a single direction, because no one accident can sever both connections. With the two circuits you feel pretty secure. But as you analyze it, you are safer where you have a single circuit which can be fed from both ends.

Of course, the question of relaying is a very important one, and I don't think there is time to go into it. But it is taken up in the paper to considerable extent. I have thought of it further than is in there, and while some new devices will be required, I believe that a relay system, at least as successful as the present one, can be devised. For example, where you have a series of stations on a long single circuit and you get a ground, it is a difficult thing to cut off the last end where the fault is and not cut off some other section. But we have an idea to work with there, which is a relatively new one, by which we can have time limits, on relays, and the relay will open quickest where the voltage on the circuit is the lowest.

On these long circuits, the voltage builds up very rapidly with distance. It is full voltage on one end and 50 or 75 mi. away there may be a ground on the other end. If the relay that has the lowest voltage on opens first, that will clear the bad section. That isn't entirely worked out.

Aluminum was used in this conductor because of its larger bulk, so we could use a smaller size conductor equivalent resistance.

I did make the statement that I don't think it is safe to infer from present troubles in interconnections, because, with very few exceptions, there are no existing interconnections of the character of this.

Suppose you do build a trunk line to a center and your load leaves it—your trunk line is worthless. This system has the same conductor all over it, and it will permit, as I say, a change of 250,000 kw. in the supply of steam or water power, which is the balance that shifts with the seasons, from one side to the other, without any distrubance of voltage that the operating man will notice. The network is the thing which can stand an unexpected shifting in load much better than any other type that is proposed.

Mr. Skinner objects to too many taps on the transformer.

I don't think this as an actual installation would call for abnormal transformers. It is true, there would be a variation of about 10 per cent in the voltage that would require two or three taps. We would size it up as to what was going to be a good voltage for that station, and put it up two or three per cent,

or down two or three per cent. The thing would go by steps. You would have to have some taps. But you have two chances for taps—a chance on the 220-kv. transformers, the lower transformers, and also the chance to lower these drops that are taken. You could make a little more to Easley and a little less to Greenville, or a little less to Easley and a little more to Greenville. There are a great many devices you can use to avoid that particular trouble.

Mr. Oliver asked a question in regard to Muscle Shoals and cutting out the power there. That brings up again the point that I raised a while ago. Until you have studied this thing, you don't realize the different numerical relations that exist. Supposing the line did fall from Muscle Shoals to Huntsville. That means 238,000 kw. would have to go over the 88 mi. of line to Warrior over a single circuit. Warrior is a steam plant. Warrior has something like 100,000 kw. capacity. From that point the circuit splits. There are two circuits. The normal load is about 42,000 kw. in each one of those. It runs down to about 6000 kw. when you get to Anniston.

Now, that 88 mi. would take the 200,000 kw. without any trouble. The load, after that, divides in two—it adds 100,000 on those other circuits. But there is a steam station in Birmingham. At Jackson Shoals there is a steam station, and that power will merge in there and sluff away, and when you read your ammeter you will find there is a little higher load, but you won't find it in other parts of the system.

But for fear that would be considered too great a risk, I have dotted in a third circuit. You will notice the dotted line from Muscle Shoals to Huntsville, which runs down to Lindale and Atlanta. I felt, myself, that the thing was too precarious, so there is a whole spare circuit which is not used in the calculation on drop, which I have installed for the sake of giving more than two circuits to take care of Muscle Shoals. That is too much power to tie up to two circuits.

The same way at Cherokee Bluffs. While the dotted line from Newnan and Atlanta is not used in the calculation, it is put in for good measure, because you shouldn't tie up too much power to so few circuits.

Carrier Telephone on Power Lines

Both of the Western Electric Company

WHILE the use of power lines as the transmission medium for telephone currents is a comparatively recent development, the fundamental problems involved and the methods employed do not differ essentially from the somewhat older arts of multiplex or carrier telephony over telephone lines, and radio telephony. The differences lie chiefly in the range of carrier frequencies which is best adapted to each scheme, and the means which are employed to connect the telephone equipment to the transmission medium.

In any telephone system, the fundamental requirements are as follows:

a. The operation from the user's standpoint must be reliable, simple and safe, the received signal must be of ample volume, free of disturbing noise, and a sufficiently faithful reproduction of the original sound to be clearly understandable.

b. The maintenance of the equipment must be simple, so that an excessive amount of neither time nor skill is required to keep the system in operation.

c. The cost of the equipment, both as regards investment and operation charges, must be such that it is at least as economical as other methods of accomplishing the same result.

When these fundamental requirements are interpreted in terms of the particular problems encountered in the design of carrier equipment for power lines, it is found that there must be provided, from the transmission-engineering standpoint, sufficient amplifying capacity to care for both normal and abnormal losses in transmission. Distortion of the wave form of the speech waves must be kept small, and sufficient selectivity must be provided to completely separate the desired frequency bands from the undesired ones. The carrier equipment must be well protected from accidental exposure to the power-line voltage. Duplex operation (without push-button control) similar to ordinary telephone practise, should be provided, as well as selective signaling. The equipment must be so designed as to be cheap to manufacture and easy to install, operate and maintain.

A knowledge of the transmission characteristics of power lines and associated power apparatus at carrier frequencies is necessary for the understanding of the transmission problems peculiar to power-line carrier-telephone systems.

While the theory and practise developed in connection with commercial telephone systems both at voice frequencies and at the higher frequencies employed by multiplex-carrier telephone systems on telephone lines[1] have made it possible to predict the order of magnitude of the characteristic[2] or surge impedance and the attenuation of the line alone, it has seemed desirable to check the computed values with actual measurements, made in accordance with methods employed in tele-

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

1. Article of E. H. Colpitts and O. B. Blackwell, A. I. E. E. TRANS., Vol. 40, 1921, p. 205.

2. The characteristic or surge impedance (Z_0) of a transmission line may be defined as the impedance of an identical line of infinite length. It may be determined on a line of finite length by application of the formula

$$Z_0 = \sqrt{Z_{open} \times Z_{short}}$$

where Z_0 = characteristic impedance
Z_{open} = impedance of open-circuited line
Z_{short} = impedance of short-circuited line

phone transmission engineering. These measurements also include the effect of grounded guard wires and the power equipment associated with transmission lines, which is more difficult to predetermine.

In Fig. 1 is shown a curve of the ratio of received current I_R to transmitted current I_T, plotted against frequency, for a power-transmission line of 100 miles[3] in length.

This curve is plotted from experimental data obtained on an actual 110,000-volt line, the line being free of all power equipment. The use of this ratio of output to

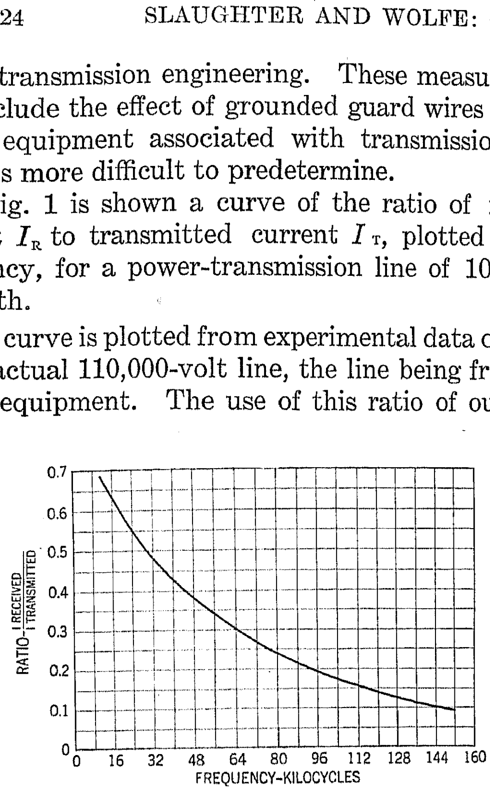

FIG. 1—ATTENUATION OF A TYPICAL POWER TRANSMISSION LINE OF 100 MILES IN LENGTH AT CARRIER FREQUENCY

input current, as a measure of the power loss in the transmission line, is, of course, predicated upon the assumption that the line is uniform and is terminated at each end in its characteristic impedance.

Although the exact attenuation of a line is dependent upon the geometry, leakage resistance, conductance and other factors, the values given in Fig. 1 may be applied to most 110,000-volt transmission systems in this country to obtain approximate values of attenuation.

The experimental data are at present meager but it seems probable that the effect of grounded guard wires may be ignored in calculating the approximate attenuation of high-voltage transmission lines.

In Fig. 2 is shown the impedance versus frequency characteristics of a typical 6600 to 110,000-volt transformer. Two curves are shown, one representing impedance with the primary open and the other with the primary short-circuited. These curves are erratic between 10,000 and 50,000 cycles showing the presence of resonant effects. However, above the latter frequency, the curves coincide and the shape of the curve indicates that the impedance is determined by the distributed capacity of the winding. The coincidence of these curves leads to the conclusion that above 50,000 cycles the impedance of the transformer is independent of the apparatus connected to the low-potential side.

The information contained in Figs. 1 and 2 gives us a basis for determining the characteristics of a transmission line and its associated power apparatus. Knowing the length of a particular line, and the extent and location of power equipment connected to it, it is possible to arrive at an approximate value of the attenuation of the system. This point, however, is not as important as the other conclusions which may be drawn from a study of the line and transformer characteristics.

Since the attenuation of the line alone is smooth and not excessive for frequencies below 150,000 cycles, it is apparent that from the standpoint of this attenuation, the frequency employed is relatively unimportant. However, a study of the characteristics of power transformers indicates that for frequencies below 10,000 cycles these transformers act as transformers and introduce large carrier-frequency losses, due to the transfer of carrier-frequency power to the low-potential network. For frequencies between 10,000 and 50,000 cycles resonant peaks are likely to occur, resulting in excessive attenuation for particular frequencies, while above 50,000 cycles, neither of these objections applies.

In selecting the frequency band best suited for carrier telephony on power circuits, the characteristics of both the line alone and the transformers indicate that the use of frequencies in the band between 50 and 150 kilocycles will result in satisfactory operation. From the standpoint of interference, this frequency band is also desirable. The frequencies are too high to interfere with commercial telephone systems since the present

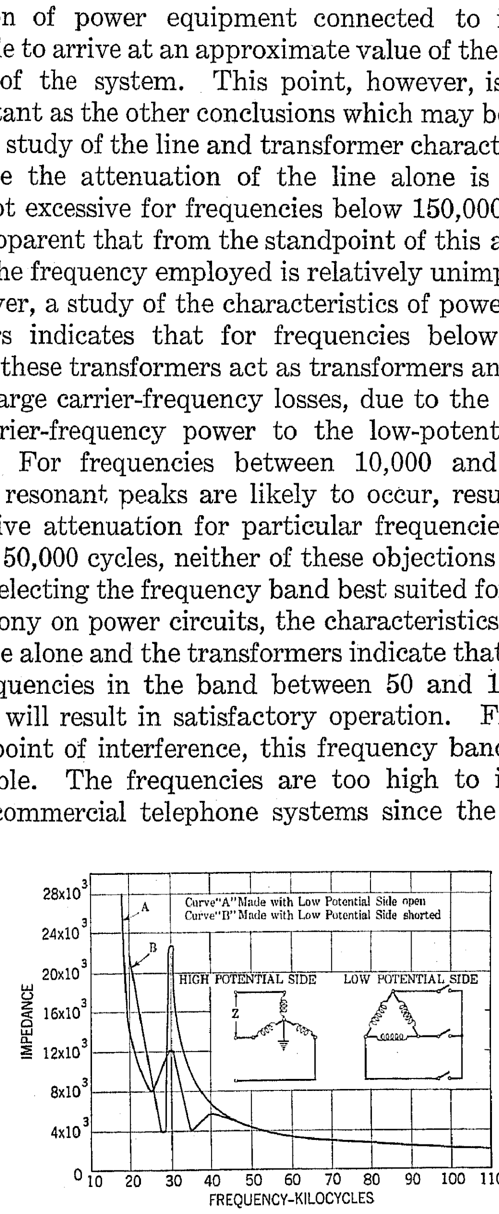

FIG. 2—IMPEDANCE CHARACTERISTICS OF A TYPICAL 6600: 110,000-VOLT TRANSFORMER BANK AT CARRIER FREQUENCIES

limiting frequency for multiplex systems is about 35,000 cycles; and they are too low to interfere with broadcasting or marine radio communication. They are, however, in the band of frequencies employed for certain classes of radio-telegraph service.

From the standpoint of coupling the carrier equipment to the power line, this frequency band proves again to be desirable, since coupling by means of capacity becomes easier as the frequency is increased.

In the development of this carrier equipment, it was early decided to employ a full metallic high-frequency

3. This curve may be reproduced for lines of a length L different from 100 by the following formula.

$$I_{rec}/I_{trans} = \frac{1}{\log^{-1}(L/100 \log X)} \quad \text{for any frequency } f_1, \text{ where } 10{,}000 f_1 < 150{,}000$$

cycles where X = the reciprocal of I_{rec}/I_{trans} as obtained from the curve

circuit rather than a ground-return circuit. The trend of the communication art has always been away from ground-return circuits because the attenuation of ground-return circuits is greater than that of comparable full metallic circuits. As the ground connection itself is unstable, such a circuit is subject to interference from other ground-return circuits and will itself produce interference in adjacent communication circuits. In addition to these objections, a ground-return circuit is generally noisy, particularly when it is associated with power equipment.

The provision of proper means for connecting a carrier telephone circuit to the high-voltage transmission lines is one of the most difficult problems involved. The coupling device must offer a safe and efficient means for transferring high-frequency energy to and from the power lines.

The use of inductive coupling did not seem feasible since it required a special transformer having a 60-cycle difference of potential between windings of approximately 65,000 volts on a 110,000-volt line. The use of existing power transformers to secure this coupling is not feasible because they do not act as transformers at the carrier frequencies.

The capacity coupling seemed to offer the most feasible solution of the problem. The first type of condenser considered was the capacity secured between a single wire parallel to the power-line conductor and the conductor itself. This type of condenser has two fundamental weaknesses. In the first place, it has what is known as distributed capacity and in the second place, its capacity to ground is generally larger than the capacity to the power conductor. The use of this form of condenser lends itself best to a tuned circuit, similar to that employed for radio-transmitting circuits. The major part of the energy which in a radio-transmitting circuit would be radiated into the ether is transferred from the antennas to the power-line conductor by virtue of the capacity existing between them. There are two serious objections to this type of circuit, the less serious objection being that since it is a tuned circuit, the frequency band which can be transmitted is very narrow which makes this arrangement not so well adapted to duplex operation as the filter arrangement described below. The second objection is the fact that a portion of the energy delivered to the antennas is radiated and may be picked up by a suitable radio receiving set. Since secrecy is not a primary object of this type of communication, this would not be objectionable but for the fact that it may require the licensing of carrier equipment by the Government and its operation by licensed radio operators. From the standpoint of reception, this type of coupling is also undesirable. It has many of the characteristics of a radio receiving set and will readily pick up radio signals lying in its frequency range. The use of concentrated capacity, such as in an ordinary fixed condenser, avoids these difficulties, but it introduces the problem of insulating the condenser plates. The development of a satisfactory condenser has been undertaken by a well-known manufacturer of power-line equipment, and this condensor will, no doubt, be available for all commercial installations.

The coupling capacity may be employed either as a part of a series-resonant circuit or as part of a filter circuit. The former lends itself to the transmission or reception of a narrow-frequency band but is not efficient for the simultaneous transmission and reception of signals of two different frequencies. Filter circuits[4] can be designed to pass a relatively wide band of frequencies with a small attenuation. The filter also simplifies the problem of static 60-cycle charges since it provides a path to ground for low frequencies without grounding the high-frequency circuit. Fig. 3 shows the characteristic of a band-pass filter, suitable for use as a means of coupling the carrier currents to the power line.

The power required for telephone transmission over power lines is largely determined by the magnitude of the disturbing currents or "noise" which are of frequencies in the range of the carrier equipment. If no

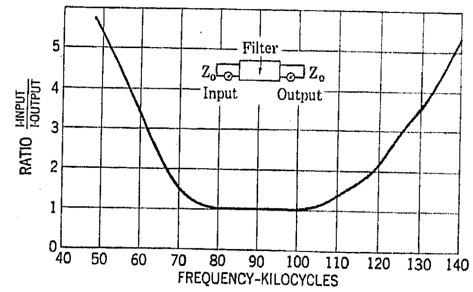

Fig. 3—Attenuation Characteristic of a Band Pass Filter Similar to that Shown in Fig. 6

"noise" were present the carrier transmitter would not be called upon to increase the power delivered by the telephone transmitter, but would have to merely change the frequency band. The receiving equipment would then furnish all the amplification needed to counterbalance losses in transmission over the system. However, in actual practice noise exists in the form of more or less infinitesimal electrical disturbances at all frequencies, the level of this noise generally decreasing as the frequency increases.

Based on a knowledge of noise conditions on transmission lines and with other practical considerations in mind, the receiving gain has been limited to a voltage amplification of about 100, which corresponds to a power amplification of about 10,000. Since it is desirable to deliver about 0.01 watt to the telephone receiving circuit, a carrier-frequency power as low as 0.000001 watt at the input to the receiving circuit will produce satisfactory results under favorable conditions. To allow for less favorable conditions, it is assumed that a power of 0.00001 watt is required. Based upon this

4. U. S. Patents 1,227,113; 1,227,114 of 1917.
G. A. Campbell, Wave Filters for high frequencies.

assumption and the curve given in Fig. 1, it is evident that an output of one watt from the transmitting circuit is sufficient for operation over 265 miles of transmission line, when the carrier frequency is 150 kilocycles and there is no loss in the coupling device or the associated power equipment. Actually, the loss due to other transmission lines connected to the line on which the carrier is operated, the loss in power equipment, and loss in the coupling device, may reduce this normal range to 100 miles or less. It seems probable, therefore, that a relatively small output from the transmitting circuit will be sufficient for normal operation on the majority of transmission lines.

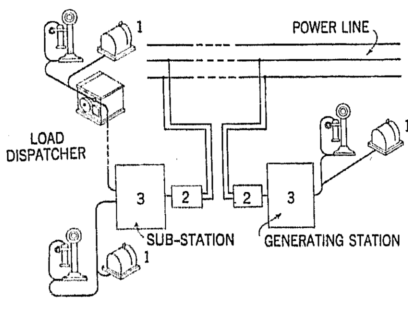

Fig. 4—Power Line Carrier Telephone System
1. Ringing Keys
2. Coupling Devices
3. Carrier Equipment—See Fig. 5

However, when emergencies arise, telephone service is of the utmost importance, and, therefore, a larger transmitting output should be available, sufficient to insure satisfactory operation under unusual line conditions and actual line failures.

In order that duplex operation may be secured, it is necessary to operate the transmitting and receiving circuit simultaneously, which means that the receiving circuit, designed to operate on an input of 0.00001 watt, must operate in parallel with the transmitting circuit which may deliver as much as 50 watts to the power line. This large power ratio makes the separation of the transmitted and received currents a difficult problem, which has been solved only because of recent progress in the art of designing electrical filters. By employing frequencies for transmitting and receiving, which differ by about 20,000 cycles, it is possible to prevent the transmitting circuit from interfering with the receiving circuit. For this purpose, a high-pass filter and a low-pass filter, similar to those described in recent literature, are employed.[5] The high-pass filter passes frequencies above 100,000 cycles and attenuates frequencies below that frequency, while the low-pass filter passes frequencies below 80,000 cycles and attenuates frequencies above 80,000 cycles.

Fig. 4 is a block schematic diagram of a carrier telephone system, developed for use on high-voltage power lines. The design of this equipment, both electrical and mechanical, has profited by the research and development work in connection with the arts of communication at speech frequencies, carrier frequencies, and radio frequencies.[6] As a result, the circuits employed and the equipment used in these circuits have the background of wide experience.

The transmitting circuit comprises an oscillator-modulator circuit which will provide sufficient output for operation on the majority of power lines. The circuit also provides a power amplifier which may be connected in the circuit by a simple operation, for use in emergencies. The operation of the circuit, while employing the 50-watt power amplifier, is in no way different from the operation without the amplifier. The transmitting circuit is entirely automatic in its operation, and is energized only when the circuit is in use.

The receiving circuit consists of a two-stage high-frequency amplifier followed by a negative grid detector. There is no tuning required in this receiving circuit. The circuit is not regenerative, this having been avoided because of the lack of stability in circuits of this type.

Signaling on this carrier circuit is entirely automatic and where more than two stations are involved, it is selective. The operation of the ringing key sends out a predetermined train of pulses at the carrier frequency. These pulses, when received and rectified, operate a selector of a type commonly used for telephone dispatching on railroad lines.

The voice-frequency telephone circuits are standard circuits suitable for either two-wire or four-wire operation. The circuit may be extended to a telephone

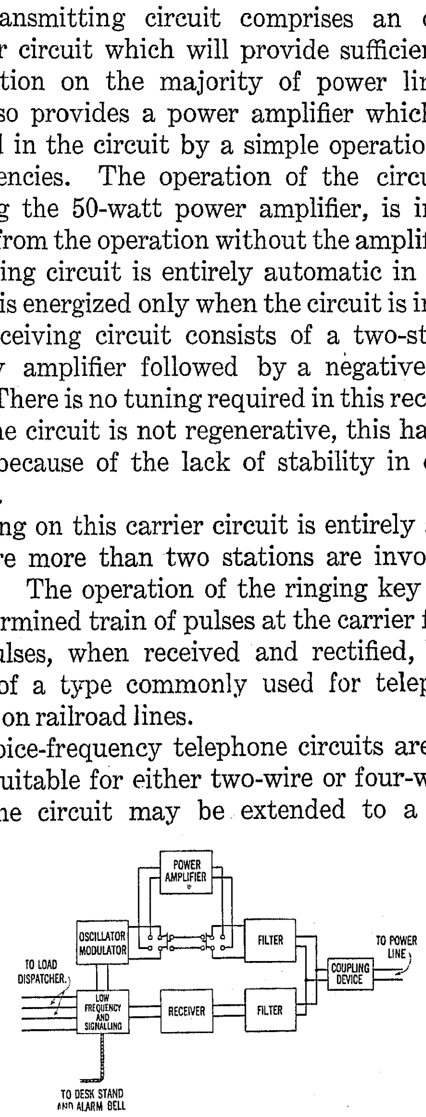

Fig. 5—Block Schematic of a Power Line Carrier Telephone Terminal

located at a point several miles from the carrier equipment with full control of the carrier, as is desirable in the case of the load dispatcher, or without control of the carrier; that is to say, where the load dispatcher is located at a point some distance from the carrier terminal, he may be provided with the same control and talking facilities as for the terminal proper. After considering the relative merits of the control arrange-

ments, employing the talking circuit for control purposes also, as compared with a separate pair of wires for the control circuit, it has been decided that the separate-control circuit results in a much simpler and more reliable arrangement. Accordingly four wires, two for talking and two for control are required. (See Fig. 5). Where it is not desirable to provide control of the carrier equipment, the talking circuit may be extended through a standard *P B X* board in a manner similar to that

employed for ordinary wire-telephone circuits. Two or more carrier systems of this type may be operated in tandem where circumstances make it possible and desirable to do this. No special equipment is required in extending the carrier circuit in any of the above ways.

The power supply for the carrier equipment may be obtained from any source which is convenient. The tube filaments require 24 volts d-c. and a current drain of only a few amperes, which can ordinarily be supplied best from storage batteries. The plate circuits of the receiver and the low-power transmitter require 150 volts d-c., with a current drain of a fraction of one ampere. This can be obtained from storage batteries, or a motor-generator driven from the 24-volt supply required for the filaments. The high-power transmitter requires 800 volts d-c., for plate potential and this can be obtained best from a 150-watt motor-generator set driven from the 24-volt source. This provides a power supply independent of the transmission line, an important point where transmission line failures or interruptions of power supply from other causes are likely to occur. Where the latter consideration is not important, both the 150 volts d-c., and 800 volts d-c. may be secured from a-c. rectifiers.

The vacuum tubes employed in this equipment are standard tubes, familiar in telephone and radio practise. The average life of the tubes employed in the receiving circuit is about 10,000 hours which is equivalent to continuous operation for a little more than a year.

Some of the tubes in the transmitting circuit have a shorter life but since they are not continuously operated, replacements will not be necessary on the average more than once a year.

The protection of the personnel operating the carrier equipment, and the carrier equipment itself, from the high voltages employed on the power line is of vital importance. In Fig. 6 is shown diagramatically the method employed in coupling the carrier equipment to the power line. The condenser (3) may be a fixed condenser or the distributed capacity secured by suspending a wire parallel to the power-line conductors. In either case, this condenser is designed and tested so that it has the accepted factor of safety required for work of this character. In event of a failure of this condenser, a momentary short-circuit current flows through the fuse (4) to ground at (1). The reactance shown, connecting this condenser to ground, is negligible at power frequencies since its inductance is a fraction of 1 millihenry. In spite of the low inductance of this coil, it is possible that an appreciable voltage may be developed across it and, therefore, heavy-duty static spark-gaps, having about ¼-in. clearance, are connected across this coil. On the carrier-apparatus side of this coil the fuses, vacuum-gap and air-gap commonly used for protection of wire telephone circuits paralleling high-voltage power circuits, are used and as a final measure of protection, a high-voltage mica condenser (*S*) separates the coupling device from the carrier equipment. This circuit has been laid out to secure the

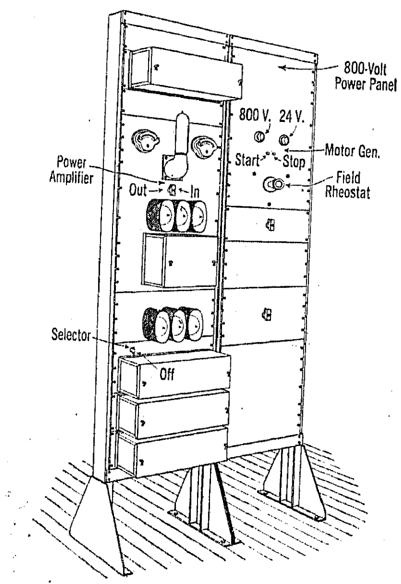

Fig. 7—Carrier Telephone Terminal Equipment

maximum possible protection both from static-power potentials and from conditions which may arise because of the failure of the coupling condensers. The fuse shown at (4) is designed to break the power arc at the line potential.

The carrier equipment, which has just been described, is suitable for power networks involving one or more transmission lines, extending for 100 miles or more from the load dispatcher's position. The exact length or extent of a transmission system over which this equipment

will operate satisfactorily is, of course, difficult to predict and each installation must be considered separately.

The number of carrier terminals which may be operated on one power-transmission system is practically unlimited. It is easily conceivable that 10 or more carrier stations might be operated on a single line. This system would then compare with a commercial party-line telephone system, except that every station may call every other station without passing the call through a common point. In some cases, it may be desirable to pass the call through a common point. The change from one standard ringing key to another standard key accomplishes this result.

For power cables, the use of carrier telephony at frequencies of 100,000 cycles is not practical except in very short lengths of cable. However, lower frequencies may be employed for transmission on cables, although the coupling to the power conductor will be considerably complicated for lines of very high voltages.

To provide for those power systems, composed of several power lines operated by different companies but connected in parallel, the carrier frequencies may be located at various points in the band from 50 kilocycles to 150 kilocycles so as to avoid interferences between carrier systems.

Discussion

H. L. Wills: When Mr. Slaughter announced that he was going to talk on one watt, I said to myself, "Good heavens, that's the same old thing all over again; that is what they always do—they keep going lower down in the scale of power, and we keep going the other way, and then they expect us to live together decently when we are both so far apart!"

So it brings to my mind this thought: What are the advantages to be gained by the use of approximately one watt in our telephonic intercommunication over the high lines? I would like to ask Mr. Slaughter if he thinks that is going to be ample to do our work?

Then there is the matter of coupling. I would like to ask if there is going to be any real gain in the use of condensers for coupling?

Then you know we have talked a lot about the telephone people getting off the ground with the power engineers, and the power engineers seem now to be getting back on the ground again. Now here comes along an organization, and they are getting off the ground again. What is the advantage of the full metallic circuit?

It seems to me that in starting out on a program of intercommunicating power lines or interconnecting power lines, our intercommunication system, if it is going to follow along our lines, should be ample; should be such that it can be used universally, and we should not spend time or effort in setting up a great number of systems and then later on in our stage of development find that some or most of it is all wrong.

Leonard F. Fuller: This paper describes work in which the interphase, or all-metallic, carrier-current circuit was employed, as shown in Fig. 1, in which 1 and 2 are coupling wires, or high-voltage coupling condensers, through which energy from transmitter T is fed to line conductors a and c and then to receiver R through coupling means 3 and 4.

The circuit comprises T, 1, 3, R, 4 and 2.

If either conductors a or c open, test has shown that although the circuit is interrupted metallically, it remains closed electrically because of the capacitance between the unbroken conductor b and each portion of the interrupted conductor. The ground of the broken conductor at each end of the break seems to make little difference.

When both conductors a and c are broken and fall to earth, the condition is serious.

In Fig. 2, is shown the ground-return carrier-current circuit, in which 1 and 2 are coupling wires, or coupling condensers, arranged to feed into line conductors a, b and c operating in

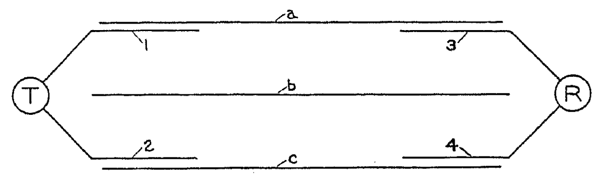

FIG. 1

parallel. In this case, the earth completes the carrier-frequency circuit, and the interruption and grounding of any two of the three conductors has very little effect upon the energy arriving at the receiver from the transmitter T.

In the case of twin-circuit lines, five of the six line conductors may be interrupted and grounded without seriously interfering with the carrier communication.

This, in itself, is a feature distinctly in favor of the ground-return method, but on the other hand, the power required for communication between two points on a transmission system is very much less with the interphase method. Thus, if the power used with the interphase connection is increased to that necessary for successful operation with the ground return method, the transmitter of the interphase system will be able to operate through even more serious line interruptions than is possible with the ground-return circuit.

The losses occurring in the case of the ground-return method, which require more power output from the transmitter, probably occur in the earth portion of the circuit.

It is possible that one reason why the interruption of all conductors is a more serious matter with the ground-return method than with the interphase system is because the group of line conductors which operate in parallel carrying the carrier-frequency current are usually considerably farther above the earth than the distance between phases, thus making the reactance of the circuit through which the carrier current is circulating much higher in the case of the ground-return method. Thus, a higher quadrature voltage is required to circulate a given current, and when all lines are down, the e. m. f. which must be induced at the receiving end of the break to produce a suitable

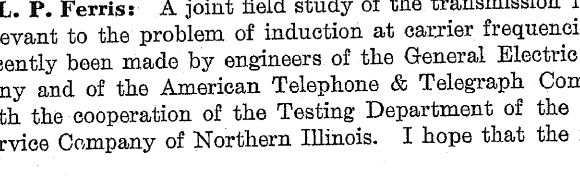

FIG. 2

received signal is much higher in the case of the high-reactance ground-return circuit.

For these reasons, the interphase method of operation is rapidly coming into favor for this type of communication.

L. P. Ferris: A joint field study of the transmission factors relevant to the problem of induction at carrier frequencies has recently been made by engineers of the General Electric Company and of the American Telephone & Telegraph Company, with the cooperation of the Testing Department of the Public Service Company of Northern Illinois. I hope that the results

of this work may be made generally available in the near future. Some of the results relating particularly to the questions of line and transformer characteristics may be of interest now in connection with the discussion of the present paper.

Fig. 3 shows the ratio between the current received at the end of a 17-mile section of a 33,000-volt transmission line to the current sent into the line, for a "metallic circuit" of one pair of wires and also for a circuit made up of the three wires of a line with ground return. These curves are not smooth because the terminating resistance departs from the exact characteristic impedance of the circuit, as defined in the paper. At the time these tests were made the characteristic impedance of the circuit had not been accurately determined. The irregularities in the curve are probably due in a large measure to this departure from the correct characteristic impedance, under which conditions reflections from the far-end of the circuit are to be expected. Because of the much larger attenuation in the grounded circuit, these reflection irregularities are less pronounced in the lower curve. Particularly at the high frequencies this curve becomes relatively smooth.

The curves in Fig. 1 bring out clearly the large difference in the attenuation in the "metallic" circuit and the circuit of the three-wires-to-ground. At 85,000 cycles the current received in the grounded circuit is 1/9 and the power, therefore, about 1/80 of that received in the "metallic" circuit for the same current and power transmitted. As noted in the paper under discussion, this difference is an important advantage in favor of the metallic circuit for this type of system.

The values of the current ratio above unity for the upper curve in Fig. 1 are due to the terminal irregularity and, of course, do not represent an increase in power although the received current may be larger than that transmitted.

In a foot note at the bottom of page 1 the authors give a formula by which the current ratio for a line of any length may be calculated from the ratios for a different length taken from the curve. This formula may be written in several other forms. For example, if R_2 is the ratio $\frac{I_r}{I_t}$ for length L_2 and R_1 is the corresponding ratio for L_1, then the equation may be written $R_2 = R_1^{\left(\frac{L_1}{L_2}\right)}$. This may also be written as $R_2 = \log^{-1}\left(\frac{L_2}{L_1}\log R_1\right)$. Either of these forms is useful in making simple calculations, and the first of the two may be particularly advantageous where use is made of the log-log slide rule.

Because of the losses in power transformers bridged across the circuit, the question of the impedance presented by apparatus of this character at the carrier frequencies is of considerable importance. Messrs. Slaughter and Wolfe show the variation of the impedance between two terminals of a grounded Y-delta transformer bank, with the secondary side sort-circuited and with it open. It is of interest to examine the variation of impedance of a single transformer with frequency, and also of the Y-connected bank when the impedance is measured from the three wires of the line to ground. Fig. 2 gives the impedance-frequency characteristic of an 8333-kv-a. transformer rated at 21,000 to 12,000 volts. This is a single-phase unit operated in a 25,000-kv-a. bank on a 33-kv. system. The curve shows the impedance-frequency variation for five resistances across the secondary terminals. These are 0, 17.3 ohms, (which is the resistance required to give full load current of unity power factor) 1000 ohms, 6800 ohms and infinite resistance The effects of resonance of the transformer windings at certain frequencies are shown very clearly The curves for low secondary impedance show low values of primary impedance in the lower frequency range with humps appearing at about 43,000 and 70,000 cycles. The high secondary impedance curves show large values in the lower frequency range, trailing off to low values at the higher frequencies Where a metallic circuit is used and transformers connected in star, the bridged impedance presented to that circuit will be twice the impedance of one transformer, as may be seen from Fig 2 of the paper where the impedance is measured between two terminals with two transformer windings included between them, In the range above 30,000 cycles, the lowest bridged impedance obtained for any value of secondary impedance shown in (Fig 2) is approximately 1500 ohms, or the equivalent of 3000 ohms for two transformers in series. For the lower secondary impedances which are much more likely to obtain under practical conditions the primary impedances are generally considerably higher.

Fig. 3 gives the impedance of a bank of three transformers of the same type as used for the measurements on the single unit just discussed. For this test the bank was connected Y-delta. The delta was closed and the impedance was measured between the three line terminals in parallel and the neutral. It will be observed that this transformer bank introduces a bridged impedance between the three wires and ground varying between 500 and 6500 ohms in the range of above 30,000 cycles. In this range the impedance at any frequency is less than twice the impedance of a single transformer at that frequency as shown by (Fig. 2). From this and other cases giving similar results, it is believed that the use of a two-wire metallic circuit is to be preferred to that of the circuit between the three wires and ground from the standpoint of bridged losses due to Y-grounded transformer banks.

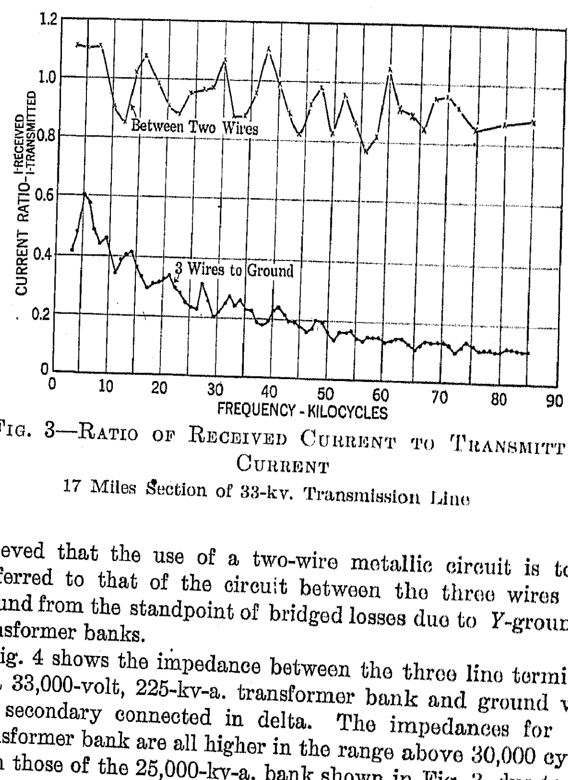

FIG. 3—RATIO OF RECEIVED CURRENT TO TRANSMITTED CURRENT

17 Miles Section of 33-kv. Transmission Line

Fig. 4 shows the impedance between the three line terminals of a 33,000-volt, 225-kv-a. transformer bank and ground with the secondary connected in delta. The impedances for this transformer bank are all higher in the range above 30,000 cycles than those of the 25,000-kv-a. bank shown in Fig. 3, due to the lower power rating of these transformers, and similarly higher impedances were found for the single units comprising this bank. The three curves on this slide show the primary impedances under the following conditions:

1. Primary neutral isolated, leads from secondary delta open.
2. Primary neutral grounded, leads from secondary delta open.
3. Primary neutral grounded, leads from secondary delta short circuited.

In the major part of the carrier range these curves show that grounding the neutral to the case reduces the impedance to about half its value with neutral isolated.

Fig. 5 is shown in order to exhibit the manner in which the impedance of the three wires of a line in multiple to ground varies with frequency. The dotted curve shows the impedance

to ground with the far-end of the circuit clear of ground, whereas, the solid curve shows the impedance with the far-end grounded. The peaks of these curves are, of course due to reflections from the open or short circuited distant end of the line and the frequency intervals between peaks are determined by the velocity of phase propagation and the length of the section measured. Because of the increase in attenuation as the frequency is increased the magnitude of these peaks diminishes towards the

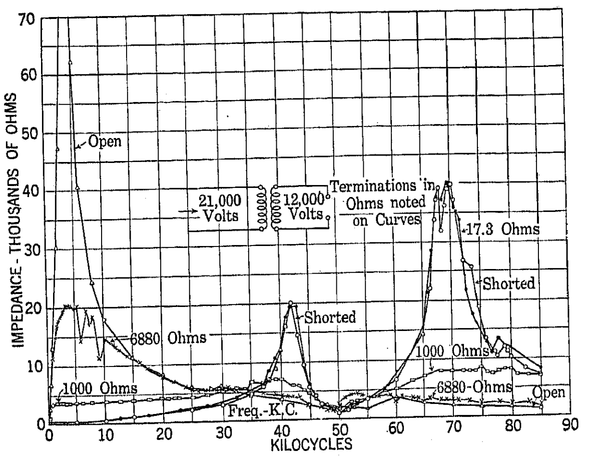

FIG. 2—TRANSFORMER IMPEDANCE
8333-kv-a. Transformer, 21,000-36,300 Y/12,000 Volts.

higher frequencies. It may also be noted that at the upper end of the frequency range these curves are approaching a common value, which is the characteristic impedance of the circuit or the impedance that the circuit would present if it were infinitely long. As noted at the bottom of page 1 in the paper the characteristic impedance of the line (or the impedance with which it must be terminated to avoid reflection) is given by the formula

$$Z_c = \sqrt{Z_o \times Z_s}$$

where Z_c is the characteristic impedance, Z_o is the impedance

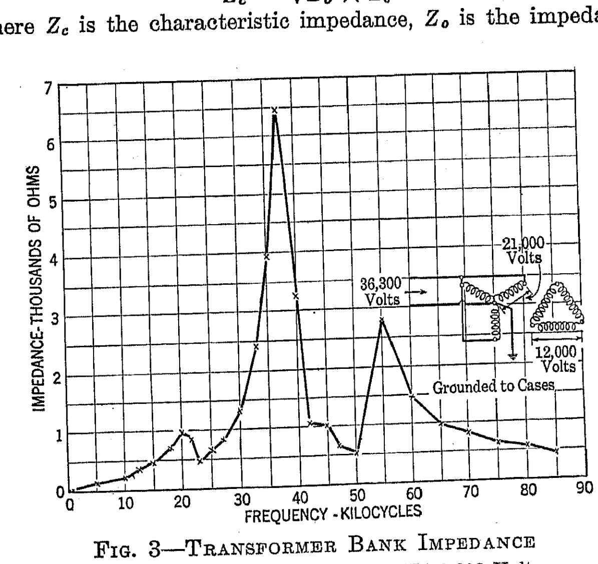

FIG. 3—TRANSFORMER BANK IMPEDANCE
3-8333-kv-a. Transformers, 36,300 Y/12,000 Volts.

with the far-end of the circuit open and Z_s is the impedance with the far-end of the circuit short-circuited. The characteristic impedance for this line has been calculated from the open and short-circuited impedances and plotted on the curve for reference. It varies somewhat with frequency and lies in the range between 400 and 470 ohms. This slight variation is explainable by variations in the gage and arrangement of the conductors along the line.

It should be pointed out that not only the impedances but also the attenuation factors for high tension lines vary over a considerable range for different types of circuits and also vary considerably for circuits of the same type, depending upon circuit conditions. Variations are produced by the presence of other wires (including ground wires) on the same lead which absorb energy. It is very difficult to say just how these variations are produced or to give any reliable method of calculating their effects. For approximate calculations, however, it is permissible to assume that the attenuation factors for one line may be applied to another line of similar construction when the appropriate circuit lengths are taken into account.

G. Y. Allen: The matter of attenuation was rather interest-

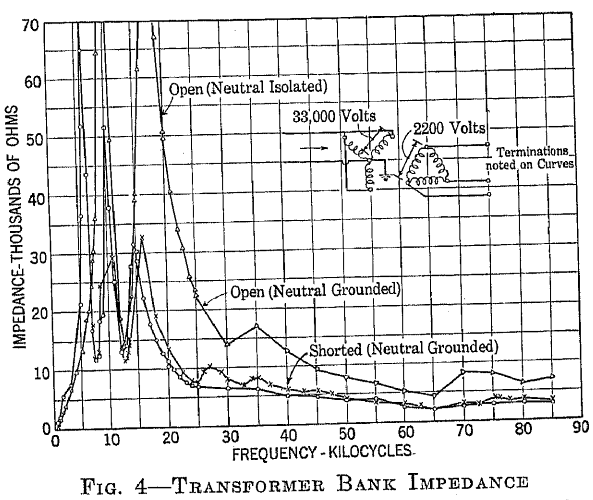

FIG. 4—TRANSFORMER BANK IMPEDANCE
3-75-kv-a. Transformers, 33,000-11,000 2420-2200-1980 Volts.

ing to me. Fig. 1 of Col. Slaughter's paper shows the attenuation for a typical power line with no connected apparatus and with an impedance connected at the receiving and transmitting ends of the line corresponding to its surge impedance. Under those conditions, of course, there will be no reflections along the system and the attenuation can be easily calculated.

Fortunately or unfortunately our pioneer experience was obtained on the lines of the Duquesne Power Company of

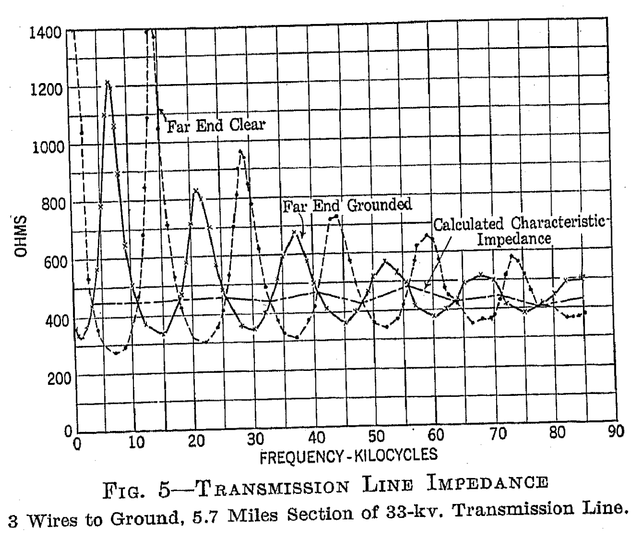

FIG. 5—TRANSMISSION LINE IMPEDANCE
3 Wires to Ground, 5.7 Miles Section of 33-kv. Transmission Line.

Pittsburgh. In contradistinction to a straight line, with no connected apparatus, the Duquesne System consists of distribution rings of various voltages to which are connected a vast amount of apparatus. In attempting to apply carrier-current telephony to this system, it was very difficult to predict the results from day to day. The apparent reason is that with so

much connected equipment and with such a complex network the constants of the line changed rapidly, even from hour to hour, and the performance of such a network cannot easily be calculated. We found, for instance, that it was necessary to change the wavelength that was used in order to insure communication even during as short periods as one hour.

I merely bring out this point to emphasize the fact that the calculation of the performance of a network is not always as simple as Fig. 1 in Col. Slaughter's paper would indicate. As a matter of fact, our experience indicates that the majority of networks are much more complex than the one Col. Slaughter has considered. It is on account of this indeterminate factor that the Westinghouse Company has constantly advocated the use of surplus power to reduce the probability of interruption of communication to a minimum. It is a well appreciated fact that communication is most essential in time of trouble. If carrier-current telephony is to serve the power industry as it must be served, it must operate during abnormal line conditions.

There is one other thing in connection with coupling that I desire to touch on. Col. Slaughter states that the efficiency of condenser coupling is much greater than antenna coupling. This is probably true. Our results have indicated that instead of getting approximately 80 per cent of the energy in the oscillating circuit on the system, which is probably the efficiency of condenser coupling, antenna coupling may give considerably less. We appreciate this relation and our only reason for continuing to use antennas is on account of the reduction of hazard, and also due to the fact that on high-voltage lines we have not yet seen a condenser that we feel will stand up. We have some thoughts worked out on paper for the improvement of antenna coupling and our present policy is to continue to use antenna coupling for potentials of about 30,000 volts.

E. R. Craft: It seems to me that what the power companies are going to need is a means of intercommunication and intra-communication which will render the most reliable service at the least possible cost. Whether or not it will be antenna-coupled or condenser-coupled, it is going to be worked out eventually and adopted.

It is not a question of using one watt or 500 watts of energy, but of obtaining the system fundamentally most efficient for the purpose. Then there can be used whatever amount of power is required.

In considering the type of system that is going to be employed by any individual operating company, thought must be given to how this is going to work into the other systems with which it must connect sooner or later. Take the Southeastern district, for instance. The system is not the system of the Alabama Power Company nor that of the Georgia Railway and Power Company. It is the power network of the entire district.

W. V. Wolfe: Considering Mr. Wills' discussion, his first question was: "What are the advantages of low power over those of higher power?" Mr. Craft has already answered that in a certain measure and there are only one or two points which I want to make in connection with that. The first is this: A telephone system must be duplex in its operation, in order to be a telephone system. The problem of making a telephone system duplex increases materially as the power which you use in transmitting increases. As we have pointed out in our paper, you have to operate your transmitting circuit in parallel with your receiving circuit. The ratio of power required to operate the receiving circuit to that required for the transmitting circuit may be of the order of 10,000 to 1, and obviously as you increase that transmitted power, the difficulties of keeping those two things separated increase very materially.

Mr. Wills' second question was with regard to the coupling wire versus the condenser. In the first place, the coupling wire does not give as safe a method of coupling to the power line as the condenser does, first, because the coupling wire extends 1000 or 1500 ft. in parallel with the power conductor itself. It is true that it is put up in the same manner, of the same size conductor, and in every way as nearly as possible the same construction as the power line itself, and the possibilities of its failure are no greater than those of the failure of the power line, but power lines do fail, and this 110,000 volts or higher may come in contact with the antenna wire over this range of 1000 or 1500 ft. By using the condenser, we put that possibility of failure in one spot: we don't extend it over 1500 ft.; and in addition to that, the condenser, because of the different methods with which it is used in coupling to the power line, gives a scheme which is very much safer than the coupling wire.

In connection with that I want to say here that in our demonstration or proposed experimental work at Magella, we had the failure of a condenser, probably due to the condenser being damaged in shipment, but at any rate, regardless of the reason for the failure of the condenser, this condenser failed while the man was talking on the circuit. This man who was talking on the circuit when the condenser failed is in the room this evening; he was listening on the circuit at the time of failure. The only thing that happened was that he got a little click in the receiver, and he was called out by the operator of the station who had heard the fuse go out. I don't think we can assume the same degree of safety with the antenna wire strung parallel to the power line wire for a distance of 1000 or 1500 ft.

Mr. Wills also asked the advantages of the full metallic circuit over the ground-return circuit. Dr. Fuller has pointed out many of those advantages; our friend from the Westinghouse Company has also pointed out some of those advantages. There is one thing which I believe neither of those gentlemen has pointed out, and that is this: That the antenna scheme of coupling on a full metallic or a ground-return basis leads to a certain loss due to radiation of power from this coupling device. With the ground-return circuit, the radiation, as measured in experimental work which we have done, is of the order of four times that encountered in the full metallic circuit. That in itself is not important, except for the fact that the business of radio communication, of broadcasting, is developing at a tremendous rate in this country, and the government is very anxious to keep radio where radio belongs. It is only a question of time till a carrier system or any other system which radiates into the ether will have to meet certain government requirements. They may not be the same requirements that are asked now for a radio station, but they will certainly have to be regulated by the government.

One question which Dr. Fuller brought up was the question of one wire failing on a full metallic circuit. The only thing I can say there, and the only thing I believe we can say for any carrier circuit or any communication or power circuit is this: That as long as the circuit is intact, you will be able to talk through it. What constitutes a carrier circuit may be something entirely different from what constitutes a power circuit. A failure of one wire may, under certain conditions, constitute a failure of a carrier circuit; under other conditions it may not constitute a failure of a carrier circuit. I may say, under certain conditions, we have not only been able to talk through it with one-wire conditions, but we have talked with three wires opened and grounded. It may result in a failure of the carrier circuit, but does not always result in such a failure.

Another thing in connection with the ground return and the full metallic circuit is this, as pointed out by Dr. Fuller and Mr. Allen: The fact that in the ground-return circuit, if you take the transformer off the line, you are going to change the character of the ground-return circuit from a transmission standpoint, and that change may be of an order of magnitude which may result in a failure of the carrier system to operate. We don't find that condition to be true in the full metallic circuit. We have at all times operated our experimental metallic circuits without information as to whether there was a transformer on here or on there; it made no difference.

There is just one other point I want to mention, and that is the cost of condensers as compared with the cost of antenna schemes. I think the point there has been overlooked. The important thing in a communication system, which may mean the successful operation or the failure of the operation of a power system, is not the cost; the cost of these condensers being small as compared with the cost of the power apparatus used in a big power network. If they are going to mean the difference between a successful carrier system and an unsuccessful carrier system, then I do not believe that any power company can afford to let the economics of that thing hold them up.

High-Voltage Oil Circuit Breaker Tests, Alabama Power Company System

BY J. B. Mac NEILL
Associate, A. I. E. E.
Electrical Engineer, Westinghouse Electric & Mfg. Co.

IN conjunction with the Alabama Power Company, a series of 50 high-voltage oil circuit breaker tests was made during May and June of 1922. The Bessemer substation of the power company was chosen as the location for these tests due to the large power concentrations that were possible on short circuit, the possibility of maintaining system voltage under short circuit to the greatest extent and because it was felt that less interruption to service would occur if tests were made here than elsewhere.

As far as is known the Alabama Power Company was the first to conduct a comprehensive set of tests with necessary oscillograph apparatus and facilities for observation on 44,000 volts and 115,000 volts. Of the fifty tests made on Westinghouse breakers, 36 were made on 44,000 volts and fourteen were made on 115,000 volts. The maximum generating capacity connected to the system on 44,000-volt tests was 145,000 kv-a. The maximum generating capacity connected to the system on 115,000-volt tests was 188,000 kv-a. in addition to a tie with the Georgia Power System. The maximum power actually opened was 3660 amperes at 44,000 volts, and 2850 amperes at 110,000 volts, which give approximately 250,000 kv-a. three-phase at 44,000 volts, and 542,000 kv-a. three-phase at 110,000 volts. A glance at the power system set-up and the amount of generating apparatus connected will show that these tests were made under power conditions comparable to those on the larger of the systems throughout the country.

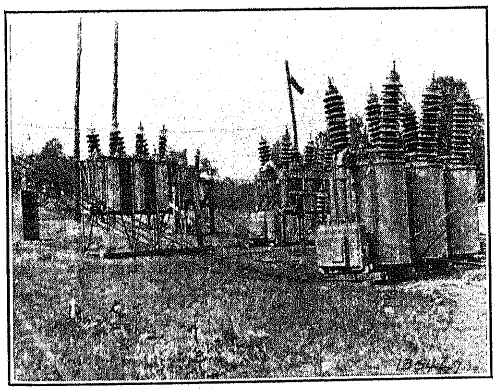

FIG. 1—TEST YARD SET-UP

Three types of circuit breaker were tested on 44,000 volts, these being the old 45,000-volt type *G B* breaker, the modern 50,000-volt *G*-11, and the modern 73,000-volt *G*-11 breaker. Two breakers were tested on 110,000 volts, namely the 115,000-volt modern *G*-11 breaker and the old 110,000-volt type *G A* breaker. It was originally intended to test the 115,000-volt type *G*-2 breaker, but this breaker was in active service in the substation and as the maximum power available did not tax the capacity of the lighter breakers, it was not felt necessary to test the *G*-2 breaker. All breakers tested were of the outdoor type, electrically operated with plain break contacts, and equipped with ordinary accelerating devices.

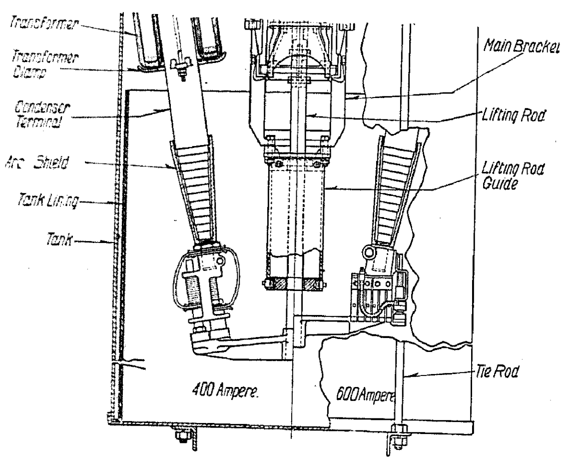

FIG. 3—50,000-VOLT G-11 CONTACTS
73,000-VOLT G-11 CONTACTS

The method of making the test has been described in another paper but we will mention that the current transformers used with the oscillographs were given a special calibration test at the factory after the tests were over, and all current values have been corrected accordingly.

TESTS ON 50,000-VOLT TYPE G-11 OIL BREAKER

Table I gives a summary of the test data on this breaker. Fig. 2 shows the breaker as arranged for test. Fig. 3 shows the standard type of contact used. This breaker is equipped with baffled vents and on heavy short circuit threw some oil through these vents. While there is nothing of particular interest in connection with the tests on the standard breaker, test No. 9 on a special arrangement of the breaker may be of some interest. For this test the breaker had been equipped with one muffler per pole, the idea being to prevent an oil spray coming through the vent. This test represented practically the maximum available on the 44,000-volt system, the oscillograph reading showing 3140 amperes on the *A* phase, and 3600 amperes on the *B* phase. The back pressure in the tank due to the muffler caused the *A* phase tank to split along the bottom seam as shown in Fig. 4. The conclusion to be drawn therefore from the application of mufflers to relatively lightly constructed high-voltage breakers is that a point in rupturing capacity is reached where the internal stresses caused thereby are beyond the strength of the breaker. The breaker when equipped with mufflers is not capable of relieving it-

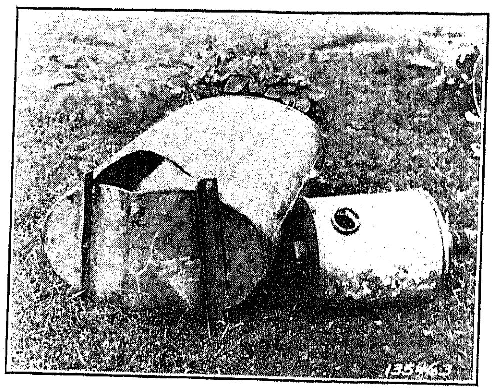

FIG. 4—MUFFLER AND TANK—50,000-VOLT G-11 BREAKER

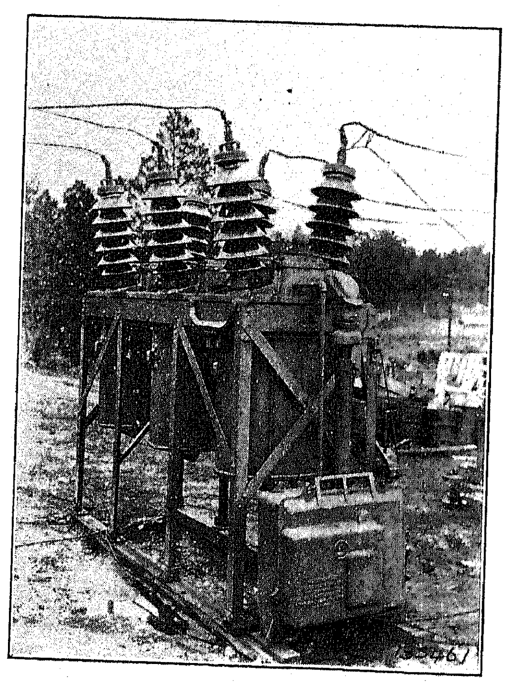

FIG. 5—73-KV. G-11 BREAKER

self as readily as with the open vent and as a result the breaker is damaged at a current below what it would have opened with the open vent. This statement has no reference to the application of mufflers to breakers constructed to withstand high internal pressures.

Deterioration of the contacts was limited to rather slight pitting of the arcing tips and there was no damage to the tank lining. Several specimens of oil were taken from tanks during the test and they indicated that

after the oil had settled a while it still retained insulating value suitable for further service, being in general well up towards normal dielectric strength.

Tests on 73,000-Volt Type *G*-11 Breakers

This breaker is rated at 2400 amperes at 73,000 volts

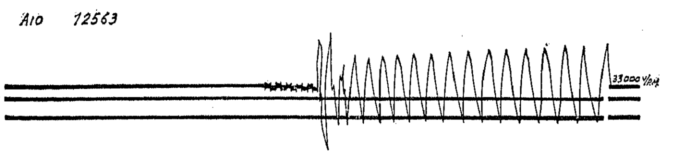

Fig. 6—Showing Voltage Reestablishment on 44,000-Volt System with No Ground Near Point of Short Circuit

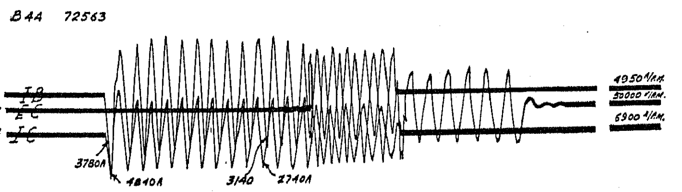

Fig. 7—Showing Voltage Reestablishment on 44,000-Volt System with Ground at Short Circuit

and the maximum current opened on it was 3660 amperes at 44,000 volts. The breaker is shown in Fig. 5 and contact construction is shown in Fig. 3. A summary of the tests on this breaker is given in Table II. Three of the tests were single interruptions of a three-phase ungrounded short circuit and the last two formed a duty cycle consisting of two interruptions at a two minute interval on a three-phase grounded short circuit. On test No. 43 considerable oil was thrown from all tanks, probably amounting to as much as ¼ in. from each tank. This was due apparently to a partial gas explosion in the top chamber which forced oil between the frame and the tank. On the succeeding test two minutes later, the oil throw was much less, probably a half gallon total from all three tanks. On the other tests the breaker threw slight amounts of oil.

In this connection, the 44,000-volt tests were made on this breaker with the short circuit ungrounded. Fig. 6 is of interest as showing a typical voltage reestablishment under these conditions, of approximately 50 per cent overvoltage. With the short circuit ungrounded, the only ground on the 44,000-volt power system was through a single transformer bank at the Lock No. 12 generating station. In contrast to this result, note the oscillogram shown in Fig. 7 taken during test No. 44 with the system grounded at the short circuit in addition to being grounded back at the

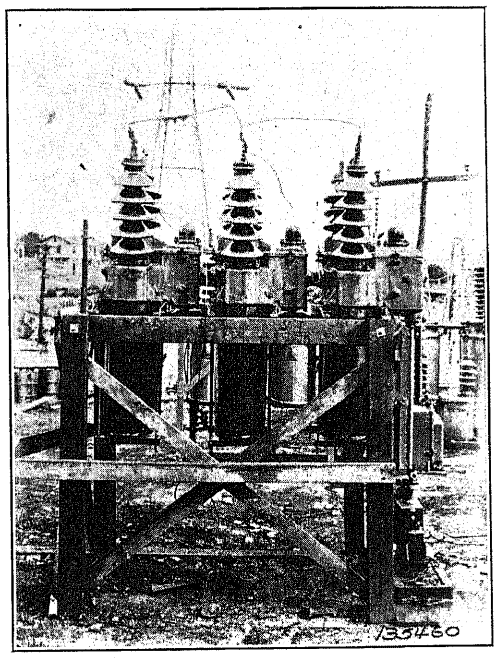

Fig. 8—45,000-Volt G. B. Breaker

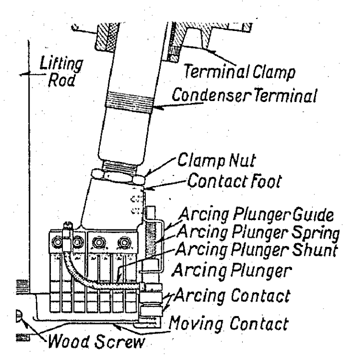

Fig. 9—G B Breaker Contacts

generating station and with approximately the same power at short circuit as in the oscillogram preceding. The complete absence of overvoltage surge with the system thoroughly grounded is of particular interest.

Tests on 45,000-Volt *GB* Breaker

The type *GB* breaker shown in Fig. 8 is an old breaker that had been on the Alabama Power Company's line since approximately 1913 and it was desirable to find out its rupturing capacity as it stood, and

with some improvements. The contact construction of this breaker is shown in Fig. 9 and the test results are given in Table III.

The breaker was tested on 44,000 volts, 60 cycles, three-phase, with grounded neutral, using a maximum total connected generating capacity of 139,000 kv-a. The breaker without modifications opened up 2000 amperes with the short circuit ungrounded with considerable emission of smoke and throwing of oil at this value.

The breaker was then altered by the substitution of some improved contact details and tested by seven single interruptions of three-phase short circuits, mostly grounded, one interruption of a single-phase short circuit to ground and one repetition on a two-phase short circuit to ground on a duty cycle consisting of two interruptions at a two minute interval, starting from the closed position. A maximum of 2900 amperes was interrupted with more or less throwing of oil on the various tests.

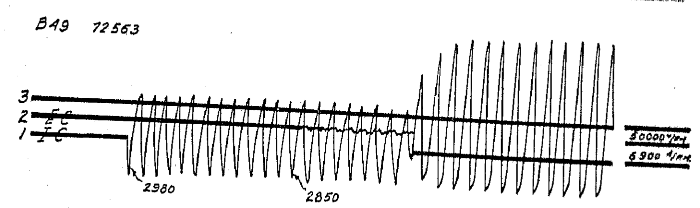

FIG. 12—115,000-VOLT G-11 BREAKER. OPENING 2850 AMPERES AT 115,000 VOLTS

Two attempts were made to close this breaker against short circuit, but they were not successful as the arrangements of the control wiring in connection with the oscillograph operation could not be properly worked out in the limited time. In the last one of these attempts, after the breaker had opened several

short circuits, and the oil was at a relatively low value, imperfect contact in the breaker caused heavy arcing and emission of flame. The breaker was mechanically undamaged except for burning on the arcing tips.

Tests on 115,000-Volt Type *G*-11 Breakers

This breaker is shown in Fig. 10 and its contact

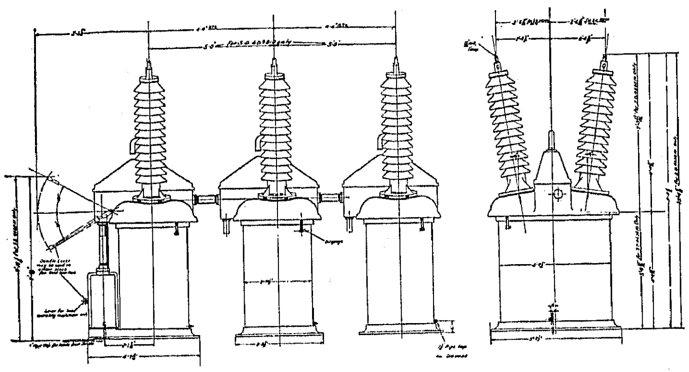

Fig. 13—G. A. 110,000-Volt Breaker

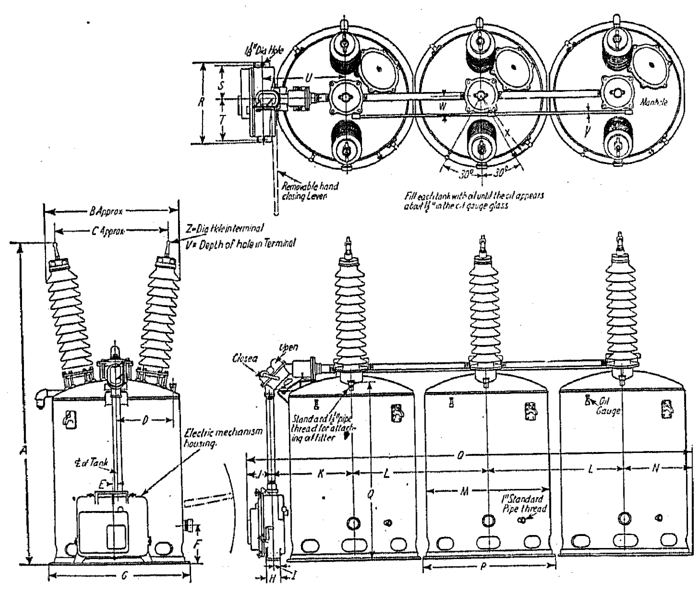

Fig. 15—115,000-Volt G-2 Breaker

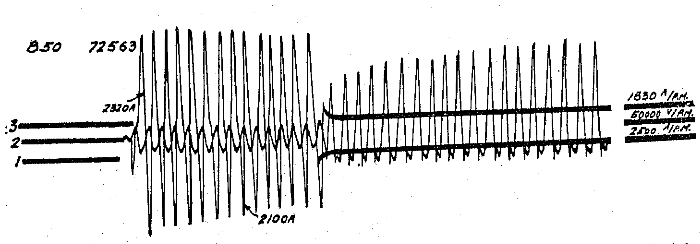

Fig. 14—110,000-Volt G A Breaker. Openihg 2100 Amperes at 115,000 Volts

construction shown in Fig. 11 while the tabulation of test data is given in Table IV. This breaker was tested on a 115,000-volt, 60-cycle, three-phase, grounded neutral system, using a maximum total connected generating capacity of 188,000 kv-a. in addition to a tie in with the Georgia Power Company which transmitted a relatively small amount. Two single interruptions were performed on a three-phase grounded short circuit; two on a short circuit from one phase to ground, one duty cycle consisting of a single interruption of a three-phase short circuit to ground followed at a two-minute interval by an interruption of a single-phase short circuit to ground; and one duty cycle consisting of three single interruptions at two-minute intervals of successive three-, two- and single-phase short circuits to ground in the order stated.

The maximum current interrupted was 2850 amperes in a single-phase short circuit to ground. At the end of the test the oil in the tanks was clear and the contacts in good condition. No oil was lost in any of these tests with the possible exception of a few drops at a terminal flange or so. These tests serve to emphasize the adequate construction of this breaker in every way and also indicate that a thoroughly grounded system such as this 110,000-volt system gives easier switching duty than one that is ungrounded or im-

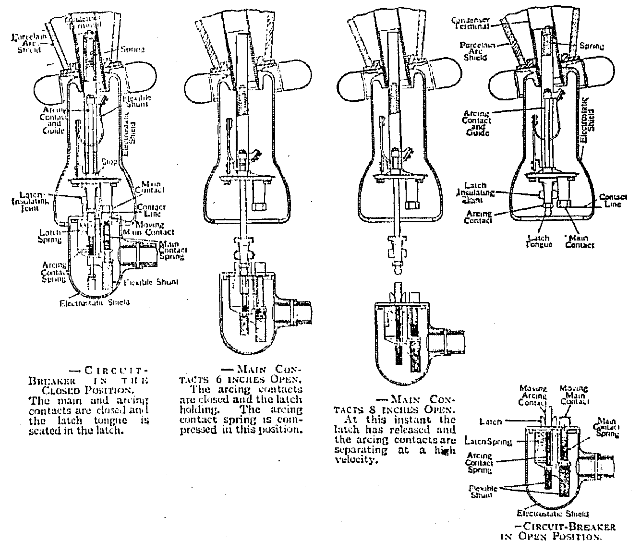

Fig. 16—High-Speed Contacts for 115,000-Volt G-2 Contacts

perfectly grounded. Fig. 12 shows an oscillogram taken in test No. 49 with the breaker opening the maximum single-phase short circuit to ground that was possible on the system, or 2850 amperes in the arc.

Tests on 110,000-Volt *G A* Oil Breaker

The 110,000-volt type *G A* breaker shown in Fig. 13 was purchased in 1913 and has been continuously in operation at the Magella substation of the Alabama Power Company. This breaker had originally an interrupting capacity of approximately 1900 amperes at 110,000-volts and was tested on the 115,000-volt, 60-cycle, three-phase, grounded neutral system, using a maximum total connected generating capacity of 169,000 kv-a. The breaker performed three single interruptions and one duty cycle consisting of two

interruptions at a two-minute interval, on a three-phase grounded short circuit. The maximum current interrupted was 2100 amperes. The only sign of distress was a slight leakage of oil from around the terminal clamps in one or two tests. It was not possible to determine the number of cycles of arcing in this breaker as the oscillograph equipment was located 14 miles away at Bessemer and the drop through the line from the point where the potential transformers were connected was so large as to make impossible the detection of the initial cycles of arcing. However, referring to Fig. 14, which shows the breaker opening a dead short circuit with 2100 amperes in the arc, and making allowance for the operating time of the mechanism, we find that the arc probably endured for 10 cycles.

115,000-Volt Type *G*-2 Breaker

As a matter of interest Fig. 15 shows the 115,000-volt type *G*-2 breakers located in the switch yard at the Bessemer station. Fig. 16 shows the contruction of the high-speed contacts used with this high-power breaker. Due to limitations of power available on short circuit, it was not thought necessary to test this breaker and it is felt that in the near future arrangements can be made for such a test. The high speed of contact separation on the *G*-2 breaker increases its rupturing capacity greatly by reducing the number of arcing. Its rupturing capacity is further increased by the mechanical strength of structure which consists of a boiler iron tank with riveted and welded top and botton domes.

Discussion

For discussion of this paper see page 655.

Circuit Breaker Tests at Bessemer, Ala.

On 300-Ampere, 110,000-Volt Breakers

BY J. D. HILLIARD
General Electric Co., Schenectady, N. Y.

THE tests herein described were made possible through the cooperative efforts of the Alabama Power Company's officials, engineers and operators. The writer desires to express his appreciation to them, and to call attention again to the value that

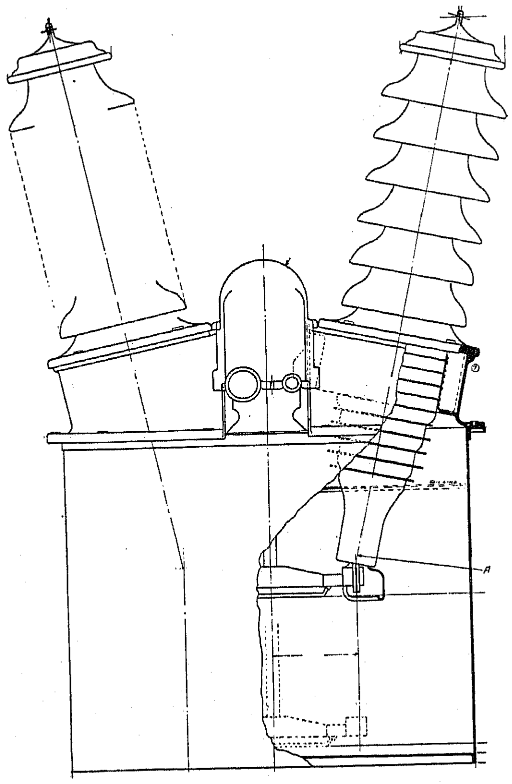

FIG. 1

properly conducted field tests have in the manufacture of apparatus.

With the increase in capacity of the generating equipment of the Alabama Power Company, the power available under short-circuit conditions became so great at various substations that it exceeded the rated interrupting capacity of the oil circuit breakers on the 110,000-volt circuits. The Alabama Company had installed on its system a large number of type *F K O-21A* and *F K O-22 A*, 300-ampere, 110,000-volt oil circuit breakers and the General Electric Company was asked if the rating of these breakers could in any way be increased and the breakers made more satisfactory to handle the increased load.

In this paper the results of the tests on the rebuilt 110,000-volt breaker, together with the tests on plain break and explosion chamber 44,000-volt breakers, are described. The 110,000-volt breakers as originally supplied to the Alabama Company were of the plain break contact-finger type shown in Fig. 1.

The arrangement of the system, the general method of test, and a discussion of the effect on the system are described in another paper presented at this session.

110,000-VOLT TESTS

These breakers were rebuilt to equip them with explosion chambers. This necessitated increasing the height of the oil tank. New insulating linings were also added. The plain break contacts originally used are shown on Fig. 2 and the explosion chamber contacts with which they were replaced and on which the tests were made are shown in Fig. 3.

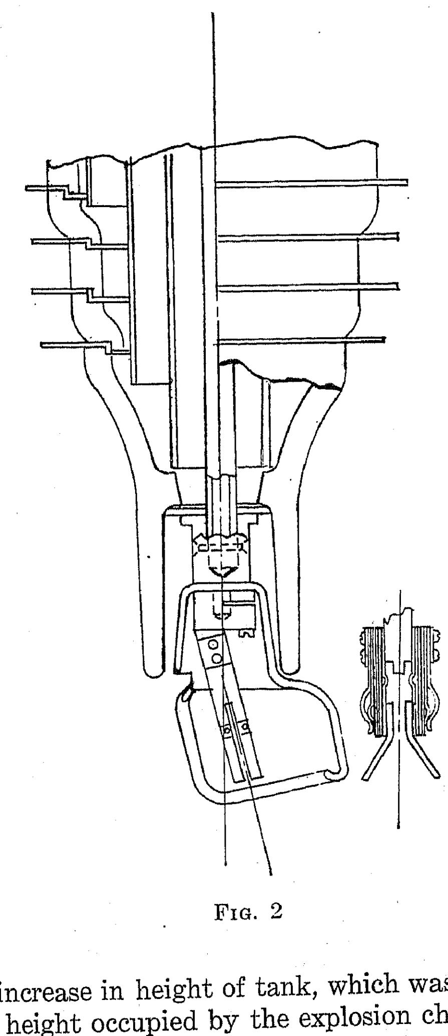

FIG. 2

The increase in height of tank, which was to provide for the height occupied by the explosion chamber, was done by the Alabama Power Company by means of an acetylene weld. The remainder of the materials necessary to make the changes were supplied by the General

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

Electric Company, all the work of installation being done by the Alabama Power Company. After the specified changes had been made on a single pole unit, tests were made upon it in order to observe its action under various short-circuit loads, and to determine that it had a safe interrupting capacity of 450,000 kv-a. under their circuit conditions. The system arrangement and line reactances upon which the tests were made are shown in Fig. 4. These tests were made during January, 1922.

During the tests, the test breaker was tapped from one line of a Y-connected grounded transmission system, namely on phase 3 of line *B* from Magella to Bessemer.

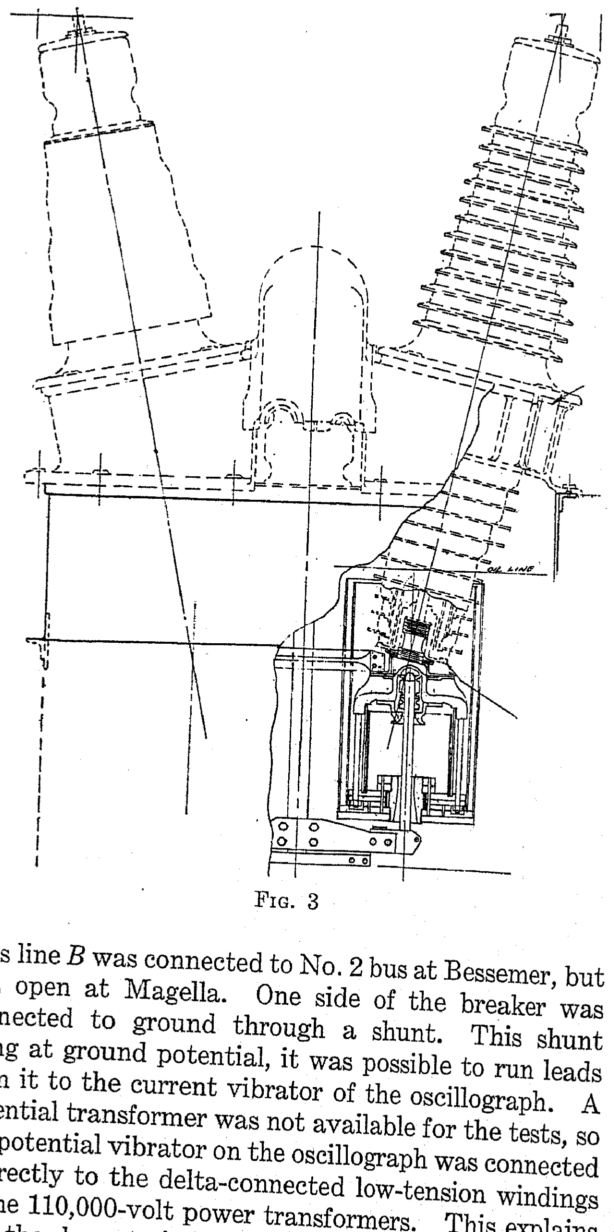

Fig. 3

This line *B* was connected to No. 2 bus at Bessemer, but was open at Magella. One side of the breaker was connected to ground through a shunt. This shunt being at ground potential, it was possible to run leads from it to the current vibrator of the oscillograph. A potential transformer was not available for the tests, so the potential vibrator on the oscillograph was connected indirectly to the delta-connected low-tension windings of the 110,000-volt power transformers. This explains why the characteristic arcing record is not shown on the oscillogram.

The short circuit was thrown on by service-breaker No. 806 and was opened by the breaker under test. In no case was the breaker under test used to close as well as to open the circuit and in this respect conformed to the Baltimore tests which preceded it. It should also be noted that all tests were made single-phase from line to ground and that the neutral of the power transformers were therefore grounded.

To avoid any possibility of injury to the oscillograph operator, the oscillographic apparatus was located upon an insulating stand.

The attempt was made in some of the tests to obtain pressure records by means of an indentation recorder—steel ball on a copper plate—but it was so slow in operation that the attempt was given up. The test records show the currents, voltages and speeds.

In considering these tests, it should be realized that an old style breaker structure was under investigation, one which had been built without any especial preventive means to guard against oil throw, and which in comparison with our present day standards was wide open for the escape of oil.

During the test, circuit connections were changed and generators added or taken off as necessary to give the desired interrupted current. The following table is a summary of the results of the tests.

R. m. s. Amps. in Arc	Equivalent kv-a. 3-Phase	Arc Length Inches	Contacts Speed Ft./Sec.	Oil Throw	Signs of Distress	Approx. Generators Connected
220	38,100	4.6	4.87	None	None	70,000 kv-a.
445	84,800	3.95	4.65	"	"	80,000 kv-a.
1215	231,000	8.35	5.56	1 pt.	2	70,000 kv-a.
1225	233,000	8.74	..	None	"	114,000 kv-a.
1560	297,000	7.87	5.48	1 pt.	"	70,000 kv-a.
1710	326,000	7.65	6.64	1 pt.	"	86,000 kv-a.
1720	327,500	8.35	5.75	1 pt.	"	144,000 kv-a.
1935	368,300	7.46	5.75	2 qts.	"	114,000 kv-a.
2010	382,500	8.86	6.25	1 qt.	"	114,000 kv-a.
2180	415,000	7.35	6.65	1 qt.	"	114,000 kv-a.
2220	422,500	7.66	6.30	1 pt.	"	144,000 kv-a.
2220	422,500	8.23	6.40	1 pt.	"	144,000 kv-a.
2225	424,000	10.00	6.55	1 pt.	"	144,000 kv-a.

The arc length was determined from the speed recorder and the design data of the breaker. The lack of a potential transformer across the breaker contacts detracts somewhat from the value of the films, but, nevertheless, there are some that are of interest in showing the nature of the results. Fig. 5 shows an interruption with a current value of 2740 amperes as the r. m. s. of the first peak of short circuit and 2220 r. m. s. amperes in the first half cycle of arc. *A* is the voltage across line 1 and 2, *B* is the current in line 3, and *C* is a speed record.

It will be noted that the decrement current was small and this is characteristic of all of the tests.

Fig. 6 shows the current and speed records on an interruption having a maximum r. m. s. at first half wave of short circuit of 2370 amperes, and 1710 amperes in the first half wave of arc.

Fig. 7 shows the current and speed on an interruption of 1610 amperes r. m. s. first half cycle at short circuit and 1235 r. m. s. first half cycle of arc. The

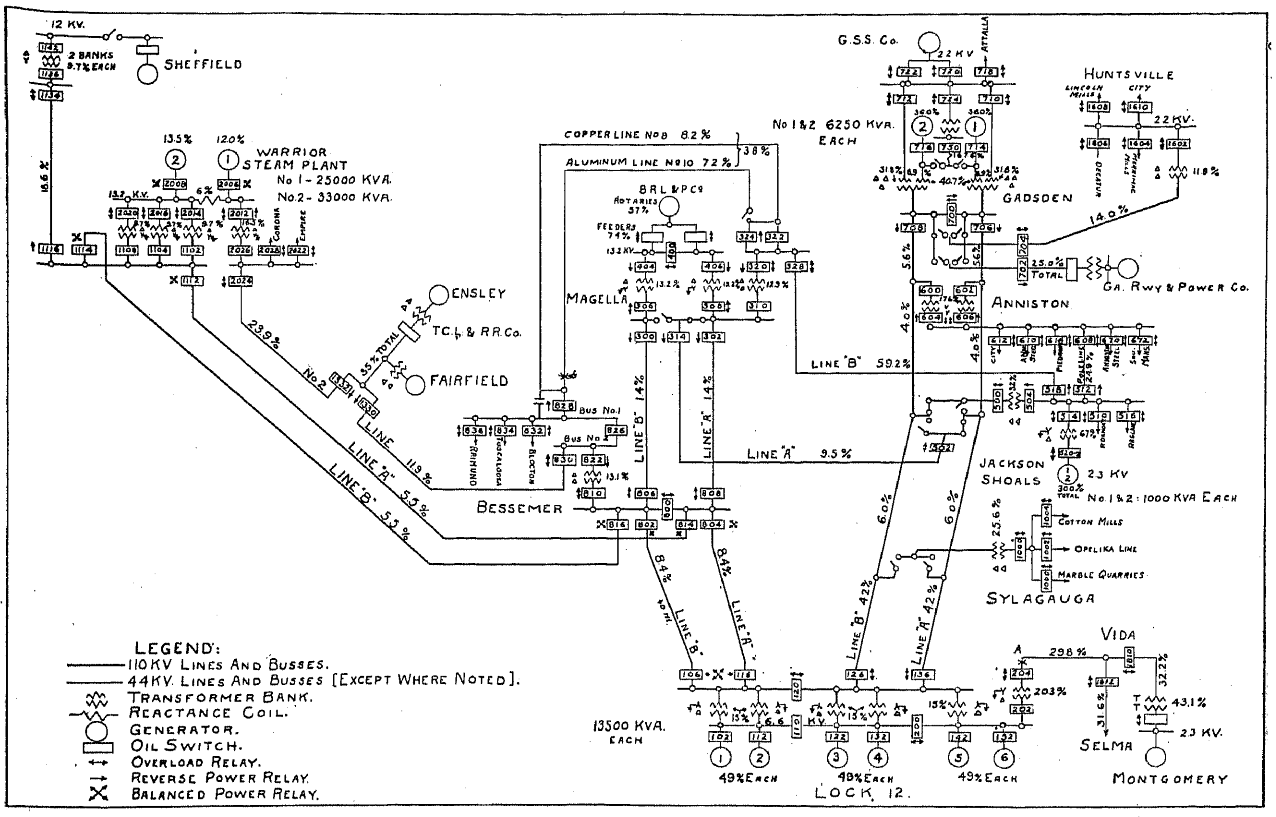

FIG. 4

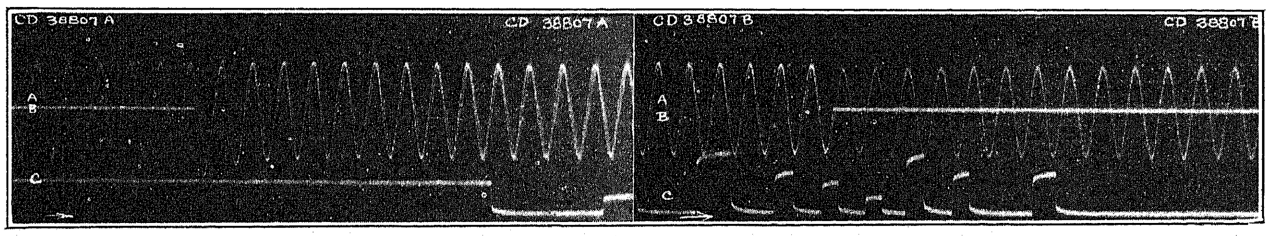

FIG. 5

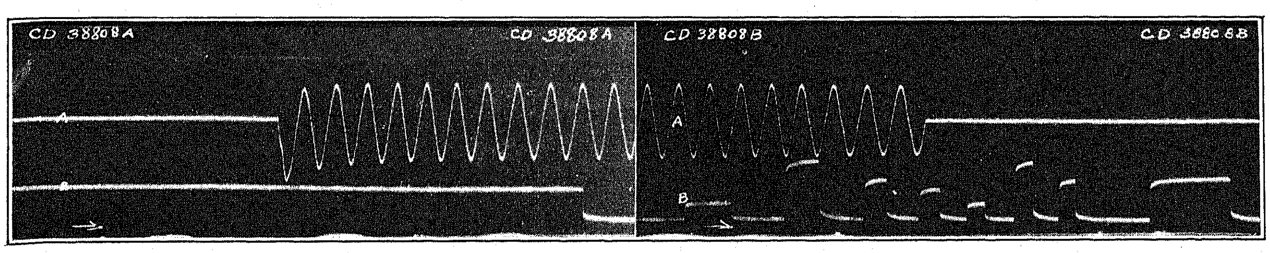

FIG. 6

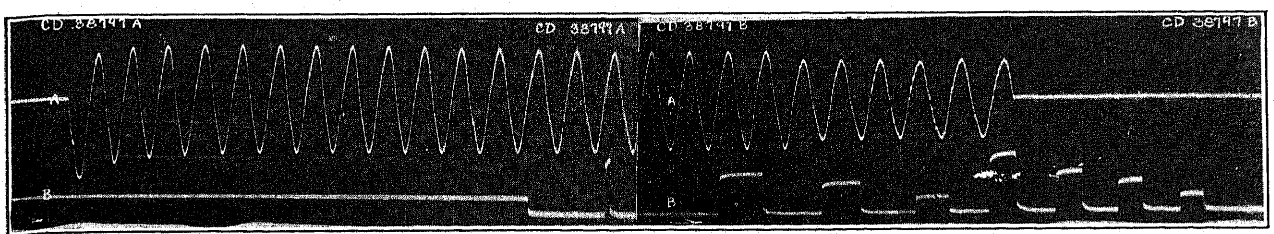

FIG. 7

falling off of current during arcing was due to breakers 106 and 308 opening before the short circuit was cleared by the test breaker.

44,000-Volt Tests

The tests at 44,000 volts were made both at Lock 12 and at Bessemer during January, 1922. The breakers

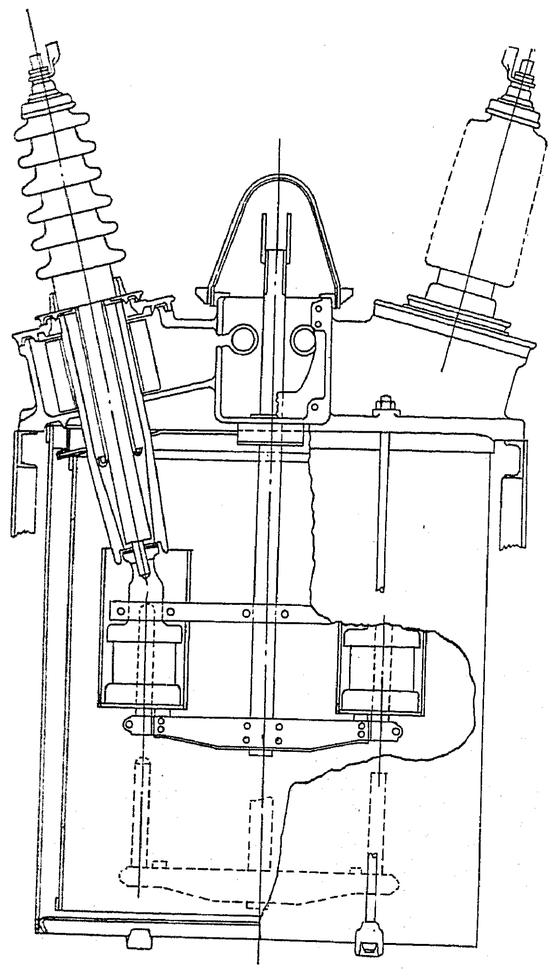

Fig. 8

tested were a 50,000-volt *F H K O*-36 *B* breaker, which had been arranged so that the explosion chamber contacts with which it is normally equipped could be replaced by plain break contacts. Both the plain break and explosion chamber contacts in this breaker were tested at Bessemer but only the explosion chamber was tested at Lock 12. The 50,000-volt explosion chamber breaker is shown in Fig. 8. The plain break contacts are shown in Fig. 9.

The 44,000-volt tests at Bessemer were made single phase by tapping the breaker onto phase No. 3 on the aluminum line from Bessemer to Magella and all tests were from No. 3 line to ground. All short circuits were closed by breaker No. 826 as shown on Alabama Power Company's diagram, Fig. 4.

On the lock 12 tests, the breaker tested was tapped onto the Montgomery circuits and the short circuits were thrown on by a transition model *K*-36-*A*, 50,000-volt breaker. All tests were made single phase from line to ground and in all cases both at Bessemer and Lock 12 the circuits from which the test line was tapped were carrying the ordinary commercial load. This latter fact should be kept in mind in considering the results of the test.

Oscillogram Fig. 10 shows an explosion chamber recorded when interrupting 1404 arc amperes. *A* is the voltage across the arcs and *B* the current interrupted. It should be noted that the arc records have all of the characteristics of the plain break arc and none of those of the explosion chamber arc. Fig. 11 shows another oscillographic record of an explosion chamber interrupting 1055 arc amperes and the remarks made above apply here also. Both of the above records were made at Bessemer. Fig. 12 shows an oscillogram of plain break contacts, when interrupting 1005 arc amperes and Fig. 13 shows the same breaker when interrupting 980

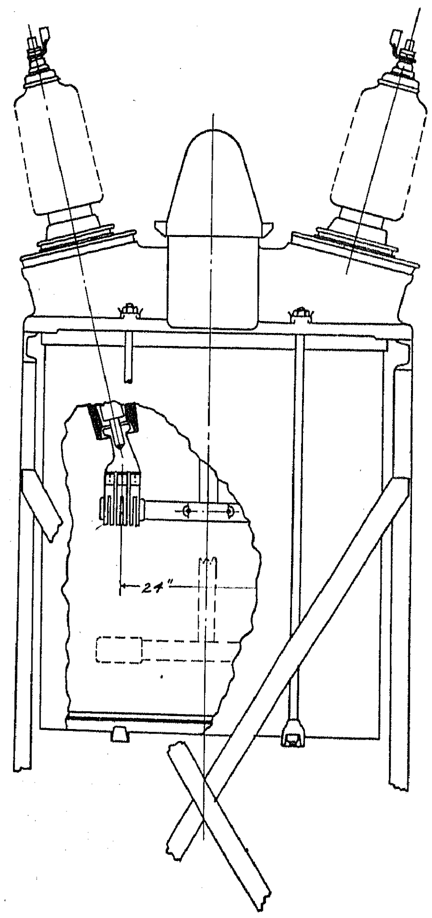

Fig. 9

arc amperes. Both the above oscillograms show the regular characteristics of the plain break arc and should be compared with the explosion chamber arcs of Figs. 10 and 11.

The results of the Lock 12 tests, as would be expected from the test conditions, did not differ from those made at Bessemer, and no especial remarks need be made

concerning them, except that they were stopped by the failure of a power transformer, failure taking place about 0.30 of a second after the test breaker had cleared the circuit. Inasmuch as the currents interrupted during these tests were comparatively small, the results, as would be expected under such conditions, do not show the full advantage of the explosion chamber. At such low currents the explosion chamber breaker functions very much as a plain break breaker.

In order to be efficient, the explosion chamber breaker must operate at high pressure in the chamber, hence a breaker designed to have an interrupting capacity of 3850 amperes at 44,000 volts, (the real interrupting capacity of the explosion chamber breaker tested) does not begin to show its remarkable current-interrupting capacity until approximately the safe limit of the plain break contact in the same tank is reached. Up to about that time it functions largely as a plain break breaker and is given the break distance required by such a breaker. From that point on, the gas pressure acting on the rod increases, the breaker speed increases, the arc becomes shorter and at maximum rating the arc duration is a minimum. The designer has full control of these characteristics and the breaker as a whole can be largely designed to meet any particular condition. The ability to control the speed of operation of the contacts by means of the gas pressure in the explosion chamber is of great operating value, as this pressure takes the place of accelerating springs, but offers no resistance to closing, as do the springs.

Conclusions

The tests herein reported indicate in the case of the 110,000-volt *K*-22 breakers that the interrupting ability of the breaker could be materially increased by the addition of explosion chambers. Although no data on the operation of the breakers without explosion chambers were obtained during the tests, the performance of such breakers was observed under actual service conditions prior to the test, so that a fairly accurate knowledge of their interrupting ability was obtained.

As has already been stated, the current available on the 44,000-volt tests was not sufficient to stress either the plain break or the explosion chamber breakers. It is not believed that the tests at Bessemer produced as severe a duty on the breaker as might be obtained under other conditions with the same current interrupted. This statement is based on the general knowledge of the factors affecting interrupting duty.

These factors, as determined by the system itself and the method of tests, operate in such a way that in my opinion the duty on the breakers was not maximum for the currents interrupted. Upon another system or in another location, the arc lengths might have been much longer at the same currents interrupted and that would mean more gas, greater pressures and decreased factor of safety.

All should realize that 1,000 amperes, for instance, interrupted at a definite voltage does not necessarily mean a definite stress to the circuit breaker. It does not mean a definite arc length nor a definite quantity of gas generated, as everything depends upon the existing conditions at the time of interruptions.

The manufacturer must necessarily design circuit breakers to safely rupture their rated current under the worst obtainable conditions. There are certain locations, however, where the conditions are such that the duty is light and it is reasonable for the power company to take advantage of such conditions in the breaker installations, provided it is understood that a change in conditions may make the breaker unsafe.

If any discounting of the absolutely safe interrupting rating of the breaker by the manufacturer is made by the power company it should be on its own responsibility, because it is the power company who has the knowledge of and control over the conditions.

It is my opinion that all primary breakers should be constructed so that they are safe with a definite minimum factor of safety under the worst obtainable conditions.

Discussion

For discussion of this paper see page 655.

Oil Circuit Breaker Investigation

as Carried on with a 26,700-Kv-a. Generator

BY J. D. HILLIARD
Non-Member
General Electric Co., Schenectady, N. Y.

Although oil circuit breakers have been used for a number of years and many successful designs produced, the work of the designer has been handicapped by the lack of definite design constants, based on experimental results. On some of the earlier designs, field tests were relied upon for the confirmation of the interrupting rating. Such tests were of great value, but, due to the inherent erratic behavior of oil circuit breakers as a current interrupting device, the data obtained was not usually of a general or fundamental nature. To remedy this situation and to permit continuous and consistent research on the interrupting characteristics of alternating-current circuit-controlling devices, a special testing equipment was installed.[1]

Testing Equipment

This station contains a three-phase specially built

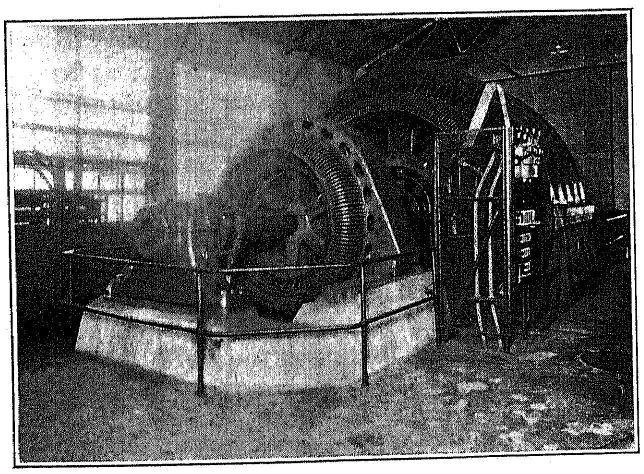

Fig. 1—Testing Generator at 1-10-26,700-300-25 13,200/7620/6600/3810 Bldg. 60E

26,700-kv-a., 25-cycle alternator of low reactance. The windings are arranged for connection to give 13,200, 7620, 6600 or 3810 volts. A three-phase 1500-horse power direct-connected induction motor is used as the driving power. The generator and driving motor are shown on Fig. 1.

The short-circuit current supplied on short circuit is controlled by means of reactors having ten taps and a maximum value of 6.1 ohms per phase.

In addition to the generator, high-voltage transformers of low reactance are provided. These transformers permit three-phase testing at any voltage up to 44 kv. and single-phase testing up to 132 kv. These transformers with the bus construction are shown on Fig. 2.

The measuring equipment, in addition to the usual

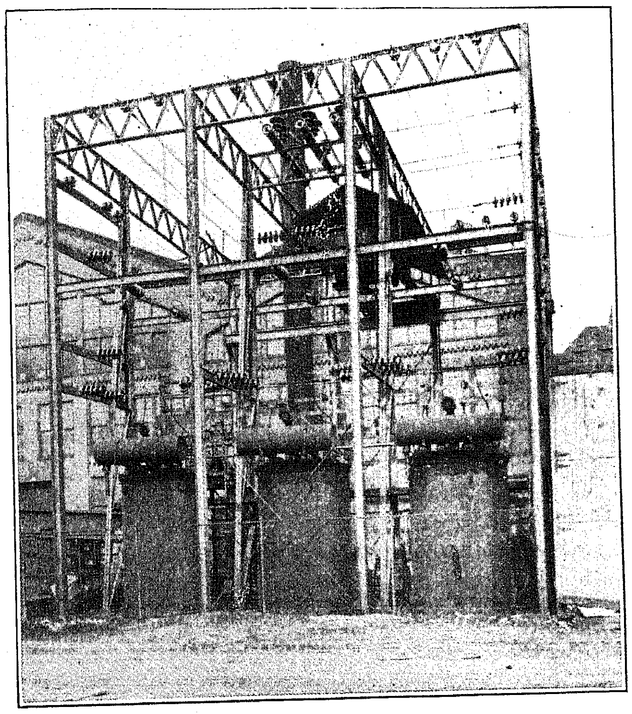

Fig. 2—High Voltage Testing Equipment of High Capacity Testing Station Bldg. 60 E

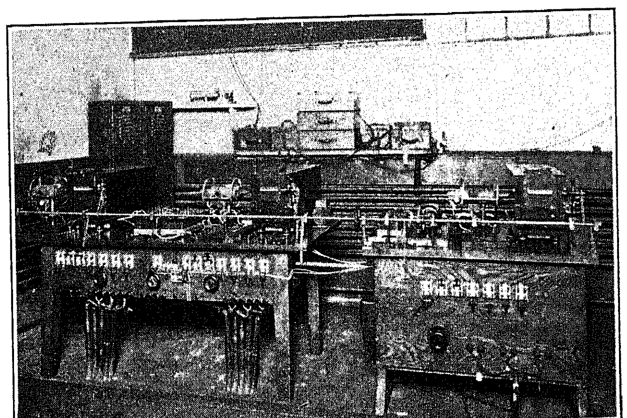

Fig. 3—Three Oscillographs on One Driving Shaft as Used in Control Room of High Capacity Testing Station, Bldg. 60 E

meters, consists of three oscillographs, pressure recorders, speed recorders, and such other apparatus necessary for the collection, analysis and measurement

1. C. E. Merris, *General Electric Review*, June, 1923.

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-10, 1924.

of gas. The oscillographs are shown on Fig. 3. The general diagram of connections of the station, together with detailed connections of the oscillographs, is shown in Figs. 4 and 5.

This equipment will produce short circuits approximating 300,000 kv-a., three-phase, at 13,000 volts.

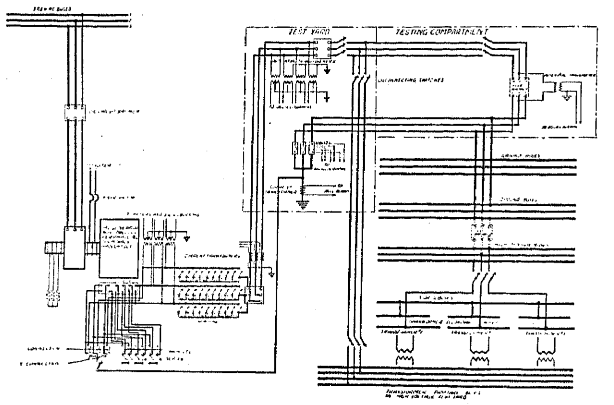

Fig. 4

The equivalent three-phase kv-a. at 13,200 volts can be increased to approximately 600,000 kv-a. by single-phase test to ground at 7630 volts. Approximations of short circuits very much higher than 600,000 kv-a. can be obtained by testing one break on single-phase tests.

In order to provide protection against injury to the

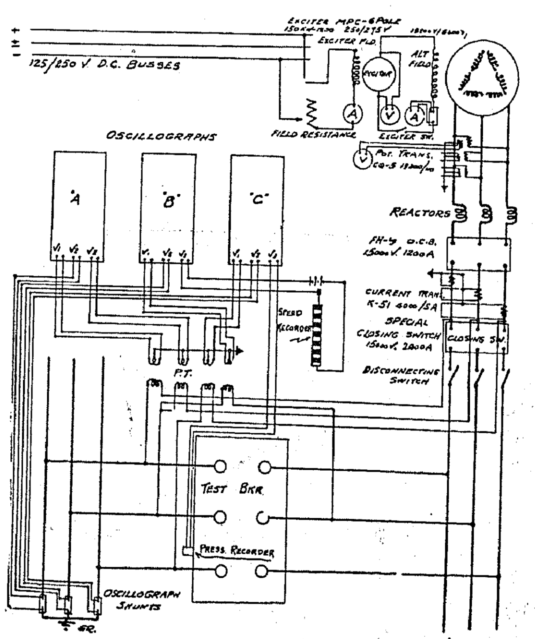

Fig. 5

observers from burning oil or flying particles during the tests, a bomb-proof of brick, steel and concrete was constructed. This bomb-proof has one side open so that observations can be made from a safe distance.

It is the purpose of this paper to discuss some of the characteristics of oil circuit breakers as determined from the tests with this testing equipment, and to indicate as far as possible the effect of some of the factors considered.

The Factors Investigated

Break Distance. The satisfactory operation of any oil circuit breaker depends upon the break distance. This break distance must be ample to interrupt the arc under the severest condition of operation or there will be a permanent gas generation which will quickly result in the destruction of the breaker. The required break distance for any given voltage and interruption is determined by the circuit connections, *i. e.*, grounded or ungrounded, power factor, connected shunt load, amperes interrupted, pressure in the oil tank, tank cross-section, etc., and it is evident that to have an absolutely safe breaker, the worst conditions must be assumed. This condition is fortunately a dead short circuit at the generator terminals on an ungrounded system without shunt load, and it is under these conditions that our rating tests are made. If the breaker is to be used on a line where easier conditions exist, then the breaker may have a larger factor of safety than under its rating condition. Cases have been observed where the break distance of breakers was inadequate for operation in generating stations but proved to be satisfactory in substations because, due to the arrangement and connections of the system, the arc length obtained for a given ampere interruption was less.

Speed of Break. The interrupting capacity of a breaker depends upon the speed of break, but one cannot say that the higher the speed, the greater the interrupting capacity in every case. The interrupting capacity of a breaker depends not only upon the quantity of gas generated, but upon the speed of generation, and it may well be that a given breaker, if operated at higher speed will have a less interrupting capacity. The higher speed may well result in a longer arc, in more gas and more pressure than if operated at the lower speed, and this condition has been observed in test. Before we can determine the effect of a speed change, we must know many factors relating to that particular breaker.

In what has been written about speed of break, it has been assumed that the moving contact was traveling at practically uniform speed. As a matter of fact, however, every breaker will have its own speed characteristic and this characteristic at no load may be decidedly different from the full interrupting capacity speed. In fact, at some load, the speed may not only slow down but actually stop and reverse in direction so as to reclose the breaker. There are several reasons for this behavior and none of the plain break breakers can be considered as entirely unaffected by it. Whether the defect is a serious one in any particular case can only be determined by actual test of the breaker under severe conditions.

In the case of fairly low voltage breakers, operating to interrupt large current, the actual speed of the moving contact may have little relationship to the interrupting capacity of the breaker, as such breakers interrupt the arc by the magnetic blowout effect instead of the physical separation of contacts. It may be found, however, that the heaviest stress is not produced by the largest current interrupted and that more gas and a greater pressure is produced when interrupting a lesser current than that of the maximum rating. It is needless to say that the breaker must be safe when interrupting these smaller currents and that this fact must be considered in the rating of the breaker.

Oil Head. The head of oil over the contacts influences the interrupting capacity of the breaker, as it largely determines the pressure above and below the oil surface and therefore tank rupture. It also determines the arc stabilizing, shock to the entire breaker structure, oil throw and gas ignition. Too much oil in the tank is as bad as too little. The correct quantity to use can only be determined by repeated tests at all loads up to the interrupting capacity rating of the breaker. In testing oil circuit breakers on skids, it is frequently noticed that the breaker jumps clear from the floor at the instant of interruption. This, of course, is due to the kinetic energy in the oil as a result of being blown by the arc gas, which is expended when the oil mass strikes the top of the breaker. This shock may be so severe as to break the top casting of the breaker.

Air Space above the Oil. The proper air space above the surface of the oil will vary with each individual breaker and the correct quantity has to be settled by the designer as a result of his observations of the action of various breakers under test. It should be noted that the tank pressure is not the only factor to be considered as affected by the air space, as there are also oil throw, arc stabilizing, secondary explosions, and gas ignition. Oil head and air space must be considered together.

Various Types of Venting. The venting of an oil circuit breaker is an important problem, as it affects the oil throw, tank pressure, and gas ignition. It has come to be recognized that the modern high class breaker must limit the ejection of oil or incandescent gases into the room at the breaker, and in order to accomplish this end a thorough investigation of the problem was made. As a result of these tests, the oil-throw problem is well in hand but it should be realized that small and inexpensive breakers will not be free from oil throwing at extreme loads. The non-oil-throwing breaker is a comparatively modern product, and the vast majority of breakers now in use were designed with little regard to the question of oil throw. Hence their construction does not readily lend itself to the rebuilding into a non-oil-throwing type.

Determination of Allowable Tank Pressure. In oil circuit breaker design, the maximum instantaneous pressure to which the structure may be safely subjected is of great importance, as it determines the safe interrupting capacity of the breaker. The foregoing statement refers particularly to those breakers having tanks of other than circular shape. Such information can only be had as a result of repeated tests when utilizing suitable recording instruments in connection with a source of power such as our large testing generator. Any calculations of static stresses which the structure will withstand are difficult to make and the results obtained, due to the lack of proper constants, are wide from the actual permissible pressures.

Method of Tank Construction and Best Material. Here also the use of the testing generator was invaluable as it settled questions which had been debated previously, but without any definite result, and the results of these tests are sure to show up in future records of performances.

Methods of Tank Support. Definite results have been obtained from the investigation of the method of supporting the tank and in all new breaker design advantage is taken of the findings from the tests.

Tank Lining Investigation. The question of the lining of the oil tank and, in fact, whether it should be lined or not, is one of great importance. The tests made with the large testing generator have definitely answered this question. They have shown that linings are in most cases necessary and that there is a decided difference in the efficiency of various linings. Just why one type is best in one case and another type better under other conditions has been determined.

Contact Investigation. One of the most important questions in oil circuit breaker construction is that of the contacts, both main carrying contacts and arcing contacts, and more attention is given this one feature than any other single feature entering into the breaker construction. The investigation of this feature included not only the burning and carrying capacity of the contacts, but also the heat generating and dissipating characterisitcs of the connected studs and bus bars, the effect on the brush by the shock of closing of the breaker, the degree of over-travel the brushes will stand, the permanency of the brush structure, the specification for the brush metal to give best results, the best contact pressure and area of contact, and the design of contacts so that they will not be affected by the magnetic stresses under short-circuit condition.

The burning of the contact members of an oil circuit breaker is a very important factor in the entire oil circuit breaker investigation and probably receives more attention, while the breaker is undergoing tests, than any other single feature. Repeated tests are made at the standard number of duty cycles. This means that the breaker is tested in closing on a short circuit, as well as opening the short circuit and under duty conditions, the equivalent of the rated interrupting capacity of the breaker and worst possible circuit conditions. Contacts are also tested to destruction in order that we may

have definite information as regards the maximum continuous duty the contacts will stand.

The brush heating is the chief feature of the circuit breaker which may be adversely affected by the action of the operating company. This may come from the improper adjustment of pressure at installation, by the use of insufficient bus bars section, by the heat insulation of that section, by the insulating tapings, by the running of cables carrying large currents causing eddy current losses, by installation of tanks close together, which decrease heat radiation, and by the installation in unventilated cells in locations where the ambient temperature is high.

Ability of Breaker to Withstand the Shock of Oil Throw. Without the generator of large capacity, it

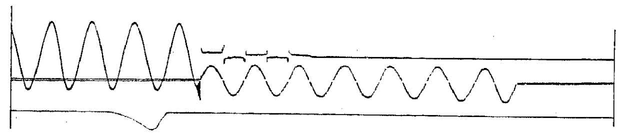

Fig. 6

would have been impossible to test for this condition which in the past has been responsible for serious breakages.

Reclosing Characteristics of the Breaker. The conditions under which the breaker contacts slow up or actually reclose have received special consideration and tests and facts have been discovered which were not suspected at the time of starting the investigation.

Oil Throw and Gas and Oil Ignition. These features have been investigated in the case of the old style breakers; the newer breakers do not have these defects. It is, of course, impossible to stop the throw of oil and gas in the old type breakers without practically rebuilding them; however, the tests have shown how it would be possible to construct the breakers and permit the oil throw while preventing ignition.

Secondary Explosions. Attention was given to the cause and magnitude of secondary explosions. The tests were made with a bomb and also upon full-size oil circuit breakers and the large testing generator. Oscillograms, Figs. 6 and 7, show such a secondary explosion. They show that the breaker interrupted the circuit with ease, that in 0.014 sec. after interruption, pressure developed in the air space (Fig. 6), that the maximum pressure was reached in 0.004 sec., that the pressure below the oil, due to the necessary acceleration of the oil mass, was delayed 0.007 sec. behind the air space pressure. The breaker was not injured. These secondary explosions are nearly always caused by a static spark igniting the explosive gas mixture and may come while the breaker is open or closed. Their cause is well understood and if the station operator takes proper care of the breakers, there should be no such explosion in the newer breakers.

Acceleration and Retardation of the Moving Contact Member. The acceleration of the moving contact member under short-circuit conditions is extremely important and equally important is the retardation, especially in the case of the explosion chamber breakers. With these latter breakers any desired speed of opening may be readily obtained. The breakers are specially designed to give the desired opening speed and means have been developed to satisfactorily decelerate moving parts.

Investigation of Magnetic Stresses Produced in the Breaker. Magnetic stresses may cause the lifting of the brush or the throwing back of some types of arcing contacts, at "Make." Such stresses may also cause movement of bushings and studs. The current limits of various designs have been determined and designs for higher duty developed.

Arc Stabilizing Tests. If the contact blocks under oil are not separated a sufficient distance or there is insufficient distance between these blocks and the metal part of the operating rod or cover or tank, an arc is liable to be stabilized across these insufficient distances and cause the destruction of the breaker. The safe distances depend upon the voltage, circuit conditions and amount of current interrupted and each type of breaker is tested many times under the most severe condition of operation, in order to prove that the distances to prevent stabilizing are ample.

Oil Viscosity and other Oil Characteristics

The characteristics of the oil used in oil circuit breakers are important factors in the satisfactory operation of the breaker, and the oil supplied with the General Electric oil circuit breakers is rigidly held to specification. Miniature tests are only made in the research laboratories, but tests are also carried out with the large testing generator. That oil is best which

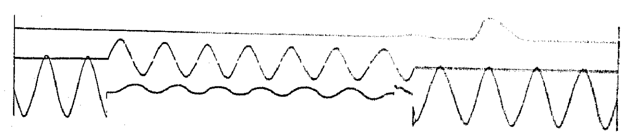

Fig. 7

produces the least quantity of fixed gas for a given interruption, which has the least carbon production, the most suitable oil viscosity for the particular breaker in which it is to be used, the highest dielectric strength for the given interruptions, the smallest quantity of oil vaporized, the greatest percentage carbon precipitation, the least absorption of moisture, and the highest flash point. The oil affects the circuit-breaker operation in ways little realized by those not intimately connected with the breaker investigation.

Other arc-extinguishing liquids, as well as the oil, are under constant observation by means of the full-size tests. Miniature tests show interesting results, but definite conclusions can only be obtained by

comparing such tests with tests made on full-sized apparatus.

Duty Cycle Tests

All breakers are tested at the new proposed duty cycle, *i. e.*, two open-close-open at the rated interrupting capacity, or if that cannot be obtained, at capacities which may be used to interpolate and thus obtain the full duty.

Tests have also been made at duty cycles other than standard, in order to determine the relative severity of these supplementary cycles.

Gas Production and the Resulting Stresses Upon the Breaker. An extended investigation into the gas generated by the arc has been carried on for months past with the large testing generator and will be continued for months to come. In these tests, the gas volume generated, the speed of generation, the pressures above and below the oil level, the current and voltage at the break, are all recorded on the oscillograph. The effect on the breaker structure are also recorded. These data

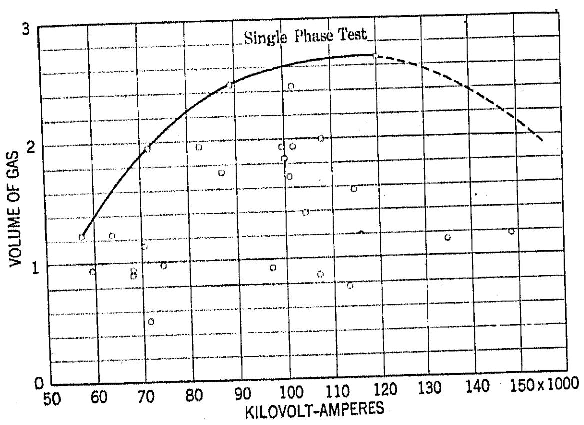

FIG. 8

are used in obtaining an empirical formula with which to calculate the interrupting capacity of any existing breaker and the design information for any new breaker of any proposed interrupting capacity. In this connection, it can be stated that, theoretically, the quantity of gas generated depends upon a large number of variables. For instance, the r. m. s. current and voltage varies throughout the arcing period, the current decreasing, the voltage at arc increasing with the time. The resistance of the gas stream and the dielectric strength of the gas vary with the pressure and temperature of the gas, and since the gas generation is a heat phenomena, this pressure affects the $I^2 R$ losses and the dielectric strength affects the duration of arcing. Then there is the effect of the magnetic blow-out which affects the arc duration. The power factor and shunt load both affect the recovery voltage, which in turn affects the re-establishment of the arc at each zero value of the current wave, the available stored energy—electromagnetic and electrostatic—in the circuit, which may be discharged through the arc at the zero current value and aid re-establishment of the arc and other causes—all of which combine to make the gas production extremely fluctuating. The extent of this fluctuation is shown in Fig. 8, on which has been plotted the volume of gas generated and current in the arc at definite voltage and circuit conditions. It is evident that our empirical formula for interrupting capacity determination must be based upon the curve of the extreme points, as plotted from the tests, and that such a curve can only be obtained by means of a large number of tests made with a generator able to produce the conditions at the desired rating.

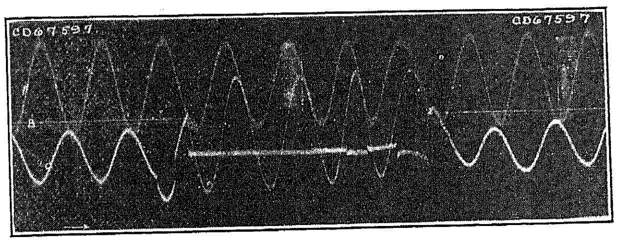

FIG. 9

Investigation into the Action of the Oil Circuit Breaker under Various Conditions. That the action of the oil circuit breaker is very erratic is soon realized when one attempts a systematic investigation of its action. Individual short circuits vary widely in effect, when all conditions of the short circuit are made as nearly identical as possible. That is, you may take a given generator, running at a definite speed, and excited to the same voltage, with the same impedance in circuit, and short circuited by the same breaker, under the same conditions of grounding, and the gas generated may vary

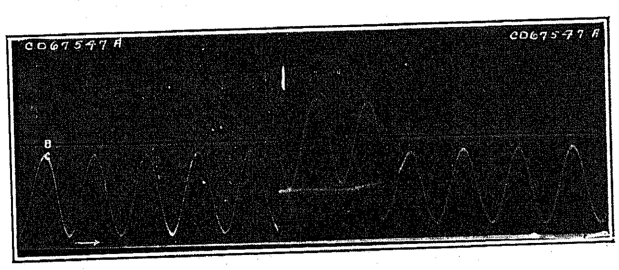

FIG. 10

several hundred per cent. The gas generated is the final measure of the efficiency of a given breaker, but the speed of generation must, of course, be taken into consideration. If fluctuations to the extent indicated above are observed under constant and controlled conditions, what must be the variation during the ordinary short circuit on commercial systems where the field excitation, power factor, shunt load, conditions of grounding, and other factors vary widely?

In general on commercial-systems, the factors mentioned above are usually combined so that the interrupting conditions are less severe than they are under the

controlled conditions of test. Therefore, it is safe to assume that breakers which will pass tests with the testing generator equipment will give satisfactory service under normal operating conditions. By normal operating conditions is meant conditions limited by the normal generator and circuit characteristics and would not, for instance, include a heavy lightning stroke or cross with a higher voltage line.

The service condition where an oil circuit breaker in a generating station controls a single feeder is, of course,

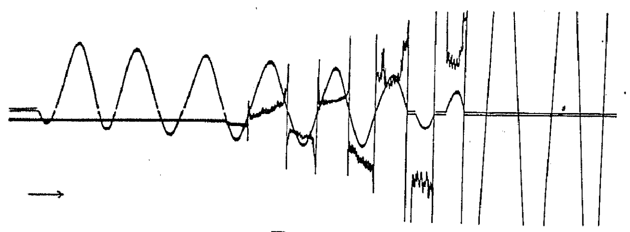

Fig. 11

in general equivalent to the condition obtained with the testing generator and should produce equivalent results.

There is, however, considerable difference in the operation of breakers on ungrounded systems, as compared with the operation on systems with the neutral grounded and a short circuit to ground.

Oscillogram Fig. 9 shows a short circuit upon an ungrounded system and oscillogram Fig. 10 shows a short circuit with the same apparatus upon the same system with the neutral grounded and a ground at the breaker.

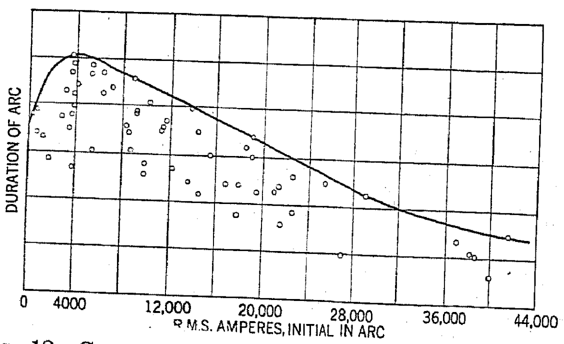

Fig. 12—Curve Showing Arc Duration as a Function of Current Interrupted by a Type F K Oil Circuit Breaker (Plain Break) Test Conditions Equivalent to Those Prevailing at Baltimore Test but Made on Basis of 13,200 Volts, 3 ϕ

The feature to be noticed is the recovery voltage, which is characteristic of the two conditions and is considerably greater in the case of the ungrounded system. The greater recovery voltage means a longer arc and more gas generated in the breaker before final interruption of the circuit. By recovery voltage is meant the instantaneous voltage rise at the instant of circuit interruption, that is, it is the voltage which tends to re-establish the arc at the zero value of the current wave. In this connection, it might be said that while we state broadly that the interruption of the circuit always takes place at the zero value of current, this statement should not be taken too literally. It takes a certain voltage to maintain an arc; the longer the arc, the higher the required voltage, so that a time must come at every operation when the circuit tends towards interruption and before the absolute zero value is reached. This fact will largely account for the "kick" which will be made manifest by the use of spark gaps, but is not shown by the oscillograph, it being a steep wave-front phenomenon. The action of this phenomenon, however, is to aid in re-establishing the arc.

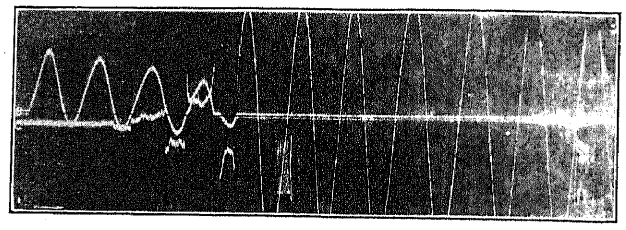

Fig. 13

That the circuit may be re-established some considerable time after the zero current value, is shown in oscillogram Fig. 11, in which case about 60 electrical deg. have elapsed before re-establishment. This case is not unusual, but on the contrary, is quite frequently noticed. The arc is, of course, an energy phenomenon and the current and voltage in the arc are substantially in phase, but at the instant of final circuit interruption there is a change in the relationship of the two and the lag of current is then determined by the circuit as a whole. This is important, because it in a way explains why the low power factor conditions are the harder

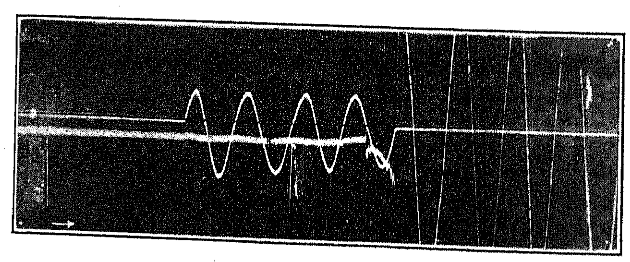

Fig. 14

to interrupt. At zero current value and 90 deg. lag, the maximum voltage is available to re-establish the arc, while at unity power factor there is zero voltage at zero current. This difference caused by power factor variation is really one of time, only because if we assume a case of unity power factor and a 25-cycle circuit, the same voltage is applied at the expiration of 0.01 second, as would have been applied instantaneously at zero power factor. During this 0.01 second, the gas has had a chance to cool, thereby increasing its dielectric strength, and the gap has been increased (assuming an opening speed of 5 ft. per

second) by 0.6 in. Both of these factors act to increase the interrupting capacity of the breaker in the case of unity power factor.

Investigation of the Magnitude of Current Interrupted upon Circuit Breaker Action. In the case of fairly low voltage, the magnetic blow-out effect has to be considered in connection with the interrupting capacity of the breaker. Curve No. 12 shows such a study.

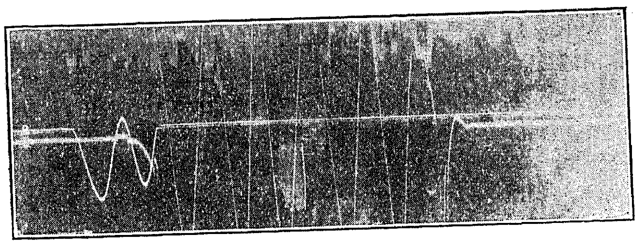

Fig. 15

This curve shows that the maximum arc length corresponds to a fairly definite current value and that any increase in current above this value acts to decrease the arc duration.

The logical deduction is that at some current value, less than the maximum interrupting rating, the breaker may fail. This deduction is correct and many breakers

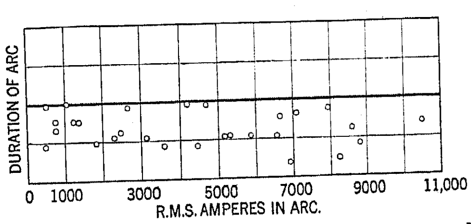

Fig. 16—Curve Showing Arc Duration as a Function of Current Interrupted by a Type F K H Oil Circuit Breaker (Explosion Chamber) Test Conditions Equivalent to those Prevailing at the Baltimore Tests but Made on the Basis of 15,000 Volts, 3 ϕ

are undoubtedly stressed more at part rating than at their maximum rating.

Comparison of the Plain and Explosion Chamber Breakers. Oscillogram Fig. 13 shows a plain break interruption, and Curve Fig. 12 shows the plot of arc lengths and currents on such a breaker. The erratic behavior of the plain break breaker is striking but is characteristic of this class of breaker. Oscillogram Fig. 14 shows an explosion chamber interruption in the same tank at substantially the same current and with the same mechanism, while oscillogram Fig. 15 shows the same explosion chamber breaker interrupting substantially double the current at 1:73 times the voltage of the plain break breaker in Fig. 13.

Curve Fig. 16 shows the plot from tests of half cycles and currents of an explosion chamber breaker.

The foregoing oscillograms and plots are characteristic of the two types of breakers and comments are not needed as to the story they tell in reference to breaker efficiency, an efficiency which increases with the voltage increase in the case of the explosion chamber breaker.

Testing of Breakers to Operate under Special Conditions. For this class of work the testing generator equipment is invaluable, as we are able to obtain results and definitely settle questions which it would be impossible to do without such an equipment. Miniature tests are of little value unless they can be compared directly with tests made on regular apparatus under operating conditions.

In order to be proven safe, every breaker must be tested under full maximum operating conditions or must be compared with a similar breaker which has operated under these conditions.

Conclusions

What has preceded shows the large number of variables which enter into the determination of the oil circuit breaker interrupting capacity. It shows that each variable depends upon the others and that the breaker as a whole must be judged from results obtained when actually performing under loads which vary from the smallest up to its maximum rating and under repeated operations at each value. A single shot at any particular load is far from conclusive and the only safe rating is that obtained from plotting many tests made at all capacities.

For this work, the large testing generator has proven invaluable. It has made clear phenomena previously not understood. It has brought out facts not dreamed of until they were shown up by the tests. It has pointed the way as to what features to avoid and what improvements to make, and its influence is showing in the design and performance of our breakers and will continue to show its value in the research which is already planned for years ahead.

Discussion

For discussion of this paper see page 655.

High Voltage Circuit Breakers

The Operator's Viewpoint—Giving Practises, Experiences and Opinions

BY J. S. JENKS

Member, A. I. E. E.
West Penn. Power Co., Pittsburgh, Pa.

THE practises of the station operator in regard to circuit breakers are largely governed by his previous experience, his system and conditions on his system. For instance, a very large system may cover a very large area and have a very great capacity connected, but be of such a character that there is very little interconnecting, with very simple switching, and it may have no very great power capacity concentrated at any one point. On the other hand, the system may be very great in power capacity and cover such a small area that the potential of the system is rather low, and on account of the dependability of low potential and the lack of the necessity of numerous ties, the concentration of power is easily limited. In the first case, we find potential so high, and the breaker has to be so large to safely handle the potential, that lightning is not much of a factor, and the current is so small that it is really insignificant in such a large breaker. In the second case, the currents are greater and the breakers of necessity have to be large and substantial to withstand the great magnetic stresses, but such systems generally are confined to a small, closely built area, largely underground, where lightning is a small factor, and they are not interconnected to a great extent on account of the greater reliability of the low potential of the system. The breakers are not subject to such excess capacities, hence the low-potential breaker problem is not such a difficult one.

In addition to the above-mentioned system, we have the system which consists of large capacities covering an area of such size and such power density that high-voltage, high-capacity lines are necessary for transmission, and a medium voltage with high current values is necessary for primary distribution. Such systems are usually highly interconnected within themselves and also with neighboring systems, hence the switching is not only complicated but is subject to great concentration of capacity, and is subject to and very susceptible to lightning and disturbances which are particularly severe on the breaker, where the current's concentration is great and the potential high enough to make arc extinguishing difficult.

The experience of the operator with breakers depends on the system; how it is built and how operated. The more exacting the service, the more experience the operator gets with breakers. For instance, if the service is not exacting, breakers can be adjusted so they will not open until the intensity of the trouble reduces, and then a number of breakers can be allowed to function and greatly reduce the individual strain and probably cut off the power from a breaker in which the arc would re-establish with disastrous results if it remained energized. If service would allow breakers to rest a while after opening so the gas might escape and the oil settle the contacts, and the oil in their vicinity cool, the breaker would perform with less trouble. On the other hand, if the system supplies much service upon which life and property depend, the breaker cannot be nursed but must be sacrificed, if necessary, for the sake of service.

My experience has been with a system and breakers in the latter class, hence I will confine myself largely to the circuit-breaking problem of the West Penn System, and endeavor to give you practises and experience with that system from its conception to its present development. The West Penn System consists of five power stations having a capacity of 226,000 kv-a. connected by and serving the public over 215 miles of 66-kv. circuits (122 miles of which are constructed and fitted for 132 kv., and shortly will be operated as such); 1350 miles of 25 kv.-circuits (25 kv. also includes 22 kv.) and 661,000 kv-a. in high-voltage transformers, covering an area of 12,000 square miles. In addition, this system is interconnected with several other large systems, embracing the American Gas & Electric Company, Ohio Power Company, Northern Ohio Traction Company, Cleveland Illuminating Company and the Duquesne Light Company—who are connected with the Pennsylvania and Ohio Power Company, and the Harmony Electric Companies, making a total connected power station capacity of 1,092,000 kv-a., with 280 miles of 132-kv. circuits; 850 miles of 66-kv. circuits, 2370 miles of 25-kv. circuits and 3,447,000 kv-a. in high-voltage transformers. Connections are now planned and rights-of-way partly secured, which will add to this group the systems of the Penn Public Service and the Potomac Edison, both of which are already connected with the Penn Central and the Keystone Power Corporation, connecting power station capacities of 1,280,000 kv-a. with 375 miles of circuit above 100 kv., 937 miles between 50 and 100 kv., 4200 miles between 20 and 50 kv., and 3,865,000 kv-a. in high-voltage transformers.

With such systems connected as they are, you can

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

understand that the switching problem of the West Penn System, with which these larger capacities are connected, is no mean undertaking.

In 1902 the West Penn started with 6000 kw., 38.5 miles of 22-kv. circuit and 10,000 kw. in transformers, using single-pole stick breakers, which I will describe at some length for the benefit of those who are not familiar with this apparatus. These breakers had a marble base 45 in. long, mounted on two pin-type insulators and having two terminals on the front 36 in. centers. The top terminal was made in hook form so that breaker would hang thereon. The breaker consisted of a handle about 72 in. long, having a contact and carbon-protected eccentric fuse clamp at the upper end which hooked on to the top terminal, said clamp being opened by cord which hung beside the handle. At the center of the handle there was another contact which fitted on the lower terminal on the base, and also was connected by a hinge to a movable arm about 30 in. long, having a conductor from the hinge to the end, where it terminated in a carbon-protected screw fuse clamp. Springs held the arm in both the open and closed position. To set the breaker a fuse 10 in. long, of the desired capacity, was fastened in the clamp on the arm, and then in the eccentric clamp, the spring putting a slight tension on the fuse. The breaker was then hung on the base and functioned automatically by the fuse melting and the arm swinging down, creating a break of 72 in., and was opened by hand by pulling the cord which released the fuse, allowing the arm to swing down the same as when the fuse melted.

We placed in series with these breakers plug switches so wired that the lower breaker contact would be disconnected by the plug to eliminate the hazard of handling the breaker with the arm energized while hanging down, after breaker had been opened, automatically or by hand, to allow the placing of the breakers in proper contact before any energy passed, and to allow the operator to get in a position of safety in event the breaker opened as soon as service was re-established.

This type of breaker was fairly satisfactory for a time, but as the system grew in line and transformer capacity trouble developed from the breakers only opening part of the phases, which resulted in insulation breakdowns from surges and the floating neutral which was not grounded, the transformers all being two-phase low and Scott three-phase high, the current also became too great for the contacts and the fuses had to be so large that when they blew they created such a quantity of metallic vapor that the arc would re-establish several times and under some line and transformer conditions would not break even with the 72 in. opening, and it was necessary to open other breakers or the plug switchers by hand to break the arc.

As a result of these limitations in 1906, when our transformer capacity had grown to 15,000 kv-a. and the transmission system consisted of 107 miles of 22-kv. circuit it was decided to discontinue the practise of installing stick breakers and place oil breakers in all of the new developments and some of the more important old ones. This breaker differed from the ordinary ones in that the top, bushings and tanks were made of wood fiber, and it had two additional tanks in which were located oil-insulated series transformers having three ratios. Inverse time-limit relays were mounted on the breaker beside the tripping coil. These breakers were remote manual control. The control consisted of a ¼-in. tiller rope, which could be run for long distances and around all kinds of corners by the use of small pulleys, and operated by a toggle handle which locked by passing over center, tripped free at the breaker, hence the control did not have to actuate in the case of an automatic operation. This breaker was a 300-ampere, 50-kv. test, and used for 22-kv. service, but at once proved it did not have sufficient capacity and gave trouble from lightning, due probably to the fact that the West Penn System had the second worst lightning condition in the United States, as shown by records compiled at the time. The line insulation, having a wet test value of about 75 kv., was about 50 per cent greater than the breaker, and the lines were not protected by lightning arresters, there only being an arrester on the bus.

I wish to call your attention to the method of installing these breakers, which consists of mounting direct on the substation wall, enclosing with ⅝-in. transite board and connecting by means of detachable-handle plug switches so arranged that the breaker could be taken out of service without interruption by plugging in a breaker jumper and removing the breaker leads, which were also connected by similar plugs.

In order to relieve the lightning stresses and to disconnect a breaker or the entire substation in event of trouble, we designed and built a combination pole-top switch and arrester, which was placed on each line that entered a substation. This was unique, in that it had a horn which was in circuit, forming the horn for the switch, the arrester and a one-turn choke coil which greatly assisted the arrester to function, due to the power flowing up the arrester horn.

We quickly discontinued the use of this switch for 22-kv. service and placed them in 6600-volt service, where they are still in use in their original condition, except that the fiber tanks were replaced by steel as the fiber eventually leaked badly, and while the leakage was stopped by encasing the tanks with tin, they proved too weak mechanically.

We then installed a 400-ampere breaker of the same make which also had top, tanks, posts and bushings of wood fiber, and tested to 125 kv. This breaker differed from the smaller breaker in that it had four breaks per pole with a series trip coil located between and connected with the center stationary contacts, which were supported by posts. This breaker was mounted and connected the same as the smaller breaker. The enclosure was similar except there were

partitions between the poles. The manual control was the same but, in addition, some breakers were electrically operated.

At the same time the lightning arrester arrangement was changed and an arrester placed on each line to protect the breaker.

During the period from 1912 to 1920 these breakers were controlled by a very simple and effective system of impedance relays designed and built by ourselves, which locked all line breakers, making them non-automatic until the potential dropped in the zone where the breaker was located, to correspond with the setting of a low-voltage relay which unlocked the breakers and allowed them to operate from overload.

This breaker was universally used by us for all 22 and 25-kv. service from 1906 to 1920, except the breakers at the main power stations, where there were breakers of a different make having two breaks per pole greater carrying capacity, a lower electrical test and about the same rupturing capacity.

During this period, the system grew from 6000 kw. to 98,433 kw. installed, and from 107 miles of 22-kv. circuits to 757 miles of 25 kv. and 26 miles of 66-kv. circuits; transformers connected from 15,000 to 161,343 kv-a. and the 25-kv. line insulators increased to a wet test of 90-kv.

All this, of course, increased the duty on the breakers, with the result that all breakers on the 25-kv. system had to be reinforced. The four-break breakers were the first to need attention, due to the weakness of the fiber tanks, which had been encased in tin to prevent breakage but with no idea of strengthening them, hence the tanks were replaced with steel tanks. At the same time it seemed advisable to strengthen future breakers, hence iron tops and moulded insulation posts and bushings were used. The tanks were made of 1/16 in. steel and baffles were provided to retard the throwing of oil, as the tanks were provided with springs to allow them to lower slightly to relieve pressures which might burst the tanks, as there was no convenient way of placing a vent in the top.

The moulded insulation-fitted switches stood a slightly higher potential test than the fiber, but did not stand up nearly so well in service. The posts gave us so much trouble we made a general replacement with wood or canvas bakelite. The bushings would stand the original test and later fail in service, due principally to the conductor being misplaced, broken or burned off in the bushing.

As the system grew and was fed from numerous points, the relays mentioned before proved inadequate. In order to provide current to operate modern relays, it was necessary to provide series transformers, which we built and placed on the breaker bushing. As the modern relays would increase the duty on the breakers, we speeded up the break by removing the series trip which released a weight that fell on the tripping lever, and placed a 12-volt, d. c. trip coil which acted directly on the tripping lever, thereby reducing the time of breaker operation 50 per cent.

At the same time, the tanks were reinforced by braces on the sides; the tank liners which were suffering from the arc at the arcing contacts were replaced by double-arc resisting liners, and the arcing contacts were placed on the inside of the main contacts to get them further from the tanks. There was also placed in the transite enclosure of each pole a container of carbon-tetro-chlorid to smother out any burning oil which might be thrown out of the tank.

These breakers, which originally would only break about 1200 amperes are still in use giving remarkable service in location, where the short-circuit current is limited to about 2500 amperes.

Connellsville Station breakers were rebuilt and their capacity about doubled by speeding up the break, reinforcing the tanks and replacing the light iron tops with a heavy iron top having a large chamber above the top, which acted as an oil separator and muffler. When these breakers again reached their limit, they were replaced by similar breakers of modern design, having heavy steel tops and tanks. The insulation value was allowed to remain about the same and this proved too low, as it was only about one-half of the line value. The consulting engineers who made this breaker change believed the breaker would have sufficient insulation, as the neutral of the system was just then being grounded at Connellsville through a 28.8-ohm resistor, but this did not prove the case and the insulation of the breakers has had to be reinforced.

We have had considerable experience with many other breakers made by different manufacturers, which we inherited or that were placed on our system by our customers, or consulting engineers of our own. All of these breakers have given trouble when their capacity was approached, and it has been necessary to limit the capacity back of them by moving them to another location, or back them up by high-capacity breakers.

In 1919, when a new station was started which would have an ultimate capacity of 300,000 kv-a., we took up with the breaker manufacturer the design of a higher-capacity breaker of the 25-kv. class, and as the result, contracted for a large number of breakers for both indoor and outdoor service, which would have a potential test of 140 kv., a current capacity of 600 amperes and a rupturing capacity of 16,000 amperes at 25 kv., under A. I. E. E. rules.

These high-capacity breakers were installed in Springdale Station in reinforced concrete compartments 10 ft. 6 in. by 11 ft. 8 in. to confine any fire or damage, but open at the top to provide large vent area to prevent the structure from being wrecked in case of an explosion. The outdoor switches are located on concrete bases under steel structures on 16-ft. centers.

All switching is single with an auxiliary bus for each transformer bank, controlled by a breaker arranged so that any circuit or group of circuits may be, without

interruption of service, transferred by disconnecting switches to the auxiliary bus and breaker in case of trouble, or to facilitate inspection and repairs, for oil breakers need servicing. In fact, they remind me of motor trucks. I was investigating trucks once, when we were about to purchase a large fleet. One of the dealers insisted on my going to see his establishment, which he claimed was the largest and most complete service station in the county, where they had the most complete stock of parts and large forces of competent engineers and mechanics on duty twenty-four hours per day, 365 days per year to give service, "and you will need it," he said. Well, I didn't purchase his truck but another, and found that it needed service, too. So it is with breakers. They all need service, and we have found that servicing breakers is one of the biggest dividend payers we have. In fact, this has so impressed some of our breaker-service men that it was intimated to me, if we had enough breakers our servicing would save so much we could pay our dividends without collecting from our consumers.

I see there is some interest in this savings department. It is under the supervision of a very high-grade relay and breaker expert. His organization consists of relay and breaker engineers and high-grade relay and breaker mechanics. They are organized into crews and are provided with motor trucks equipped for and supplied with all kinds of instruments, apparatus and tools for testing and doing every kind of relay and breaker work. This organization checks, adjusts and tests all new relay or breaker installations before being put in service; inspects and tests all relays and breakers at regular intervals; repairs and rebuilds relays and breakers whenever necessary; checks every important relay or breaker operation, examining the relay and breakers to determine their condition, particularly contacts, insulation and oil; investigates—with the idea of determining the cause—every faulty relay or breaker operation on our property and the important ones on other properties. By this method we are able to keep our breakers and relays in infinitely better condition than we could by having the regular construction or repair forces who are not especially trained to do the work. That is what we call "servicing breakers."

All disconnect switches indoors have a dry test of 101 kv., and outdoors 150 kv., and are all provided with a type of lock that breaks the seal of the blade in the jaws, and bars it out at least ⅛ in., in order to make it operate easily and prevent damage to disconnects as the result of sticking.

In January, 1923 it became apparent that we would need breakers of still greater capacity on our 25-kv. system. As our plans for connecting additional properties acquired and interconnecting with other large utilities with high-voltage transmission made it possible to develop short-circuit current too great for the 16,000-ampere breakers, the matter was again studied and contract made for a large number of breakers, guaranteed to have a potential test of 140 kv., current capacity of 600 amperes and a rupturing capacity of 25,000 amperes at 25 kv.

The three 25-kv. breakers which will most generally be used on our system are the 2500, 16,000 and 25,000-ampere breakers. In the case of the middle size breaker the conduit runs are long and expensive as the relays are mounted in substation buildings, and in some cases buildings have to be erected to protect the relays, while with the larger breaker the relays can be placed in the operating mechanism box, which is made large to accommodate same and thus save the cost of the conduit run and relay housing. Therefore, the cost of the two larger breakers installed is about equal, even though the breakers are quite different.

In the case of the higher potential, we have followed the manufacturer's standard more closely, using 73-kv. breakers for 60 to 69-kv. service, and 135-kv. breakers for 120 to 132-kv. service, because practise has shown that these classes are not so affected by lightning disturbances, and the cost of extra breaker insulation in these classes is so great that we allowed the breaker to have a lower insulation value than the lines and breaker auxiliaries, which are of the unit type and may have a defective unit which would lower the over-all insulation if a reasonable margin of safety were not allowed. Further, we are depending upon the arresters to protect the breakers.

The same general wiring plan is followed with these breakers as with the 25-kv. breakers, but the disconnect switches are of a very different type. Those disconnecting the breaker are two-post, horizontal-break, steel-protected, self-alining jaws, gang-operated, mechanically interlocked with the breaker so they cannot be operated except when the breaker is open, and of such rigid construction that several hundred pounds can be hung on the end of each blade and the switches will retain proper alinement and make proper contact. In fact, I have hung on the end of the blade when these switches were frequently operated, so I might see how they functioned under severe service, and they worked perfectly. Horizontal break was used to economize in head room and to keep the number of posts to a minimum, as the blades are connected directly to the breaker leads and are dead whenever the switch is open, there was no objection to the reduced clearance between phases.

In the case of the disconnecting switch to transfer from the main to the auxiliary bus where it may be completely energized in the open position, vertical-break, gang-operated switches were used to maintain the phase spacing. These switches, likewise, have self-alining jaws with sleet protection, and are so counter-weighted that they would take the open position any time the control failed. They also have horns and are guaranteed to break full-load at normal potential.

We do not expect to use them for such service, but they are located on top of the structure so they could be so used if necessary.

When completed, the high-voltage switch gear of our largest substation, located at Charleroi, will consist of twenty-seven 37-kv., and thirteen 135-kv. high-capacity breakers and their auxiliaries, representing half a million dollars.

All operators have had more or less trouble which originated in or outside of the breaker itself. These difficulties will again depend largely on the system of which the breaker is a part, where located and how operated. Let us first think of those troubles which originate in the breaker itself, and then those which originate from causes outside of the breaker, and try to suggest ways of correcting improper happenings.

The principal cause of trouble originating in the breaker itself is a reduction in the insulating value of the various insulating mediums, and that reduction is generally due to the presence of moisture. I have often been asked "how does the moisture get in?" and counter with "what keeps the moisture out, that stays out?" and as I could never find what keeps it out, will give you a few ways in which it gets in.

We pour it in with the oil, yes, even if the oil does test up very high, moisture is generally present in such small particles and so separated that it is not detected by the normal methods of testing but can be detected by some forms of heat tests. These moisture particles are collected on the surfaces of breaker members by the electromagnetic field, which generally holds the moisture in the small globule form where it deposits until it is absorbed by insulating material or the breaker is de-energized, when the small globules combine and form large globules which descend by gravity and capillary attraction until they come in contact with insulating material which will absorb them, or descend through the oil to the bottom of the tank, if the oil does not have such an affinity for moisture that it will again absorb it, in which event the cycle repeats. This may be prevented by using an oil which has very little affinity for moisture and is free from moisture when placed in the breaker. But what about the moisture which accumulates in breakers from condensation or is taken in by the breaker breathing? We all know that breakers breathe, but I am afraid none of us realizes to what extent moisture is taken in by breathing. Breathing was brought very forcibly to my attention a short time ago. When investigating breaker failures, it was found that the breakers were taking in a great deal of moisture, in fact, to such an extent that water would gather in the bottom of the tanks and freeze, and could be lifted out and the oil still test fair. Just how much moisture, had been taken in could not be determined, but you may get some idea from the fact that the bushings themselves breathed and accumulated water very rapidly. One bushing, the conductor of which was a one-inch inside diameter, brass tube 4 ft. 8 ⅜ in. long, accumulated about a teaspoonful of water in a week's time. A hydrostatic test showed there was no leak at the bottom end where the contact was screwed on, but the top end where the terminal was screwed on leaked slightly at 5 lb. per square inch, hence the moisture got in by breathing through a leak that took 5 lb. to develop. If this tube, having a cubical content of 42 cu. in., sealed as tight as it was, and wrapped up as the conductor of a 73-kv. breaker bushing is, breathes a teaspoonful of water a week, will someone tell me how much moisture a breaker can absorb in a week's time if it has a cubical content of 83,160 cu. in., with no wrappings whatever to protect it from atmospheric changes, a vent that offers no resistance to breathing, and a top on which snow and ice accumulate, assisting in the condenser action and even covering the vent so the breathing is through snow or ice? Well, if you don't know, I will tell you—enough to ruin the best breaker ever built, and so far, we have never really made an effort to keep moisture out of breakers. I know of one instance. Shield and drains were placed in breakers to shed and conduct the water from the more vital parts, rather than take steps to remove and keep out the moisture.

Can moisture be kept out of a breaker? Let us return to the tubes in the terminals. While the majority of these tubes accumulated water, some accumulated oil only, while others both oil and water, which showed they were breathing at either or both ends. Some were about full, which showed the content stood high above the oil in the tank, while others were absolutely dry, which proved they had not breathed at all and no moisture had been condensed on the inside.

Breakers can and should be made moisture proof and provided with quick opening vents, which would relieve gases but prevent moisture from entering the breaker, and then the many failures which originate from moisture in breakers will be a thing of the past, providing proper oil is used.

Other causes of trouble originating in the breaker itself are the many mechanical weaknesses which develop, some from expansion and contraction, others from material deterioration, but generally due to the design, particularly the very sudden starts and stops which create excessive strain and shock, resulting in the failure of many parts and very faulty latch operation. We have had cases where we had to put on a latch to latch the latch, and others where the latches would latch, but on account of their having to be so sensitive, would often vibrate off. While all these mechanical failures are serious, the worst are those which result in the indicating switch giving a false indication. The majority of the mechanical failures can be prevented by a substantial, simple mechanism, using the principle of the crank traveling through about 180 deg., so arranged to give the breaker a retarded movement at both ends of the closing travel and accelerate the middle of the travel, so the total closing time remains normal, the time curves being spiralled as a modern

railroad spirals its curves. On opening, the minimum of the mechanism should trip free very speedily but come to rest through a spiralled motion, at the same time interlocking with the closing mechanism ready for closing. The latch should be positive in action and not depend upon spring or gravity devices which could kick or vibrate open. The false indications can be prevented by arranging an indicating switch operated from the movable contact in each breaker pole. For about a year we have been buying high-voltage breakers only that were so fitted.

When thinking of those troubles which originate from causes outside of the breaker, let us include breaker failures for which the breaker is solely responsible but which follow outside disturbances. The most common causes of such troubles are lightning, surges and over-capacity. The first two generally result in electrical breakdowns but there have been cases where breakers have been wrecked by lightning as if blown up from an explosion, when no electrical breakdown was apparent. Electrical failures generally happen to the bushing, although we do have electrical breakdowns from the contacts through the oil and lining to the tank, from those which take a path to ground via the insulator supporting the movable contact and also from the top of the bushing to the breaker mechanism, wrecking it and rendering the breaker inoperative. Bushing failures are usually the most disastrous of the electrical failures and if we only stop to consider a second the duty expected of a breaker bushing, I am sure we would realize that breaker bushings should be more liberally designed and tested than any other bushing for like service, as the breaker bushing is frequently the end of a circuit where the electrical stresses build up very high, as there is no beyond over which the stresses may distribute, or discharge, as is the case with bushings such as transformer, inlet and arrester bushings. The remedy for these troubles is more liberal insulation, which, it is true, may mean a larger breaker. "But how much more liberal?" I have been asked. That depends upon your system, its size, how the lines are insulated, how effective the arrester equipment and what kick it is possible to get when switching. More than a quarter of a century of experience has shown that the most satisfactory bushing for all kinds of service is one that is free of stresses caused by the method of support, takes its load under compression and has a loose insulated conductor fastened at one end only. Such a bushing is hardly feasible for extremely high potential and some types of outdoor equipment.

Over-capacity failures are the most disastrous. I have seen breakers that were completely demolished by explosions; others that were completely destroyed by the fire following an over-capacity explosion, and frequently great damage done to both indoor and outdoor substations. An over-capacity failure is any failure which results from a breaker being susceptible to greater capacity than it can successfully interrupt, that is, the capacity may be in excess of that for which the breakers were designed, or may be considerably less, and the breaker capacity reduced even below such values by defective oil. I remember a case of oil carbonizing greatly as the result of a single-breaker operation. Under normal switching, the oil did not seem to deteriorate at all but if the breakers opened on a short circuit, the oil would carbonize to such an extent that its test of 30,000 volts would be reduced to less than 7000 volts, and if the breakers were put back in service without correcting the oil and were subject to a second short circuit it would result in a failure even though the short circuits were only a small fraction of the breaker capacity. This resulted in the necessity of changing oil after every short circuit before the breaker was put back in service.

Other oils vaporize, volatilize and decompose very readily and create gases which have a very low dielectric strength and are so inflammable that they ignite as soon as they come in contact and form certain mixtures with the air, or are ignited by arcs which are formed or maintained as the result of the low dielectric strength of such gases. I have seen breakers which had, apparently, functioned properly and opened the circuit but which were wrecked as the result of gas being ignited by an electrical breakdown outside of the switch, caused by the low dielectric value of the gas.

All oils, however, are not bad. Different oils will make a difference in the functioning of a breaker. The best oil, however, is far from being a perfect circuit-breaker fluid. The expression brings mirth, but let's laugh on and try to imagine some of the characteristics of a perfect circuit-breaker fluid.

A perfect circuit-breaker fluid should be non-vaporizing or non-volatilizing, non-inflammable and non-absorbent of moisture, yet have a specific gravity considerably less than water; be non-corrosive, non-poisonous, non-adhesive and not subject to capillary attraction, but be capable of high heat conductivity so that the heat might be transferred directly to the container without motion of the fluid. It should extinguish the arc at the first electrical zero and prevent it re-forming; should have a very high and permanent dielectric strength and low viscosity; should not change through a temperature range from 100 deg. minus to 900 deg. cent. Its dielectric strength should have a negative coefficient, when in contact with arcs, which would dampen out arcs as a resistor to reduce shock, then return to its original state.

With such a breaker fluid the circuit-breaker problem would be very much simplified, but since we do not have such a fluid and have to be content with oils of various grades, the best of which rapidly deteriorates in any of the present day breakers, let us consider what kind of a breaker should be provided to give good service with poor oil, as I feel that it will be infinitely easier to design and build a better breaker than it would be to always procure the better oil.

In attempting to produce a better anything it seems logical that we should first familiarize ourselves with what has been done or thought out by others in the line in which we are interested, and as we are all more or less faimiliar with the standard lines of breakers in common use today in this country, I will pass that and consider some of the breaker designers' ideas not in general use, to see if we might not determine some things to do and some things not to do, and as the operating mechanism is such a simple problem I will pass that also and confine myself to those things which pertain to the inside of the breaker.

The thought that seems to have been uppermost in the minds of designers to interrupt a circuit, has been to extinguish or displace the arc by interposing between the breaker contacts fluid, solid or gaseous barriers. The most common of these devices depends upon the unconfined arc at the breaker contact creating the force to cause an oil barrier to extinguish the arc. This idea has not proven very effective, due to the fact that there is more power in the arc itself, repelling the barrier, than can be produced to establish a barrier and extinguish the arc. Hence, mechanical and chemical means have been employed to try to accomplish the same end. These consist of movable contacts being of such form as to direct a stream of oil into the arc, and depend on the inertia of the oil, which, of course, will not produce sufficient force to overcome the arc. Another plan contemplated a piston or diaphragm attached to the movable contacts, closely fitted to the wall of the tank, which had a by-pass from the bottom to a point near and directed at the contacts. This device was not effective because the underside of the piston had a larger area than the top and the pressure in the neighborhood of the arc, which was connected to the bottom of the tank by a by-pass was greater than the pressure above the piston. The explosion from the arc, the inertia of the oil and the dashpot effect of the piston all tend to retard the breaker action and, if speeded up by great external mechanical force, would create a void or partial vacuum into which the arc would be drawn. Such a breaker would not be very successful.

Other plans provided a pump which would start and force a stream of oil in the path of the break, but it was impossible to start a pump and a stream of oil quick enough to be of any value. Then tests were run with the pump kept in continuous operation, but as stated before, the power in the arc was too great for the pump and the stream of oil which had to pass through a body of oil was easily diverted by the arc, and the breaker did not prove any better than a breaker having still oil.

A closed oil-pressure system provided for the interruption of the circuit in a confined stream of oil. This meant that the pump had to be so large and the power consumed so great that it was a failure, or the oil-confining chamber was so small that it was damaged by the arc before extinguishing could take place. The power of the arc was also greater than could be maintained by a reasonable pump.

Another design which would seem worthless is one having cylinders of insulation in which are mounted the stationary contacts. The movable contacts are mounted on the end of plungers which fit said cylinders and are held against the stationary contacts by springs. High-pressure oil is admitted to the cylinder and forces the plunger out, opening the contacts, and at the same time is supposed to completely fill the cylinder, thereby preventing an arc from forming.

We also have numerous explosion-chamber types wherein the oil and arc are confined until the movable contact, gas and oil are expelled, as the result of a pressure being built up in the chamber, due to metal and oil volatilizing, thus extinguishing the arc, and while this is the most practical of such devices I feel that the greatest value of this device is in the directing of the results of the power interruption. In order to speed up the extinguishing of the arc and increase the capacity, it has been proposed to circulate and direct oil into the arc by the means of a pump. Here again we have the objection to and insufficiency of the pump.

A breaker design which appears to me to have merit is one having series breaks arranged so that the early opening of some contacts produces arcs in enclosures, forming gas which expels oil from the enclosures right in the break of later opening contacts extinguishing the arcs and interrupting the power to the early opening contact and the circuit.

A large number of breaks in series have not been received with much favor in this country but foreign designers have used large numbers of breaks in series, simultaneously opened, with very great success, and in cases of great single-phase capacities shunt a part of the breaks with resistance, to increase the breaker capacity by retarding the potential rise following the current zero, thus preventing the arc from re-forming. We have an American designer who has suggested a large number of breaks in series opened successively, the idea being that with the successive opening of contacts an opening will occur without arcing when the current is at zero, hence the oil insulation will not have deteriorated, no arc will establish and the circuit will be interrupted.

Other designers provide for injecting solid barriers into the arc to break it. In fact, one came to my attention that was designed to cut the arc off, as you would cut a piece of paper with a pair of shears, by closing refractory barriers between the contacts as soon as they parted.

We also have the gaseous barriers which consist generally of containers filled with various gases or fluids, which would be gasified by the heat of the arc or an explosive, and extinguish the arc, the gas to be liberated by several means, such as puncturing with a sharp instrument actuated by the breaker mechanism, the

melting of a fuse plug by the arc, the bursting of the container by expansion or explosion of its contents from the heat of the arc or the explosion of explosives placed therein and set off by a fuse lighted by the arc. It has also been suggested that the arc be blown out by an explosive. Just imagine placing a sufficient charge of explosive in a breaker to insure the blowing out of a million kv-a. arc! Well, don't get scared, none of these devices is practical in its present state and I do not think any of us will be using any of them, but we may soon be using a breaker in which the arc is extinguished by steam generated by the arc.

The steam reminds me of a breaker designed some time ago, which had an insulated tank with a stationary contact at the bottom and a movable contact which was raised completely out of the tank. The bottom half of the tank was filled with water, the top half with oil, hence when the contacts were separated, the water functioned as a resistor and the current was finally broken in the oil, but as the oil might become wet from its contact with the water, the movable contact was raised completely out of the tank to prevent any leakage through wet oil.

The inflammable gases which accumulate in the top of a breaker have been a real menace, and designers have different ways of correcting this hazard. One suggests injecting into the top of the breaker inert gas or vapor to prevent the formation of explosive mixtures, also to wash the breaker of all gaseous products. Others would separate the gas in small cells where it would be cooled, and conducted away in volumes so small it would not be dangerous. Others have elaborate cooling systems. A German turned his military training to good account and placed in the top of the breaker a wire entanglement to cool the gases and to prevent any sparks or flames from getting beyond the entanglement and igniting the gas.

I have only found where one designer made any effort to prevent breathing and eliminating moisture due to condensation, and I fear he has "foozled" for he has suggested an unlined, reinforced concrete pit large enough to hold all three poles of a breaker—including the operating mechanism, series and shunt transformers, and deep enough that the temperature of the oil will remain practically constant all year, and provided with a cast iron cover above the ground, having a manhole which serves as a vent.

This designer, apparently, did not know that oil quickly penetrates and disintegrates concrete, and that it would be impossible to permanently waterproof a pit, as he suggests, so moisture would not penetrate it; that the enormous cast iron top with the extreme difference of temperature above and below it would cause it to sweat very profusely, and a manhole vent would do some breathing.

But what is the real trouble with the breaker? The trouble is not with the breaker; poor, innocent thing, it is just what we made it and I have never seen a breaker that was as good as it could be reasonably made. The real trouble is with us.

(1) The operator has not determined his breaker needs.

(2) The manufacturer has not fitted himself, by research work, to meet the operator's needs.

(3) The operator and manufacturer have not co-operated to develop, operate and service breakers as they should.

These are the three cardinal points in the breaker problem. If we get into the matter conscientiously, the job is done.

Discussion

PAPERS ON OIL CIRCUIT BREAKERS

(MAC NEILL, HILLIARD, JENKS)

BIRMINGHAM, ALA., APRIL 9, 1924

J. D. Hilliard: On Mr. Jenk's paper, I heartily concur in his final conclusions that the operator has not determined his breaker needs. It seems to me rather absurd that the whole line of stations should be held to the expense of building a breaker at a definite rating, to take care of the severe conditions of some particular circuit. It seems to me the thing to do is to get after the particular circuit and ease up on the condition.

He mentions, in his various types of breakers, the series break, but it is a debatable question whether the series break has any advantage over the ordinary breaker.

"The manufacturer has not fitted himself, by research work, to meet the operator's needs." That, with the General Electric Company, has been done away with; we have fitted ourselves.

"The operator and manufacturer have not co-operated to develop, operate and service breakers as they should." That is undoubtedly true, and there should undoubtedly be many more tests made in the field than have been made in the past.

A series of tests was made upon plain-break and explosion-chamber breakers, and operating in the same plant, with the same mechanism, by the same generator, under the same circuit connections and load. Broadly speaking, we found that in that particular test the maximum amount of gas with the explosion chamber at 1200 amperes, at 63,000 volts, was about one-third of the minimum amount with the plain break; that the maximum amount with the explosion chamber was about one-tenth of the maximum amount with the plain break. With increased duty the explosion-chamber breaker has a speed increase due to the increased pressure in the explosion chamber. The plain breaker, shows very little change in speed. Whatever change there will be, however, in the plain-break breaker is a decrease in speed, rather than an increase. That comes from the increased pressure in the tank acting upon the rod passing through the tank, and also upon other factors which all tend to decrease the speed of operation. The rod passing through is acting as a piston, and the force on that piston is acting opposite to the force of acceleration given by the spring and this tends to slow up the breaker.

A series of tests was made recently by the A. E. G. Company of Germany to determine arc duration. In a two-break explosion-chamber breaker at 80,000 volts the longest arc duration was 9 half cycles on a 50-cycle circuit; at 70,000 volts the arc duration was about 7 half cycles. In the plain-break breaker, with six breaks in series the maximum arc duration at about 67,000 volts

was 25 half cycles. These tests bear out the tests we have made in Schenectady very closely.

J. B. Mac Neill: In the years 1913 and 1914, the Westinghouse Company had available, due to cancellation by a large customer, a 15,000-kv-a. low-reactance alternator on which a considerable number of tests were made in our factory. Our experience since has indicated that the results of those tests were to some extent not borne out by subsequent field tests.

We account for that by the inherent rapid decrement characteristic of a single machine when subjected to short circuit. This decrement takes place in the short-circuit current and also in the terminal voltage, so that the arc kv-a. delivered to the breaker decreases approximately as the square of either current or voltage.

Mr. Hilliard's remarks regarding the tests at the General Electric factory are very interesting. I was surprised, in looking over his paper and in looking over my paper, to see the apparently relatively large concentration of power that was available at Bessemer for the Westinghouse 44,000-volt tests. Mr. Hilliard draws the conclusion that the power available was not adequate to stress either the plain-break or the explosion-chamber breakers. We reached 3600 amperes at 44,000 volts,

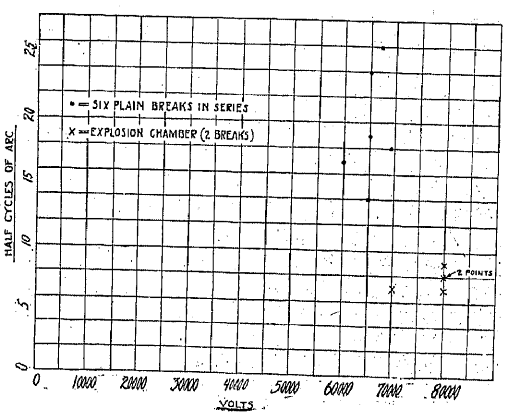

FIG. 1—ARC DURATION IN PLAIN-BREAK AND EXPLOSION-CHAMBER OIL CIRCUIT BREAKERS

Arc duration with different voltages at 50 cycles per minute. The length of time is given in half cycles. The plain-break breaker has six plain breaks in series; speed, 5 m. per sec.; amperes, 234-290. The explosion-chamber breaker has two breaks; speed, 3.23 m. per sec.; amperes, 330-410.

and that would seem to me to be adequate power for those purposes.

On page 4 of Mr. Hilliard's paper, regarding the ability of the breaker to withstand the shock of oil throw, in 1915 the Westinghouse Company, in conjunction with the Detroit Edison Company, made a series of tests at the Connors Creek Station, where there was available approximately 12,000 amperes at 24,500 volts on short circuit which still stands as one of the highest power tests ever made. At that time the conditions in the top chamber of the breaker, the possibility of breaking castings due to the upward impact of the oil, and more especially the actual explosion in the top chamber, of gases hot enough to ignite with oxygen, were rather fully gone into before the tests were over.

In 1920, we made at our factory, under the direction of our Research Department, a series of tests involving bombs. Those tests were under the direction of Mr. Escholz and Dr. Rodman, and were of considerable interest and some help in determining breaker structures. The particular difficulty with those tests was controlling the rate of propagation of the disturbance, but by certain investigations of powder proportions the resulting and mixtures which burned with different rates of rapidity and it was possible to simulate in some way the action that obtains in high-power breakers.

I just wanted to add to Mr. Hilliard's comment on the bottom of page 4 regarding secondary explosions, that they are nearly always caused by static sparks. Cases are on record where these explosions were caused by hot gases such as hydrogen igniting with the oxygen in the top chamber and not static sparks, though undoubtedly there are cases where static sparks are the cause of the trouble.

On the subject of oil viscosity, the Westinghouse Company has conducted a series of researches in the last two years on the subject of oil viscosity and has found that the question of flash-point has been much overstressed as affecting circuit-breaker operation. We have found that the lighter oils of late years have given very successful operation in breaker structures. Dr. Rodman has been in charge of those experiments. Briefly, years ago the high flash-point oils did not contain the same proportion of highly volatile matter that the lighter oils did, but due to the activity of the people who make gasoline nowadays, those extremely volatile constituents are removed, with the result that the lighter oils are now considered adequate by us and even superior to the heavier oils for circuit-breaker use. You will be interested to know that within the last year we have therefore standardized for indoor circuit breakers on the use of transformer oil.

In my paper, I deal somewhat with the extremely high reestablished voltages experienced at Bessemer on the 44,000-volt system. These are probably due to the fact that this 44,000-volt system is not as completely grounded as the 110,000-volt system and this in the minds of our engineers accounts for the tremendous kick we got upon opening the arc. It is doubtful whether anything of the same magnitude of these same voltage kicks can be obtained unless there is connected up a large high-voltage system with many transformers and interconnected lines which have a tendency to cause surges and re-establish the arc.

W. E. Mitchell: I am glad that we have had two types of papers presented here, because the two sides of the story must be worked out together to get the right answer. We have had the operator's viewpoint and we have had the manufacturer's viewpoint, and only as these two are co-ordinated will we get a satisfactory answer.

I think that the design is absolutely the function of the manufacturer. About all the operator can do—and it is what he should do, as Mr. Hilliard and Mr. MacNeill both brought out—is to the best of his knowledge and ability give the facts to the manufacturer as to what he requires. But, gentlemen, when that is all said and done, what we want are circuit breakers that will open the circuits, exactly as we want transformers that will stand the bumps.

If I had any criticism to make of the manufacturers, it would be that they have in the past years spent too much time trying to convince the operators that what they had manufactured was exactly right, and there was nothing whatever wrong with it—instead of correcting obvious faults that have been brought out in operating practise. It may have been the operator's fault; he may have put the switch in a place where the duty was a little too severe, but after all, what we must have are oil circuit breakers so substantial in design that they will stand some abuse.

Today the oil circuit breaker is immeasurably better than it was three or four years ago, but it still has altogether too much trigger work and too many jim-cracks on it. When you have to come down to adjusting breakers to two thousandths or four thousandths of an inch, to get them to operate properly, and if when you fail to do that you break the operating rods or links, or something else, it is too delicate a piece of mechanism to give to the ordinary electrician. We are not running a laboratory; we are giving service to our customers and what we must have are very rugged switches. As I looked through one of the factories a month ago and saw some of the changes that have been made, getting away from the old elliptical tank which was formerly used, to a round, welded tank with cast steel tops of such

construction that it would not blow up every time there was an explosion, I felt much better; and I realized that really great advances have been made in the past four years. We must get switches that won't be wrecked when opening a short circuit.

Probably you can come back from a design standpoint and say, "Tell us exactly what duty you want," and I will admit we ought to tell you, but only within broad limits, gentlemen. We want to get things simplified into big classes. Then we want the switches to come onto our system so that we can work them, so that ordinary men and not factory men can put them up, can repair them and can give service to the people whom we are supposed to give service to with them.

J. M. Oliver: On the Alabama Power Company's system considerable trouble has been caused by secondary explosions in oil circuit breakers, especially in those of rather old design. There were several instances in which the breaker ruptured the circuit without very much evidence of distress and probably a minute after the opening, due to some unknown cause, an explosion would occur which practically wrecked the switch. We believe that oil circuit breakers should be designed to withstand the maximum pressure which can obtain in the switch tank, as it is very difficult to prevent secondary explosions.

I would like to hear a little more discussion on the question as to whether the heaviest duty on an oil circuit breaker is at the generating station or at the substation. Mr. Hilliard pointed out that low power factor causes a heavier duty on the breaker, and others maintain that on the substation breaker the recovery voltages being higher, the duty is greater.

On our system the maximum short-circuit current at this time is about 800,000 kv-a. Looking ahead for several years we find that short circuits as heavy as 1,500,000 kv-a. may be expected, and we begin to question whether the system should continue in operation interconnected as one network, or whether it will be necessary to separate the system into two or more parts. We find it desirable to operate as one network in order to secure the best efficiency in plant and line operation. If it is impossible to secure oil circuit breakers which will successfully handle short circuits as high as 1,500,000 kv-a., it will of course be necessary to look for some means of reducing the short-circuit duties.

P. M. Downing: The function of the operating company is to give service—not service when conditions on the system are absolutely right, but service under all conditions. If the manufacturers are unable, with their present equipment, to provide facilities to the operating companies with which they can give service, the operating people, I think, feel that it is up to the manufacturers to provide those facilities, if it is humanly possible to do so, to give that service.

We realize that the operating companies and the manufacturers are up against two problems. First, to provide a switch that will function properly from an electrical standpoint, and the other problem is to provide that switch at a price that the operating companies can afford to pay. Only very recently, within the last two years, the company with which I am associated had occasion to purchase a good many 220,000-volt oil switches. I am not at liberty to quote prices, but the prices of those switches were not low; they were a very important item of expense.

So the manufacturers must get this idea firmly fixed in their minds: That systems cannot be designed around the oil switches. You can't arrange your circuits so as to meet the convenience of the designers or the manufacturers. The public demands service. You must take on any load that comes along, and supply that service. If the present design of switches is inadequate to handle the loads that are carried, then they must be changed, because after all, when you consider that there is a legal and a moral responsibility resting upon the operating companies to give service, it is up to the manufacturers and to the operating companies to provide facilities for giving that service.

E. E. George: I just wanted to express my appreciation of Mr. Jenks' remarks about the need of restoring service promptly. I think it is quite a step in the right direction. The schedules we usually have,—of one minute or two minutes,—for restoring service, ought to be obsolete; they are a relic of the old days when you couldn't get a call through central in less than a minute, when the operators closed all the switches by hand, before we had any dependable relays that we could time accurately. Instead of talking about restoring our service in thirty or sixty or ninety seconds, we ought to speed up to suit the fastest customers, instead of trying to accommodate the slowest ones.

From the standpoint of public relations, probably the residential customer is the most important. He can't protect himself; he has to depend upon the electric company to do it for him. This involves no problem the electric company can't take care of by relay, and at a relatively small expense.

Instead of talking about twenty to eighty seconds before coming back on the line after an interruption, we ought to be able to get back in twenty or thirty cycles.

Mr. P. H. Thomas: Mr. Hilliard, I understood you to say that it was probable that some of the tests made here in the Alabama Power Company on the 44,000-volt breakers were under conditions not as severe as might occur in practise. Could you give some idea what the nature of those conditions are?

Another question: What is the action that actually suppresses the arc—is it the pressure developed, or what is it?

A question to Mr. Jenks: With the study he has made of new ideas, has he something definite to recommend to us better than what we now have in switches?

G. H. Middlemiss: I think there is one paragraph in Mr. Hilliard's paper, of considerable significance. Tests have been made at duty cycles other than standard, in order to determine the relative severity of these supplementary cycles.

There has been a lot of discussion of late as to the standard duty cycle which should be adopted, and I am frankly of the opinion that it is going to be very difficult to secure a duty cycle which is universally acceptable to operating engineers all over the country, due to varying conditions of service and other factors at each particular location.

In our own operation we close some breakers at two-minute intervals, some at one-minute intervals, and others at less. If these breakers are operating at somewhere near their maximum rating of interrupting capacity, we would like to have the manufacturers tell us what multipliers to use in connection with these breakers, so that we could determine their rating at the duty cycles other than standard.

Another point in connection with contacts is this: We cannot dismantle the breaker every time it functions in accordance with a duty cycle and find out what is wrong with the contacts, or if the contacts are all right. We have other troubles to worry about. We would like to have investigations made, and have the manufacturers give us an idea of how many standard duty cycles the breaker will stand at capacities somewhat near its rating, before we will have to pull the breaker down and redress the contacts, and make other adjustments.

J. D. Hilliard: Answering Mr. Thomas' questions as to what really causes arc interruption in an oil circuit breaker, there is no doubt the arc is interrupted by the dielectric strength of the gas in the arc stream and this strength is a function of the temperature and pressure of that stream. In the explosion-chamber breaker we deliberately produce a high pressure and the gas stream is very effectively cooled by the atomized oil injected into the stream as it escapes from the chamber. We also have a high speed produced by the chamber pressure and all of these act to produce a remarkably efficient breaker.

The interrupting capacity of any oil circuit breaker depends upon the quantity of gas generated by the arc within the breaker and the speed of the gas formation.

The rate of gas formation at a given electrode speed varies as the *square* of the time of arcing, not *directly* as the time of arcing, as is generally believed. This can be readily seen if we draw a

triangle in which the base represents the duration of the arc in half cycles, the altitude the length of arc in inches, the speed of break being assumed as constant. If we assume that the arc length is the same irrespective of any slight speed variation, then it is evident that the area of the triangle, which represents the gas volume, varies as the square of the half cycles of duration of arc.

If the recovery voltage of the circuit is such as to increase the arc length, then it is probable that the arc will hang after the end of the stroke has been reached and gas will be generated at such a rate as to destroy the breaker. The only safe way is to have the break distance such that the arc is certain to be ruptured by the time the end of the stroke is reached. In oil circuit breakers, where large quantities of gas are formed, the oil is violently projected against the top of the breaker and will lift the breaker from the floor unless it is bolted down.

It is practically impossible to have the gas escape from the tank as fast as generated especially as the projected body of oil plugs the outlet and it is, therefore, necessary to make the tank and top sufficiently strong to stand the gas pressure. The volume of gas is considerably greater than it is generally thought to be, rates of generation exceeding 100 cubic feet per second having been observed in tests. This rapid gas formation greatly stresses the tanks and tops and it is necessary that the construction be made very substantial or disaster will result.

There are various ways of decreasing the quantity of gas generated and the one the General Electric Company has found to be most effective is the explosion chamber. In this breaker we deliberately use high pressures within the chambers to increase the dielectric strength of the gas and to supply a cooling blast of atomized oil which also increases the dielectric strength. The gas is moreover projected vertically downward into the cool body of oil in the outer tank which again acts to cool it and by the time it has risen to the surface of the oil it is at such a temperature that ignition cannot take place from the heat, and moreover a gas mixture containing over 60 per cent. gas cannot be exploded, and at the interrupting rating of the breaker the mixture is always richer than this, so there can be no secondary explosion until diffusion has taken place. We build our newer high-class breakers of such a strength that they will withstand a secondary explosion without damage should one occur.

Answering Mr. Thomas' question as to the conditions at the Alabama Company test, these were all made single-phase at Bessemer, and both single-phase and three-phase at Lock 12, but on the three-phase tests the neutrals were grounded and the short-circuiting breakers were also tied into the ground so that the maximum voltage obtainable across any break was 57 per cent. of line volts.

During all the tests made at Baltimore, I never observed a recovery voltage equivalent to the initial voltage, whereas if the ground had been taken off either the neutral or the short-circuiting breaker, many observations would have been made showing a recovery voltage in excess of line volts. In Schenectady we test with but a single ground so as to obtain the highest possible recovery voltage. It might, of course, be possible to have surges or resonant conditions which would boost the recovery voltage, but no such evidences were observed in the Baltimore or Alabama Power Company tests.

In reference to the quantity of gas generated in an oil circuit breaker, Fig. 2 herewith shows the relative volumes very clearly. The figure shows the result of tests with an explosion-chamber and a plain-break type of breaker when tested in the same tank under the same load conditions and with the same operating mechanism.

The tests were made in such a way that the measurements of gas volume were correct within two per cent., the gas being measured very carefully after the rate of leakage, which was very small, had been found by test. The method consists in catching the gas and measuring it under standard conditions, *i. e.*, at atmospheric pressure and temperature. The measurements were made upon the fixed gas and any vaporized oil which might be later condensed was not measured. However, the pressure measurements, made in the outer tank of a circuit breaker check the volume measurements and show the remarkable decrease in pressure in the outer tank due to the use of the explosion chamber.

The oil question is one which needs considerable more thought than is given it by the ordinary station man. It is very important that the oil specified by the maker of the breaker be used. We have made a large number of tests upon oil and other liquids and find a wide difference in viscosity, freezing point, quantity of gas formed, carbon precipitation, etc.

The minimum gas formation may be represented by 8, the maximum by 90 when interrupting the same load, and while the pressures are not represented by the same figures, they do correspond in a way. The reason they do not conform closer is undoubtedly due to the presence of the vapor of the liquid which later condenses and consequently is not measured. There is, of course, no such great variation as indicated above in the oils we ordinarily use in the circuit breakers.

J. V. Jenks: Mr. Hilliard questioned my statement that the

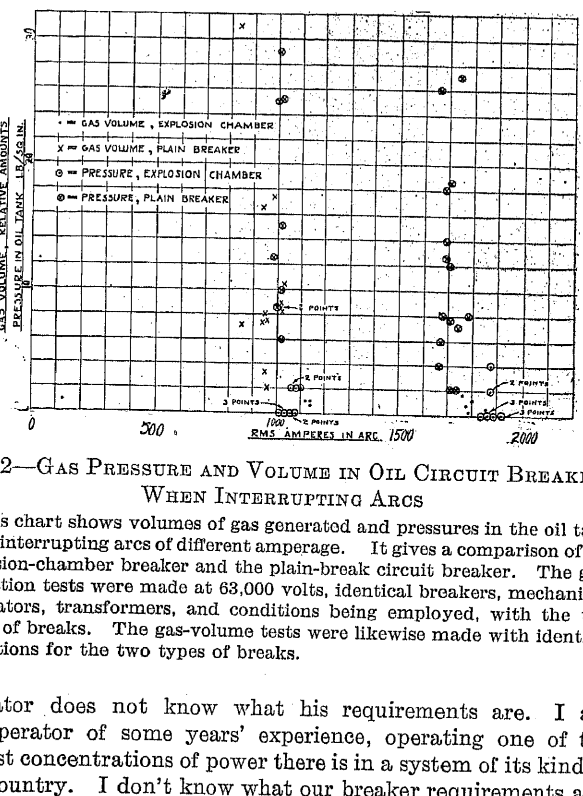

Fig. 2—Gas Pressure and Volume in Oil Circuit Breakers When Interrupting Arcs

This chart shows volumes of gas generated and pressures in the oil tank when interrupting arcs of different amperage. It gives a comparison of the explosion-chamber breaker and the plain-break circuit breaker. The gas-formation tests were made at 63,000 volts, identical breakers, mechanism, generators, transformers, and conditions being employed, with the two types of breaks. The gas-volume tests were likewise made with identical conditions for the two types of breaks.

operator does not know what his requirements are. I am an operator of some years' experience, operating one of the largest concentrations of power there is in a system of its kind in the country. I don't know what our breaker requirements are, and I have never met any other operator who did, and on that basis I made the statement.

Mr. Hilliard said that my statement, that no manufacturer had properly equipped himself, is incorrect. I bought from the General Electric Company 51 circuit breakers, guaranteed to break a three-phase arc of 1,000,000 kv-a. I asked the General Electric Company to produce a test to substantiate that guarantee. They said they were not in a position to do it. Mr. Hilliard, himself, admits that his test on his generator which can produce that amount of power might be somewhat different from line conditions; that the resonance or surges of the line might affect it.

We operators don't buy a circuit breaker to be tested and to serve up against a generator—we buy one to be served and serve the public miles away where there are many possibilities of resonance and surges and transformers and other apparatus which which might kick into that breaker.

Mr. Hilliard said there was no advantage in the additional multiple break. The facts are these: That the operator has no facilities for determining many of these theoretic things; we are not equipped to make these tests, and should not be asked to. About the only thing we really have, that means anything, is the "eating of the pudding."

We have on our system General Electric breakers of two breaks, which have a break much more than twice the length of break on the four-break breakers. They never have given, and I don't think it is possible for them to be made to give, the service the four-break breakers do.

Mr. Thomas asked if I had any idea as to what a breaker ought to be. I am going to tell you, in short, the specification which will largely govern the next half million dollars' worth of breakers the West Penn Company buys.

The operating device shall consist of a small motor, which will draw from the supply battery, which is always provided to insure continuity of operation, the minimum current.

The operating mechanism and all breaker units will be rigidly tied together with a steel structure, so that any failure of foundation will not interfere with the operation.

All the multiplying levers will be removed from the breaker proper and put in the operating housing, which will be an all-open-housing, so that all parts possible may be reached without entering the tank. This housing will be large enough to accommodate all necessary relays.

The operating mechanism will be trip-free, leaving as little of the inert mass to be moved by the breaker as possible.

The hand-closing device will be so arranged that a minimum of power will close the switch; also provided with a trip-free mechanism. The trips shall be positive and resetting upon the opening of the breaker. I can point out to you cases where circuit breakers are operating with three trips, three trigger arrangements—one really to hold the contacts, another one to hold the first and another one to hold the second. All of those things are supposed to function and operate properly almost instantaneously. The breaker comes in with a bang, and the triggers are supposed to catch and latch, but they don't do it. We have to adjust to thousandths of an inch, and yet we can't get the results desired. If we get a slight excess pressure on a trigger, the breaker won't trip properly.

So there is no excuse for the tripping mechanism not being made in such a way that it resets itself when it has plenty of time to do it, and then that the mechanism comes up against that locking device and is carried into the closed position.

The tripping device should be so arranged, interconnected with the operating mechanism, that the breaker would be instantly reclosing. Of course, the type of contact we are using now has to stop, but the mechanism does not need to stop. It can be started and continue on, and close the breaker again, re-establishing service as it ought to be re-established at once, not in a minute or two minutes, or some other period. That is necessary for several reasons: One of them is that in order to segregate a system, we find from time to time it is necessary, in order to conserve investment, to install air-break apparatus. Air-break apparatus should disconnect faulty pieces in small units where you cannot afford to put a costly circuit breaker, an attendant, and everything else that goes with it. These air breaks will open simultaneously with the oil breaker, but the oil breaker being a little speedier and so relayed, will interrupt the circuit. While the main circuit is interrupted, the air break will open the branch circuit to the part in trouble, and the oil breaker will immediately re-establish service again on the remainder of the system which is not at fault.

The method of transmitting power from the operating mechanism to the various breaker units should be by a torsion shaft, which can be closely fitted and packed to prevent gas passing from one unit to another and to prevent the entrance of moisture.

The series transformer should be sectional-wound, making it impossible to get a number of different ratios. It should be confined in a part of the supporting casting which normally supports a bushing; be sealed absolutely from the gas in arc chambers; removable integral with the bushing and connected on its low-voltage side by weather-proof conduits entirely outside of the breaker. The bushings, themselves, should be very liberally designed and of a very rigid nature, so that great magnetic stresses will not damage them.

The tank should be top-attached, to eliminate the possibilities of voids at the top which occur when tanks are supported from the bottom. Switch tanks do bulge and bolts do stretch, and when a tank bulges or a bolt stretches, if supported from the bottom, it leaves an opening around the top of the tank. The top of the tank should be sealed by a gasket on the order of a pump-sucker, which would close tighter with pressure, instead of opening on a slight movement of the tank at the top. The tank should have a bump bottom with an internally packed drain at the lowest possible point. It should be equipped with permanent lifting facilities in the case of those tanks which are lowered for inspection.

All openings to the tank or top should depend upon gaskets only for preventing capillary attraction of moisture. The idea of manufacturers building a breaker with a top of such form that the water remains on it and is prevented from going into the breaker by only a gasket, is something that the operator ought to insist on having corrected.

Linings should be of fire-resisting material. Particularly an inner lining should be designed to withstand arcs rather than have any particular insulating value. The lining next to the tank should have a high dielectric strength. Liners should be supported in a manner which would keep them from the moist oil in the bottom of the breaker, where they absorb the moisture, and which reduces their dielectric strength.

At least six, magnetically directed, barriered contacts should be provided, to assure series breaks which will speed up the break, which will keep the gases segregated, so that they can be cooled and conducted to the air chamber in the top of the breaker without danger of ignition from over-temperature.

The top of the breaker should be provided with a suitable baffle arrangement, which will absolutely prevent oil from being discharged from the vent. The vent should be self-hermetically sealed, and the breaker should be provided with a dependable breather. The manufacturers have for years done all within their power to keep moisture out of a transformer, which in reality can stand more moisture than a breaker. Because of the temperature in the transformer and the viscosity of the oil generally being kept at fairly constant value, the moisture does get to the bottom of the tank without doing much damage. The oil is not agitated in the transformer as it is in the breaker, where the moisture is stirred up. Yet, they build breakers with unprotected vents, so arranged that a very light snow will build snow all round them and then the breakers breathe through snow—and we do know that breakers breathe. It seems to me that instead of trying to keep the moisture out of the breaker and make the breaker the most dependable thing, we have lost sight of some very essential things which we have found in other electrical apparatus.

Such a breaker should, without throwing oil, still be fit for service at its rating after opening at least five times consecutively, under any system condition, irrespective of power factor, grounds or number of phases. If we get such a breaker—and I believe it can be developed at not much greater cost than what we are paying for the present-day breaker—I think that our breaker problem will be largely solved.

A New Self-Excited Synchronous Induction Motor

BY VAL. A. FYNN
Fellow, A. I. E. E.
Consulting Engineer and Patent Advisor, St. Louis, Mo.

Review of the Subject.—*Two early forms of the synchronous induction motor are described and their performance analyzed with special reference to synchronizing torque. A new self-excited form of this type of motor devised by the author is then described, its mode of operation and characteristics are elucidated and the principles governing its design explained with the help of vector diagrams. An analysis of the synchronizing torque shows that whereas prior machines all exhibit an alternating synchronizing torque of either slip, or double the slip frequency, the synchronizing torque in the new motor is substantially unidirectional and pulsating. The machine is particularly well suited for smaller units and operates with unity or leading power factor throughout its normal load range without taking an excessive current at any load or requiring any adjustment other than that automatically provided by its inherent regulating capacity.*

* * * * *

It is believed that the first synchronous induction motor was conceived and built by E. Danielson in 1901, while in the employ of the Allmaena Swenska Elektriska Aktiebolaget. (See E. T. Z., year 1901, page 1065). Danielson used a standard polyphase slip-ring motor with a three-phase winding on the revolving secondary in conjunction with an external source of

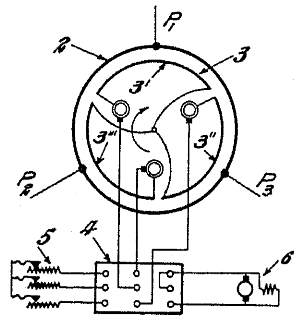

Fig. 1—Separately Excited Synchronous Induction Motor Danielson, 1901

unidirectional current. A two-pole machine of this type is diagrammatically illustrated in Fig. 1 where 2 is the primary three-phase stator winding, 3 the secondary three-phase rotor winding connected to slip-rings, 4 a three-pole two-way switch, 5 the starting resistances and 6 the source of unidirectional current. The machine was started in the usual way by inserting resistances 5 between the slip-rings and reducing these resistances to zero in one or more steps. When up to speed the switch 4 was thrown to the right, shortcircuiting two of the rotor phases in series and connecting all three to the d-c. exciter 6 as more clearly shown in Fig. 2.

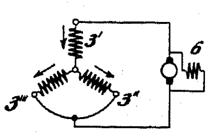

Fig. 2—Synchronizing and Exciting Circuit of Danielson Motor

Danielson found that with a unidirectional excitation which allowed of a 50 per cent overload as synchronous motor and yielded a leading power factor of 0.86 to 0.9 at full load, the synchronizing torque was about equal to the half-load torque. It was also observed that when loaded beyond its load limit as synchronous motor, the machine did not stop like an ordinary synchronous motor, but continued to operate as an asynchronous motor. Under these overload conditions the speed fluctuations were very marked and the motor would not go back to synchronism unless the load was reduced to about half normal, notwithstanding the fact that the machine was considerably over-excited.

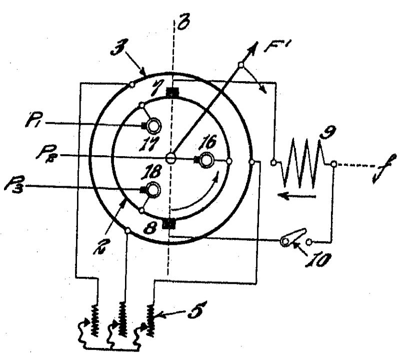

Fig. 3—Self-Excited Synchronous Induction Motor. Fynn, 1906

Whether the excitation could be sufficiently increased to synchronize the motor with full-load torque was not ascertained. It is not thought that materially different results have ever been noted with this type of machine.

The next step in this field was probably taken by the writer, who devised the machine diagrammatically shown in Fig. 3. (See B. P. No. 11, 298 of 1906). In the two-pole embodiment which is illustrated, the high-tension three-phase winding 2 is on the rotor and provided with slip-rings for connecting to the supply P_1, P_2, P_3. The three-phase low-tension winding 3 is on the stator and connected to the adjustable starting resistance 5. The unidirectional excitation is taken from the rotor and conveyed to the exciting winding 9

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala.. April 7-10, 1924.

located on the stator. To this end the high-tension winding is connected to a commutator as well as to slip-rings, and brushes 7, 8 carried by the secondary, cooperate with the commutator and are connected to the exciting winding. The axis f of this exciting winding is displaced 90 electrical degrees from the brush axis b. At synchronism the machine acts like a synchronous converter as well as a motor and delivers unidirectional current to the winding 9. In this way an external or independent exciter is dispensed with and the operating characteristic is considerably modified.

Let us now analyze the performance of these early machines a little closer. Fig. 4 shows another diagrammatic view of the Danielson motor. The three-phase rotor winding is here shown in the form of three belts, the direction of the direct current in the active part of the belts being indicated by dots and circles. The dots indicate current directed down through the plane of the paper and the circles denote the opposite direction of the current. The axis of the unidirectional rotor ampere-turns, or of the magnetization F produced by the direct current in the rotor, is f. It does not change its position with relation to the rotor windings unless the rotor connections or the polarity of the direct-current source is changed and neither happens in normal operation.

When the high-tension winding 2 is connected to the supply, a primary revolving flux F' is set up, as is well understood, and when the secondaries are closed, as happens in Fig. 1 when switch 4 is thrown to the left, secondary currents are induced in them and while they bring the motor very close to synchronism, they cannot possibly pull the machine into step or synchronize it, for the simple reason that these induction-motor torque-producing currents diminish very rapidly as synchronism is approached and become zero at synchronism. These currents are not indicated in Fig. 4.

When the machine is near synchronism, Danielson introduces his unidirectional excitation, the connections then being as shown in Fig. 2. The phases 3'', 3''' are connected in series and short-circuited while the phases 3', 3'' and 3', 3''' are closed over the exciter 6, which has a certain amount of reactance. This destroys the induced-current balance in the rotor and therefore the constancy of the induction-motor torque, and increases the slip. So far as the exciter 6 is concerned, phases 3'' and 3''' are connected in parallel and the two of them are in series with phase 3', which produces the distribution of unidirectional ampere turns shown in Fig. 2 by arrows and in Fig. 4 by dots and circles. Notwithstanding the unbalancing of the induced currents in the rotor as to phase and magnitude, all of these still become zero at synchronism. The approximate shape of the resulting unbalanced induction-motor torque T_i is shown in Fig. 5. Its magnitude diminishes as synchronism is approached and it becomes zero at synchronism. Because of friction and windage losses, the useful induction-motor torque becomes zero before synchronism is reached.

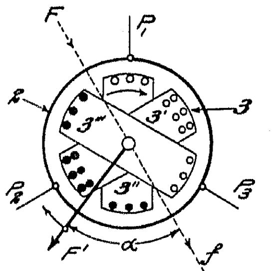

FIG. 4—SHOWING HOW SYNCHRONIZING TORQUE IS PRODUCED IN DANIELSON MOTOR

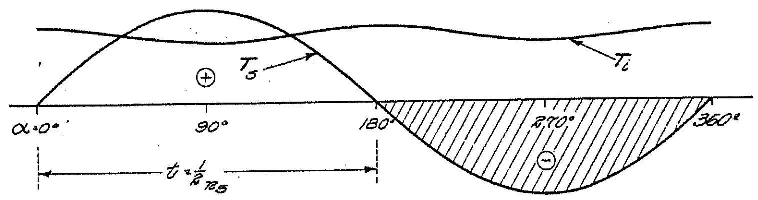

FIG. 5—INDUCTION MOTOR TORQUE T_i AND ALTERNATING SYNCHRONIZING TORQUE T_s NEAR SYNCHRONISM. DANIELSON, 1901.

To bring the rotor into synchronism, it is necessary to dispose of a torque which will accelerate the rotor and the load from the asynchronous speed, at which it is being driven by the induction-motor torque, right up to the synchronous speed. In so doing, this torque must overcome the inertia of the rotor and of the load. The greater the inertia and the "slip" and the shorter the time available for the acceleration, the greater this synchronizing torque must be.

Disregarding the hysteresis torque, which is very small in an induction motor, the only possibility of developing a synchronizing or "pull in" torque in the Danielson motor lies in the added unidirectional rotor magnetization already described.

The unidirectional ampere-turns on the rotor can and do produce a torque with F'. The difference in speed between their axis f, which revolves clockwise with the rotor, and F', which revolves clockwise at synchronous speed, is equal to the "slip" of the rotor, and the interaction can be most conveniently studied by assuming that the rotor stands still and that F' revolves clockwise at slip frequency. It is at once clear that F' can produce a torque with the unidirectional rotor ampere-turns whenever its axis does not coincide with the axis f of the latter. Referring to Fig. 4, let α be the angle denoting the displacement between f and the axis of F'. Beginning to count this displacement at the instant when F' coincides with and is of the same direction as f, we find that for $\alpha = 0$ the synchroniz-

ing torque is zero. As F' continues on its way the revolving flux begins to enter that side of the rotor which carries upwardly-directed unidirectional current, thus producing a clockwise and here positive torque, which reaches a maximum when F' is displaced 90 electrical degrees from f and goes back to zero when F' coincides with, but opposes f. A further movement of F' causes this flux to enter that side of the rotor which carries downwardly-directed unidirectional current,

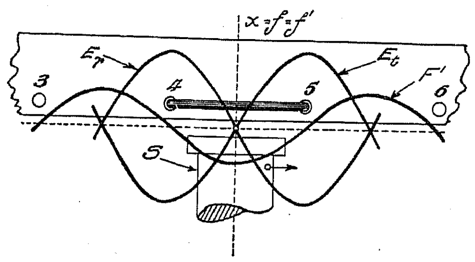

FIG. 6—PERIODICAL SPACE RELATION BETWEEN STATOR COILS AND ROTOR POLES AT NO-LOAD IN IDEAL SYNCHRONOUS MOTOR

producing a counterclockwise and here negative torque, which reaches a maximum when F' is again at right angles to f. In Fig. 5 this torque is represented by the curve T_s of slip frequency. The time t, during which this torque is positive, equals $\frac{1}{2\ n_s}$ where n_s is the slip frequency. The amplitude of T_s for a given rotor winding depends on the magnitude of F', which is practically constant near synchronism, and on the

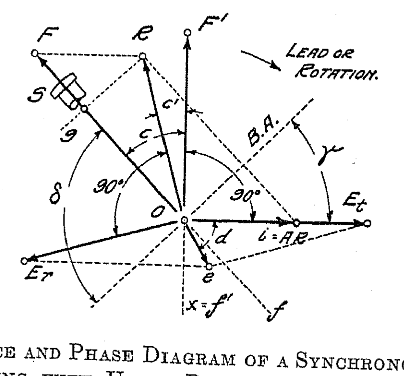

FIG. 7—SPACE AND PHASE DIAGRAM OF A SYNCHRONOUS MOTOR OPERATING WITH UNITY POWER FACTOR (i = 30)

Also applies to new motor when the brush-axis of the latter is at right angles to the total unidirectional magnetization produced by the secondary.

magnitude of the unidirectional current which is also constant so long as the resistance of the exciting circuit or the unidirectional voltage of the exciter are not intentionally varied.

The usual simplifying assumption is made throughout this paper that all fluxes have sine distribution and all e. m. fs. and currents vary according to the sine law.

While T_s is negative it can, of course, not accelerate the rotor into synchronism. In fact, it retards its speed and makes it all the more difficult for the positive wave to bring about synchronism. This negative torque has to be met by an increased induction-motor torque and said torque cannot increase unless the rotor speed is lowered. The only hope lies in the positive wave of T_s.

So long as the machine operates as an induction motor the revolving flux F' produced by the primary lags about 90 electrical deg. behind the terminal voltage E_t as shown in Fig. 6. The primary back e. m. f. E_r is then generated by F' in the windings located in the stator slots 3, 4, 5, 6. A certain amount of lagging magnetizing current is necessary to produce F' and the power factor of such a machine is low on that account, particularly when the motor operates at no-load. If now, at no-load, the rotor is driven synchronously and so excited by unidirectional current as to produce a flux F of same magnitude and direction as F', then the machine will operate as before, except that the rotor must now preserve its synchronous speed and the power factor will now be unity because it will no more be necessary for the primary to carry a magnetizing

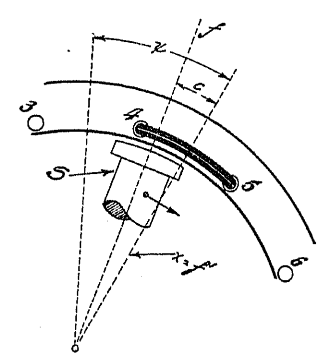

FIG. 8—PERIODICAL SPACE RELATION BETWEEN STATOR COILS AND ROTOR POLES IN PRACTICAL SYNCHRONOUS MOTOR

current. The flux F, thus produced by the unidirectional rotor magnetization, will replace the original revolving flux F' produced by the stator and will perform all of the latter's functions.

The machine has been converted from an asynchronous to a synchronous one and it is seen that the axis f of the pole S coincides with the axis f' of F' and with the axis x of the primary stator coil 4, 5. This, however, is an ideal condition, true only in case the reactance of the motor is nil, which is never the case. In a practical machine unity power factor cannot be secured even at no-load unless E_r is so out of phase with E_t as to produce a resultant e leading E_t by an angle d equal to the lag of the primary current i behind e, which lag depends upon the impedance of the primary. This is well shown in the phase and space diagram of Fig. 7 in which the impedance of the primary has been chosen unduly large in order to secure a clear diagram. It is here convenient to measure all space displacements from the axis x of the coil 4, 5 of Fig. 6 and to deal with fluxes rather than e. m. fs. Thus F' which lags 90 deg. behind E_t is a measure of the latter. The resultant

flux R leads the back e. m. f. E_r by 90 deg. and is a measure for same. The angle c' measures the space displacement of R from x and the phase displacement of E_t and E_r, the actual phase difference between the last two always being equal to $(180-c')$ deg. The angle c measures the space displacement of the unidirectional flux F, therefore of the axis f and of the pole S, from the axis x. It is seen that E_r must lead E_t by less than 180 deg. and the pole S must move back, against rotation, by some angle c in order to secure unity power factor

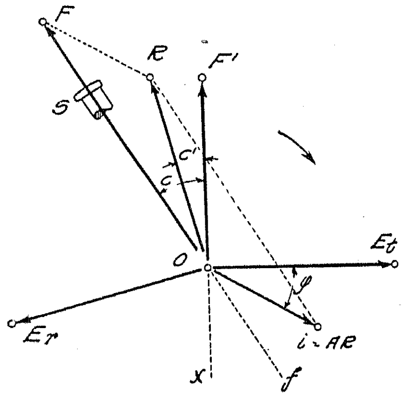

FIG. 9—SPACE AND PHASE DIAGRAM OF A SYNCHRONOUS MOTOR OPERATING WITH LEADING POWER FACTOR (i = 30)

for even very small currents. This is also shown in Fig. 8, where ψ measures the pole pitch. Under these conditions the axis f of the pole S will be c degrees short of the coil axis x, or of the axis f' of the revolving induction motor flux F', when E_t passes through zero on its way from a negative to a positive maximum. The angle c is greater than the corresponding angle c' for R or E_r because of the influence of the armature reaction.

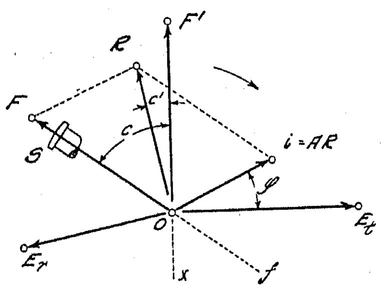

FIG. 10—SPACE AND PHASE DIAGRAM OF A SYNCHRONOUS MOTOR OPERATING WITH LAGGING POWER FACTOR (i = 30)

To secure a leading primary current the unidirectional excitation must be increased, which will bring about a reduction of the angle c, see Fig. 9, but an increase in maximum torque. Fig. 10 shows the relations for a lagging current of same magnitude as in Figs. 7 and 8 and Fig. 11 illustrates what happens when unity power factor is secured for a larger current than that in Fig. 7. For a given excitation c' increases as the torque is increased. In a machine with constant self-induction coefficient and without armature reaction, the torque reaches a maximum when c' = 90 deg., *i. e.* when E_r leads E_t by 90 deg.; thereafter it falls off and the operation becomes unstable. For these conditions $c = c'$.

In practise c is always larger than c', the lower the power factor the greater is the difference in favor of c, as well shown by Figs. 9, 7 and 10. Maximum torque is actually reached for values of c' smaller than 90 and for values of c of about 90 deg. When the load on the machine is increased while the excitation is kept constant, the rotor is retarded more and more, c and the torque increasing and the power factor decreasing until the maximum torque is passed, when the machine falls out of step. Because the value of c is limited the overload capacity of an over-excited motor, Fig. 9, is greater than that of an under-excited machine, Fig. 10.

This consideration shows, among other things, just what the synchronizing torque must accomplish. Fig. 5 shows that this torque is exerted over an arc equaling one pole pitch ψ. The time in which this arc is covered depends on the slip of the rotor and increases as the slip diminishes. This time is $\frac{1}{2\ n_s}$ where n_s is the slip fre-

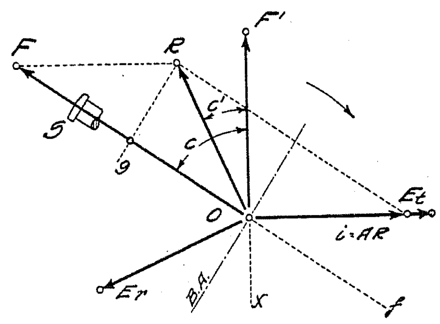

FIG. 11—SPACE AND PHASE DIARGAM OF A SYNCHRONOUS MOTOR OPERATING WITH UNITY POWER FACTOR (i = 43)

quency per second. Within $\frac{1}{2\ n_s}$ seconds or less, T_s must accelerate the rotor and the load to synchronous speed and bring about a certain angular space relation between S and F'. When synchronism is reached the space angle between the axis f' of the revolving flux F' and the axis f of S or of the unidirectional rotor magnetization must be equal to or less than c_{max}, the latter lagging behind the former. The angle c_{max} is that which, for the prevailing excitation, corresponds to the maximum available synchronous torque. If acceleration is completed when S lags c_{max} degrees behind F', then the synchronous motor torque will take control of the action of the rotor. If the maximum synchronous torque is just sufficient to deal with the prevailing load, the rotor will continue to operate with a periodical space lag of c_{max} degrees with respect to x. If the maximum synchronous torque is in excess of that required by the pervailing load, the rotor will be drawn into its proper periodical space relation to the axis x,

i. e. the angle c will be suitably reduced and the rotor will continue to run synchronously.

The difficulty with this type of machine appears to lie in the fact that if it is built with an induction motor air-gap and without defined polar projections, conditions necessary to a good asynchronous motor starting and operating performance, it becomes extremely sensitive to armature reaction, calls for a comparatively small number of no-load exciting ampere-turns, corresponding to the small asynchronous motor magnetizing current, and requires a very large change in exciting ampere-turns from no-load to full-load, in order to keep the power factor at all constant. Even with exciting ampere-turns corresponding to a leading power factor at full load, the synchronizing torque is only about 50 per cent of the full-load torque and if the load is thrown off without changing the unidirectional excitation, the machine takes an unduly large leading current. Synchronous conditions can be much improved by sacrificing the induction motor characteristics, but even then this type is not suitable for smaller sizes because of the necessity of a separate exciter.

Turning now to Fig. 3, when this machine is connected to the supply, a revolving flux F' is produced and revolves synchronously in space so long as the rotor, here the primary, is at rest. At this time the brush voltage is of full frequency. When the primary moves it does so in a direction opposed to that in which F' rotates and as the primary speeds up so does F' slow down in space, *i. e.*, relatively to the stator. When the rotor is as near to synchronism as the secondary 3 can bring it, F' revolves with slip frequency with respect to the stator but still synchronously in so far as the rotor conductors are concerned. The brush voltage is now a single-phase current of slip frequency. The maximum value of this voltage is the same throughout, as long as F' does not change, but its frequency is always equal to that with which F' moves with respect to the stator because the brushes are stationary. When F' coincides with the brush axis b, the brush voltage is zero, when it is displaced 90 electrical deg. from said axis, it is a maximum, when F' is directed from left to right, brush 7 is positive and vice versa. The curve e_b of Fig. 20 shows how the brush voltage changes; it is plotted against α, the angle by which F' is displaced from the brush axis, the zero value of α being assumed to exist when F' coincides with the brush axis and is directed from brush 8 to brush 7. The positive voltage value is that corresponding to its direction in normal operation.

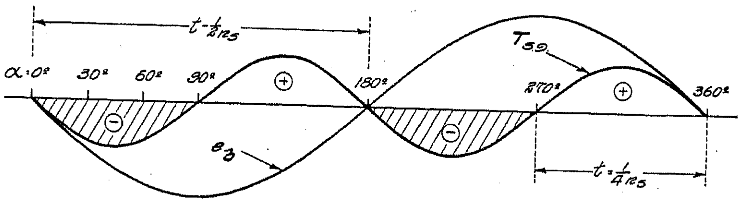

FIG. 20—SYNCHRONIZING VOLTAGE AND ALTERNATING SYNCHRONIZING TORQUE IN FYNN 1906 MOTOR

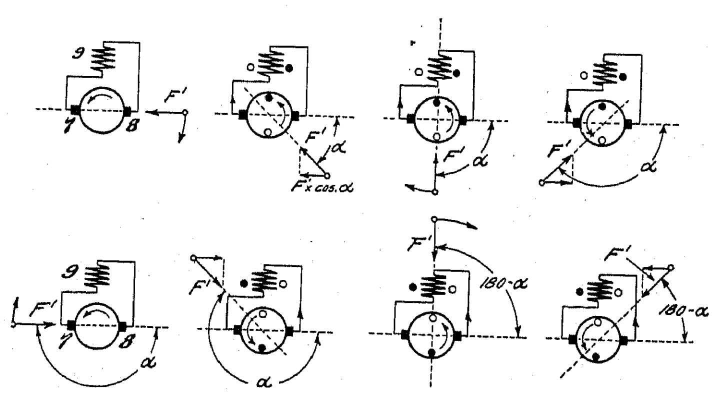

FIGS. 12 TO 19. SHOWING HOW THE ALTERNATING SYNCHRONIZING TORQUE IS PRODUCED IN FYNN 1906 MOTOR

This torque forms one component of total synchronizing torque of the new motor.

If switch 10 of Fig. 3 be now closed, the alternating brush voltage will send a current of slip frequency through the exciting winding 9 and an additional torque, over and above the prevailing induction motor torque, will be developed between the primary revolving flux F' and the ampere-turns in 9. It is true that when 10 is closed an additional secondary circuit is provided, which is inductively responsive to F' and which, therefore, will have generated in it secondary induction-motor torque-producing currents closing over the brushes 7, 8, but this torque, such as it is, may be disregarded, since it merely adds to the induction-motor torque produced by 3 without qualitatively changing the performance.

As a first approximation, it is permissible to assume that there is no phase difference between the brush voltage and the current it produces in 9, because the slip frequency is very small even when the full-load induction-motor torque is being developed and further diminishes as synchronism is more closely approached.

Figs. 12 to 19, inclusive, give a clear view of how the synchronizing torque is produced in this case. The brush voltage is always proportional to *sine* α and the component of F' at right angles to the axis of the exciting winding 9, which is the only part of F' available for producing torque with the ampere-turns in 9, is proportional to *cosine* α. The synchronizing torque T_s is proportional to *sine* α $\times$ *cosine* α, as may be seen, for instance, by reference to Fig. 13. Bearing these conditions in mind, it is only necessary to follow the movement of F' relatively to the brush axis and in each case note the direction of the brush current.

In Fig. 12 the brush voltage e_b is zero and the torque is also zero because the current in 9 is zero. In Fig. 13 the brush voltage and current are negative, producing the current, distribution in, 9 shown in the figure by dots and circles. The horizontal component of F' is the

only one which can produce torque with the ampere-turns in 9. The brush voltage, and therefore the ampere-turns in 9, are proportional to *sine* α, since $\alpha = 45°$ *sine* $\alpha = 0.707$. The horizontal component of F' is proportional to *cosine* α or to 0.707 and the torque T_s is, therefore, proportional to one half. In this case this is the maximum value of the torque. As appears from the direction of the ampere-turns in 9 and from that of the horizontal component of F', this maximum torque is clockwise and here negative.

In Fig. 14 the torque T_s is zero, although e_b is a maximum because the axis of F' coincides with that of 9. When $\alpha = 135°$, Fig. 15, T_s has reached a positive maximum. The changes of e_b and of T_s with varying α are plotted in Fig. 20.

It is seen that for otherwise equal conditions the self-excited motor of Fig. 3 develops a maximum synchronizing torque of half the value and double the frequency of the maximum synchronizing torque produced by the separately-excited motor of Fig. 1. Being of double the frequency a positive, or useful, half cycle of the synchronizing torque of Fig. 3 lasts but half

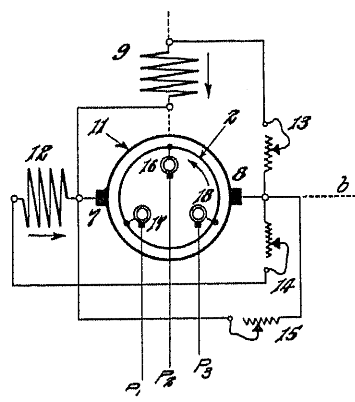

FIG. 21—SELF-EXCITED SYNCHRONOUS INDUCTION MOTOR. NEW FYNN

the time, $\frac{1}{4\ n_s}$ seconds, of the corresponding torque wave of Fig. 1. The synchronizing requirements are, however, exactly the same for both machines. They have been discussed in connection with Figs. 6-11 inclusive.

Another difference between the two machines is that in Fig. 1 the armature reaction only affects the magnitude and space position of the resultant magnetization by adding to or subtracting from the unidirectional magnetization F, whereas in Fig. 3 this reaction also affects the brush voltage through its effect on the resultant magnetization.

The self-exciting feature of Fig. 3 is, however, vital in the case of machines with an output smaller than that corresponding to, say, 150 horse power at 1000 rev. per min., and this type was, therefore, thought worthy of further effort. The writer presently devised the machine shown in Fig. 21, which overcomes many of the drawbacks of the earlier forms and exhibits some quite interesting and novel characteristics.

Fig. 21 diagrammatically illustrates the new motor in its simplest and two-pole form. The rotor is the primary member, it carries a polyphase winding 2 adapted for connection to the supply P_1, P_2, P_3 through the slip-rings 16, 17, 18 and a commuted winding 11 with which cooperate brushes 7, 8 carried by the secondary member which is here the stator. In order to avoid all uncertainty as to the brush position it is assumed throughout that the brushes bear directly on the commuted winding. The secondary carries an "exciting" winding 9, connected to the brushes 7, 8 by way of the adjustable resistance 13 and displaced 90 electrical deg. from the brush axis, and a "neutralizing" winding 12 coaxial with the brush axis and connected to the brushes by way of the adjustable resistance 14. In addition, an adjustable resistance 15 is connected to the brushes 7, 8 to shunt the commuted winding 11.

This machine can be operated with and without the resistance 15. Assuming that 15 is not used, the slip-rings are connected to the supply with the circuits of the windings 9 and 12 open or each closed over a predetermined amount of resistance. The polyphase rotor currents produce a revolving flux in the usual manner and the latter generates secondary torque-producing currents in the stator windings 9 and 12 displaced by 90 electrical deg. which are, therefore, in the most favorable position for producing a uniform torque with the primary flux. The secondary currents generated in 9 as well as in 12 close over the brushes and the rotor winding 11 and can be regulated by manipulating the adjustable resistances 13 and 14, whereby the torque developed and the current taken by the motor can be adjusted like in a slip-ring induction motor. In this manner the motor reaches a speed very close to the synchronous. At such time the primary revolving flux moves with slip frequency with respect to the windings 9, 12 and the brushes 7, 8. The low periodicity single-phase brush voltage sends a considerable current through the windings 9 and 12 and the secondary conduced ampere-turns thus set up in said windings, reacting with the primary revolving flux, develop a powerful synchronizing torque in a manner to be more fully explained. The synchronizing torque, developed by the windings 9, 12 which first did duty as polyphase secondaries of a polyphase asynchronous motor, brings the motor into step, producing a further change in the reactions within the machine. As soon as synchronous speed is reached the primary revolving flux becomes stationary in space; it can, therefore, be replaced by a unidirectional magnetiation, stationary in space. Similarly, the primary armature reaction is stationary in space so long as the load and the excitation are constant, this reaction can therefore also be opposed by a unidirectional magnetization. When the load or the excitation is changed, the axis of the armature reaction alters its position in space and then continues stationary. Because the primary revolving flux is now stationary in space, the brush voltage is unidirectional and the magnetizations pro-

duced by the stator windings 9 and 12 are, therefore, also unidirectional at synchronism. Broadly speaking, 12 opposes the primary armature reaction or at least a component of same, and 9 produces the excitation with or without the help of 12 as will hereafter appear.

Small machines can be started and operated without the use of adjustable resistances in the circuits of the windings 9 and 12. For larger machines adjustable resistances should be used and reduced in one or more steps as the speed increases. It is quite possible to use but one adjustable resistance, placing it in a conductor carrying the current of 12 as well as that of 9. This single resistance can, for instance, be located between brush 7 and one terminal of 12 and one of 9. For still larger motors, or when the starting conditions are particularly severe or the winding 11 operates close to the limit of good commutation, it is advisable to use the adjustable resistance 15 to shunt the commuted winding at starting. At starting, the voltages generated by the primary revolving flux in 9 and 12 are considerably higher than the voltage generated by it in 11 and appearing at the brushes. Furthermore, the periodicity of the stator-generated voltages is, at starting, equal to the frequency of the supply, with the result that the iron-surrounded commuted winding 11 offers considerable reactance to the secondary currents. For these reasons, it is quite possible to shunt the commuted winding with a value of non-inductive resistance 15 which will allow large starting-torque-producing secondary currents to pass, while restricting to a small value that current which the brush voltage is able to force through it. When the resistance 15 is used, its value should be increased with increasing speed and made infinite, preferably before synchronism is reached.

Instead of using two independent windings 2 and 11

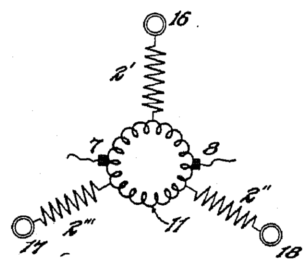

FIG. 22—PRIMARY WINDING OF SELF-EXCITED SYNCHRONOUS INDUCTION MOTOR. FYNN 1906

on the primary, it is more economical and more efficient to combine them, for instance, as shown in Fig. 22, where the commuted winding 11 is located in the center or zero point of the three-phase star connected winding 2′, 2″, 2‴. The winding 11 here operates under the conditions prevailing in a synchronous converter with a single winding on the primary. It is known that under load the losses in such a winding are less than if the direct current was suppressed without changing the value of the alternating current or vice versa. By making use of this condition, the losses in the primary can be somewhat reduced and the arrangement shown in Fig. 22 also permits of the best possible utilization of the winding space on the primary, with due regard to commutation requirements.

It may be stated that nothing, insofar as the principle of operation is concerned, is changed when the primary is located on the stator instead of the rotor. When the primary is stationary, the revolving flux always revolves synchronously with respect to it, and

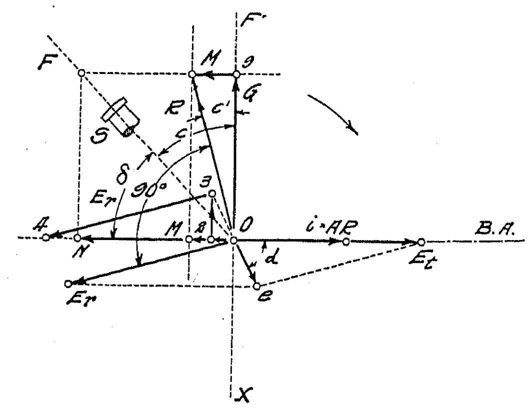

FIG. 23—SPACE AND PHASE DIAGRAM OF NEW MOTOR FOR FULL-LOAD UNITY POWER FACTOR AND RESULTANT MOTOR MAGNETIZATION LAGGING ABOUT 90 DEGREES BEHIND THE BRUSH AXIS

therefore in space, and the secondary revolves in the same direction as this revolving flux. In asynchronous operation the speed of the secondary is a little short of that of the revolving flux and at synchronism the speeds of the two are the same. When the primary is located on the stator, the brushes cooperating with the commuted winding on the primary must revolve with the secondary.

The various windings may be variously dimensioned according to the desired characteristic, but to fix ideas, let it be assumed that 9 and 12 are designed to produce, with given values of the resistance 13 and 14, a number of conduced ampere-turns which will insure unity power at the terminals of the motor at full load. The rotor winding 2 must be able to carry the load current and be adapted to the voltage and the periodicity of the supply. The winding 11 must be dimensioned with two ends in view which, however, are not antagonistic. On the one hand it is necessary to secure perfect commutation at starting as well as at synchronism; on the other hand, the brush voltage should be as low as possible so that the number of turns in the windings 9 and 12 on the secondary can be kept down to a value which will not make the value of the voltage generated in 9 and 12 at starting so high as to be dangerous to life or to the insulation. In addition to this, the resistance of one or both of the windings on the secondary must be made so low that when the resistances 13 and 14 are short-circuited the number of available conduced ampere-turns

on the secondary is sufficient to produce the desired synchronizing torque. For reasons which will presently appear, it is best in this connection to rely on 12 rather than on 9 and to dimension 12 accordingly.

The phase and space diagram of Fig. 23 will help to make clear the conditions which govern the design of the windings 9 and 12. Let E_t represent the terminal e. m. f. and i the full-load current. For unity power factor at the motor terminals, the phase of i will coincide with that of E_t. The armature reaction ampere-turns or the armature reaction flux $A\,R$ is of the same phase as i and may be represented by the same vector. Because of the impedance of the primary the current i will cause an ohmic drop 0-2 and a reactive drop 2-3, the first displaced 180 degreės from i, the second lagging 90 deg. behind i. The impedance drop 0-3 must be equaled and opposed by the resultant e. m. f., e acting on the armature circuit in order to produce the current i lagging d degrees behind e. The angle d is determined by the time constant of the armature which here is $\frac{2\text{-}3}{0\text{-}2}$. Now e must be the resultant between the terminal e. m. f. E_t and the back e. m. f. E_r which settles the phase and magnitude of 3-4 or E_r. The resultant flux R (or the corresponding ampere-turns) must lead E_r by 90 deg. and its magnitude is determined by that of E_r. The dimensioning of the windings 9 and 12 depends on the relation desired at a given load, say at full load, between the axis of the armature reaction and that of the brushes 7, 8. A number of solutions are

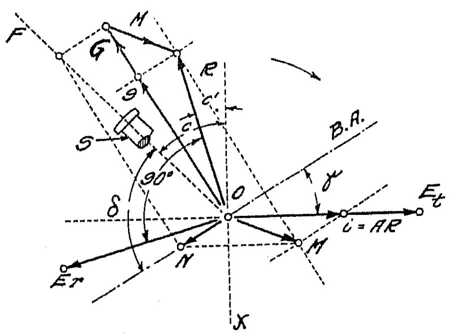

Fig. 24—Space and Phase Diagram of New Motor for Full-Load Unity Power Factor and Resultant Motor Magnetization Lagging Less than 90 Degrees Behind the Brush Axis

possible, each giving a different operating characteristic, particularly as to maximum torque and as to power-factor change with load. Fig. 23 shows the case for which the armature reaction flux coincides with the brush axis at unity power factor and full load. To secure this condition the flux N produced by the conduced ampere-turns of the winding 12 must exceed the armature reaction flux $A\,R$ by the vector M and the flux G produced by the conduced ampere-turns of the winding 9 must be such that the vectorial sum of G and M equals R. If the brush axis coincides with i then N must be in phase opposition to i since 12 is coaxial with the brush axis; and G must be at right angles to and lead N since 9 is placed 90 electrical deg. ahead of 12. The end of the vector M is found as the intersection of a parallel to N drawn through the end of the vector i with a parallel to G drawn through the end of the vector R. The flux available for the generation of the brush voltage is 0-9 which is here equal to G. The resultant flux R is larger than 0-9. This diagram settles all design details for this particular case.

But unity power factor at full load, *i. e.*, for the same

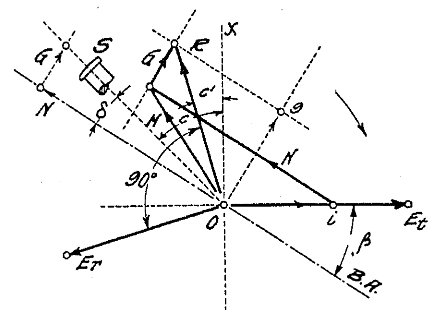

Fig. 25—Space and Phase Diagram of New Motor for Full-Load Unity Power Factor and Resultant Motor Magnetization Lagging More than 90 Degrees behind the Brush Axis

current as that sssumed in Fig. 23, can be secured with the axis of the armature reaction leading the brush axis. When the armature reaction axis is said to lead the brush axis, it is displaced from the latter *in* the direction of rotation of the primary as shown by γ in Fig. 24. N is coaxial with the brush axis and the resultant M, of N and $A\,R$, combined with G which leads N by 90 electrical deg. must produce R. The magnitude and phase of the latter must, of course, be the same as in Fig. 23, since the load and the power factor are the same. The end of the vector M is found as the intersection of a parallel to N through the end of i with a parallel to G through the end of R. This determines the magnitude of N and G, in other words, the ampere-turns in the windings 12 and 9. The flux available for the generation of the brush voltage is 0-9; it is less than R and less than G.

It is seen that N becomes zero and G a maximum as soon as the brush axis is displaced 90 electrical deg. from the line joining the ends of the vectors i and R. This limiting case is that of the machines shown in Figs. 1 and 3 and is positively characterized by the phase and space diagram of Fig. 7, except that the brush axis line has no significance in connection with Fig. 1.

Similarly, unity power factor may be had at full load with the axis of the armature reaction lagging β degrees behind the brush axis. This may also be expressed by saying that the axis of the armature reaction is displaced by β degrees from the brush axis in a direction opposed to that of the rotation of the primary member. This case is illustrated in Fig. 25 and the end of

the vector M is found as in Fig. 24. The flux available for the generation of the brush voltage is 0-9, which, in this case, is larger than G but again smaller than R.

When, in continuing its clockwise rotation, the brush axis comes to occupy a position parallel to the line joining the ends of the vectors i and R, the ampere-turns in winding 12 or the flux N becomes a maximum and the ampere-turns in winding 9 or the flux G zero, R is now simply the resultant of N and i or $A\,R$ and $N = F$. This, however, does not mean that there is no flux displaced by 90 electrical deg. from the brush axis. As before, this flux is the component 0-9 of R and is here much smaller than R. Even in this limiting case a brush voltage is available and the machine is operable, but its operation is likely to be unstable because but a slight variation in the position of the brush axis can cause sharp variations in the power factor, even when the load is constant. This limiting case is shown in Fig. 26.

It is now seen that beginning with the limit case of Fig. 7, where the brush axis is displaced 90 electrical

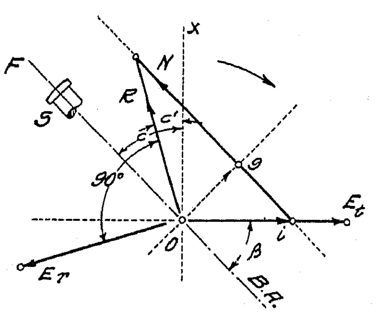

FIG. 26—SPACE AND PHASE DIAGRAM OF NEW MOTOR FOR FULL-LOAD UNITY POWER FACTOR AND BRUSH AXIS COINCIDING WITH TOTAL UNIDIRECTIONAL MAGNETIZATION PRODUCED BY THE SECONDARY

deg. from the axis of the resultant unidirectional magnetization produced by the secondary member and shows the maximum lag with respect to the axis of the armature reaction, the windings 12 and 9 can be dimensioned to cause this axis, under given load and power factor conditions, to occupy any position within 90 electrical deg. measured in the direction of rotation. When unity power factor is desired at full load, the better proportions to be given to the windings 12 and 9, from the point of view of maximum synchronous operating torque and power-factor change with load, are those which cause the brush axis either to coincide with the axis of the armature reaction or to lead the latter by less than the maximum permissible angle. For the constants chosen, this maximum leading angle is shown in Fig. 26 and happens to be in the neighborhood of 45 electrical deg., it always occurs when the brush axis coincides with the axis of the resultant unidirectional magnetization produced by the secondary member. To secure the one or the other condition, it is necessary to suitably select the ratio of ampere-turns in 9 and 12, yet a bare statement of this ratio does not positively characterize the operating characteristics of a machine, unless the ratio of resultant flux and armature reaction flux, or of their equivalents, is also given. Thus, for the machine under consideration, the brush axis coincides with the armature reaction axis at full load and unity power factor, when the ratio of "neutralizing" ampere-turns in 12 to "exciting" ampere-turns in 9 is about unity. If the full-load ampere-turns of this machine were 50 per cent higher, the above ratio for unity power factor at full load and for coincidence between armature reaction and brush axis would be about one and one half.

A very welcome feature of this motor is the fact that when the windings 12 and 9 are proportioned in the manner set forth, the power factor will have acceptable values at all loads without it being necessary to make any adjustments whatsoever with changing load. This is an absolutely necessary condition in all smaller sizes and is only little less important in connection with large motors. By large is meant anything exceeding an output corresponding to about 150 horse power at 1000 rev. per min. The power factor may be kept at near unity for all loads in excess of about one fifth of full load, in which case, it will be lagging at lighter loads, or, and this is usually the better choice, it can be made leading at no load and about unity at full load. In no case will the machine take an excessive leading current and hand adjustments during normal operation are, therefore, not necessary.

The next point of interest is the synchronizing ability of the new machine and the relation of its winding 12 and 9 and of the ratio of the ampere-turns they produce to the magnitude and conformation of the synchronizing torque.

Reference to Figs. 3 and 21 shows that the "exciting" winding 9 occupies in both machines exactly the same position with reference to the brush axis b. The variation of the brush voltage e_b must be identical in the two motors and it follows that so far as winding 9 of Fig. 21 is concerned, the synchronizing torque it produces and the voltage to which it is due are correctly represented, at least as to form, by the curves $T_{s.9}$ and e_b of Fig. 20. The magnitude of $T_{s.9}$, other conditions being equal, is proportional to the number of ampere-turns carried by 9, and that of e_b can be and is assumed to be the same in both motors.

Just what the "neutralizing" winding 12 contributes to the synchronizing torque may be determined by following the line of thought adopted in deducing the shape and magnitude of $T_{s.9}$. The simplifying assumption will again be made that the frequency of the brush voltage e_b is so small very near synchronism that there is no phase difference between said voltage and the current it determines through the winding 12. Figs. 28 to 35, inclusive, really tell the whole story.

Starting with that position of the slowly revolving primary induction motor flux F' in which its axis coin-

cides with the brush axis and this flux is directed from brush 8 to brush 7, and assuming that the positive voltage (and current) direction is that which corresponds to its direction in normal operation as shown in Fig. 27, we can plot in Fig. 37 the volt and torque curves as they are deduced from Figs. 28 to 35. For the conditions of Fig. 28, $\alpha = 0$ and both e_b and $T_{s \cdot 12}$ are zero. After the primary flux F' has moved through $\alpha = 45$ deg. in a clockwise direction, the voltage generated at the brushes is negative, as indicated by the dot and circle within the armature, and proportional to *sine* α. The torque between F' and the ampere-turns in 12, due to e_b, is at this time proportional to e_b and to that component $F' \times$ *sine* α which is displaced 90 electrical deg. from the axis of 12. For $\alpha = 45$ deg. $T_{s \cdot 12} = 0.707^2 = 0.5$. The direction of the torque exerted on the rotor, deduced from the direction of $F' \times$ *sine* α and the current distribution in 12 shown by dots and circles, is seen to be counterclockwise or positive. Throughout this paper the full circles or dots indicate downwardly-directed current.

In Fig. 30 the primary flux has progressed through located and connected as 12 in Fig. 21 produces a maximum torque equal to just twice that produced by a winding located and connected as 9 in Fig. 21.

Fig. 36 is added for the purpose of an easy check as to the direction of the torque in Figs. 28 to 35 and also in Figs. 12 to 19. Fig. 36 reproduces the conditions of Fig. 30. The flux F' emanating from the rotor is directed upwardly, the winding 12 is distributed on the stator 20, as shown by the dots and circles, which also indicate the direction of the current in the conductors of 12. It is seen that the interaction of F' and the ampere-turns in 12 exerts a clockwise torque on the stator, and consequently a counterclockwise, and here positive, torque on the rotor.

In Fig. 31, where $\alpha = 135$ deg. $T_{s \cdot 12} = 0.5$ and is still positive. When $\alpha = 180$ deg., e_b and $T_{s \cdot 12}$ are both zero.

The next position of F' relatively to the brush axis is again of the greatest interest. In Fig. 33, $\alpha = 225$ deg., e_b has changed its sign and is now positive *but* $T_{s \cdot 12}$ is *again positive* as is seen by reference to the direction of $F' \times$ *sine* α and to that of the currents in 12.

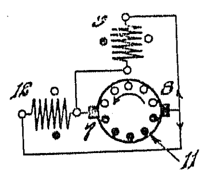

Fig. 27—Direction of Brush Current in Rotor and Stator of New Motor at Synchronism

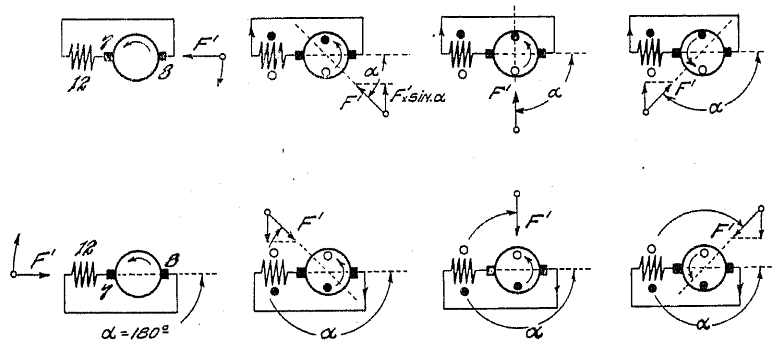

Figs. 28 to 35—Showing how the Unidirectional Pulsating Torque Component is Produced in the New Motor

amother 45 deg. and $\alpha = 90$ deg., $e_b =$ *sine* $\alpha = 1$ or a maximum and the full flux F' is effective in producing a synchronizing torque with all of the ampere-turns in 12. This torque is still positive and now proportional to the maximum value of e_b and to all of F'. This is the highest instantaneous value of synchronizing torque it is possible to produce in such a motor, because the voltage e_b responsible for the ampere-turns in 12 is a maximum at a time when the space relation between said ampere-turns and the co-operating flux is at its best.

The very important fact is hereby made clear that, when in a self-excited synchronous-induction motor a secondary winding is located coaxially with and connected to the brushes cooperating with the commuted winding on the primary, such a winding produces in conjunction with the primary revolving flux a synchronizing torque proportional to *sine*^{2} α. The maximum value of this torque is proportional to the product of the maximum value of the ampere-turns of said winding and the full magnitude of the revolving flux. This means that, under otherwise equal conditions, a winding

The second wave of $T_{s \cdot 12}$ is identical with the first as to shape and direction, as shown by Figs. 32 to 35 and 28.

Another remarkable feature in connection with this winding 12 is that, located as it is with respect to the brushes to which it is connected, it produces, in conjunction with the primary induction motor flux, a varying *but always positive synchronizing torque* independently of the direction of the alternating brush voltage.

A third feature of importance is that each wave of this *pulsating* torque $T_{s \cdot 12}$ lasts $\dfrac{1}{2\,n_s}$ seconds and not $\dfrac{1}{4\,n_s}$ as is the case for each wave of the *alternating* torque $T_{s \cdot 9}$ to which winding 9 contributes.

The motor of Fig. 21 evidently produces two synchronizing torques, one due to the winding 9, the other due to the winding 12. The former alternates with

double the slip frequency. It is of interest to consider the resultant synchronizing torque and to determine how 9 and 12 should be dimensioned in order to produce the most advantageous resultant synchronizing torque as to value and shape.

The torque values deduced in connection with Figs. 20 and 37 have been deduced on the assumption of an equal number of ampere-turns in the windings 9 and 12 of Fig. 21. This condition happens to correspond to that of Fig. 23, where the armature reaction axis coincides with the brush axis and a combination of Figs. 20 and 37 will, therefore, give the resultant synchronizing torque available under the conditions fixed by the vector diagram of Fig. 23 where the ampereturns in windings 9 and 12 are equal. Fig. 38 shows the resultant torque. It is positive during $\frac{3}{8\,n_s}$ seconds and negative during $\frac{1}{8\,n_s}$ seconds, the maximum negative torque is but 18 per cent of the maximum positive torque.

To fairly compare this performance with that of a corresponding Danielson motor, the latter must have the same design constants and a unidirectional exciting winding with a number of ampere-turns equal to the square root of the sum of the squares of the ampere-turns in 9 and 12, under which conditions both machines will show unity power factor at the same load. The maximum positive equals the maximum negative synchronizing torque in the Danielson motor and is 18 per cent greater (1414 to 1200) than the maximum positive synchronizing torque of the new motor of Fig. 21 when the comparison is based on equal ampere-turns in the windings 9 and 12. See Figs. 23 and 38. The positive torque in the new motor lasts $\frac{2 \times 3}{8\,n_s}$ as against $\frac{4}{8\,n_s}$ seconds per slip cycle in the 1901 machine. The negative torque of Fig. 21 is only 15.6 per cent (220 to 1414) of the negative Danielson and lasts $\frac{2 \times 1}{8\,n_s}$ as against $\frac{4}{8\,n_s}$ seconds per slip cycle.

If the comparison is made on the basis of the ampere-turn relation in the windings 9 and 12 of Fig. 21 defined by the vector diagram of Fig. 26, it is found that the positive maxima are the same in both machines but that the newer machine develops *no negative torque at all* and each of its unidirectional impulses is available for the same time interval as each of the alternating impulses in the motor of Fig. 1.

As to the motor of Fig. 3, it develops an alternating synchronizing torque like that produced by the Danielson motor except that it has double the frequency and half the maximum amplitude of the latter and is, therefore, inferior in this respect.

The result of these considerations is that excellent synchronizing conditions will be secured whenever the relation of ampere-turns in 12 and in 9 is so chosen that, at full load and unity power factor, the brush axis either coincides with the axis of the armature reaction or leads the latter by any angle right up to the limiting case of Fig. 26, where the ampere-turns of 9 are zero and the synchronizing torque a maximum. There is, therefore, no conflict between operating and synchronizing requirements and the machine can be readily designed to satisfy most exacting specifications as to both of these features. Within the limits named, the proportioning of the ampere-turns in the windings 9 and 12, in other words, the choice of the angle between the brush axis and that of the resultant unidirectional magnetization due to said windings, is just a matter of design.

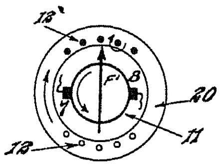

FIG. 36—EXPLANATORY DIAGRAM TO BE READ IN CONJUNCTION WITH FIGS. 12 TO 19 AND 28 TO 35

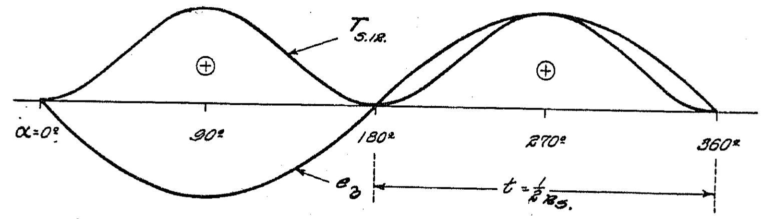

FIG. 37—SYNCHRONIZING VOLTAGE AND UNIDIRECTIONAL PULSATING SYNCHRONIZING TORQUE COMPONENT. NEW FYNN MOTOR

The advantage of a pulsating over an alternating synchronizing torque is not to be measured simply by the maximum values of the two, because the retarding effect of the negative wave of an alternating torque is another and very important factor which reduces the effect produced by the corresponding positive wave. As a consequence, the new machine with its substantially unidirectional torque will quite readily synchronize with a torque equal to its maximum load torque as a synchronous motor.

The synchronizing torque is also produced when the machine falls out of step upon an increase of the load beyond the maximum, which the motor can deal with synchronously and here the effect of an alternating as against a pulsating torque can be very clearly observed. The machine with a pulsating synchronizing torque runs much more uniformly and exhibits, for otherwise

equal conditions, a higher asynchronous overload capacity.

One more word about the brush voltage. Having brought the motor to synchronism, it becomes unidirectional and, as the load varies, it is subject to variations in magnitude brought about by the effect of the varying armature reaction on the other unidirectional magnetizations present in the machine and the consequent change in magnitude and displacement of the resultant magnetization with respect to the brush axis. The degree to which e_b varies and the way in which it varies in synchronous operation depend on the relation of the ampere-turns in the windings 9 and 12.

In Fig. 7 the axis f of the total magnetization F produced by unidirectional ampere-turns on the secondary, is displaced by 90 electrical deg. with respect to the brush axis. This diagram is one of the limiting cases previously referred to and represents the conditions of operation of Fig. 21 when the ampereturns in the winding 12 are zero and those in 9 are responsible for all of the magnetization F. In this case the brush axis leads the resultant magnetization on R by less than 90 electrical deg. and the brush voltage increases as the load decreases. See Figs. 7 and 11. This fact is most readily recognized by assuming that the machine is perfect and requires no current to run it light. For zero current E_r must equal and oppose E_t, then R will coincide with x and F with R. Not only will R increase a little, but all of R, instead of the component 0–9 only, will be effective so far as brush voltage generation is concerned, because R is then perpendicular to the brush axis. This increased exciting voltage increases F and tends to increase R. To keep the latter at its proper value, which is unavoidable, the motor takes a demagnetizing or leading current which increases as the load decreases. If the excitation is set for unity power factor at full load and the resistance of the exciting circuit is not changed as the load varies, the motor will take an objectionably large leading current at no-load if designed with due regard to a good starting performance and high-weight efficiency.

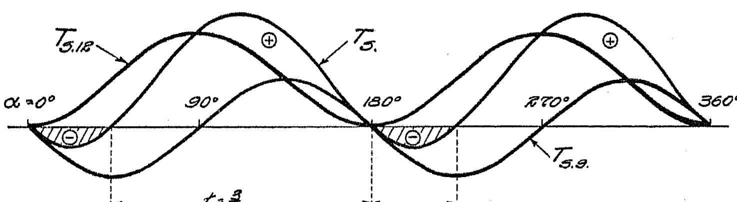

Fig. 38—Resultant Synchronizing Torque of New Fynn Motor When the Ampereturns in the Exciting and Neutralizing Windings are about Equal

The other limiting case is that of Fig. 26. Here the axis f of the total magnetization F, produced by unidirectional ampere-turns on the secondary, coincides with the brush axis. This diagram represents the conditions of operation of Fig. 21 when the ampere-turns in the winding 9 are zero and those in 12 are responsible for all of the magnetization F. In this case the brush axis leads the resultant magnetization R by more than 90 electrical deg. and the brush voltage increases as the load increases. Making the same simplifying assumption as in the case of Fig. 7, it is at once seen that for zero current and coincidence between x, R and F the brush voltage should be zero since R then coincides with the brush axis. To keep R at its proper value the motor will, however, take a magnetizing or lagging current and bring about a corresponding adjustment of the vectors R, F, N and i. The brush voltage varies with R and with the sine of $(c - c')$.

Generally speaking, the brush voltage e_b is proportional to $R \times \text{sine}\,[\,(c - c') + \delta]$ where δ is the angular displacement of the axis of F with respect to the brush axis. The angle $(c - c')$ varies with the load and with the power factor.

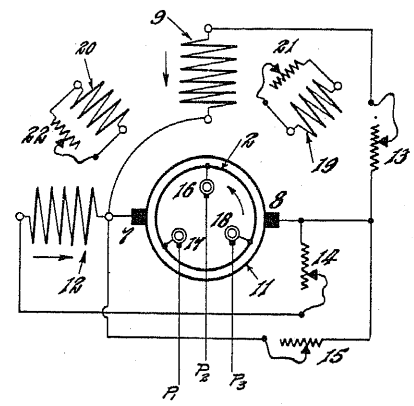

Fig. 39—Self-Excited Synchronous Induction Motor New Fynn

Between the above limits lies a wide range of ratios of ampere-turns for 9 and 12, which enable the designer to cause the power factor to vary with the load in almost any desired manner and even to closely approach a nearly constant power factor for all loads. It is thought that a moderately leading power factor at noload and a slightly leading power factor at full load will usually be the most acceptable power factor performance, due regard being given to overload capacity and high synchronizing torque. For the machine constants forming the basis of Fig. 23 a somewhat higher ratio of "neutralizing" to "exciting" ampere-turns than that shown in Fig. 23 would yield such a power factor curve, together with excellent synchronizing and high overload capacity.

This variation of the brush voltage, which is the unidirectional exciting voltage at synchronism and the

alternating synchronizing voltage at sub-synchronous speed of the machine shown in Fig. 21, particularly its rise with rising load, makes it possible to operate this motor efficiently and safely with high power factor at all loads and without it being necessary to resort to external automatic or hand-operated regulating devices. The fact that the brush or exciting voltage can be made to rise with increasing load by suitably proportioning the windings 9 and 12 makes it possible to run the machine with unity or even leading power factor at full load, without the risk of being confronted with an unduly large leading current at noload. Unity or leading power factor at full load means high overload capacity and good weight efficiency. This automatic regulating capacity is inherent in the machine of Fig. 21, its mechanical expression is the momentary acceleration or deceleration of the primary member, consequent on a change in load which brings about different periodical space relations between the brush axis, or the unidirectionally excited secondary member which carries the brushes, and some selected point on the primary member. When the stator is the primary, then it is the secondary which is subject to this momentary acceleration or deceleration. This phenomenon has been fully analyzed in connection with Figs. 6, 7, 8, 9, 10 and 11, also in connection with Figs. 23, 24, 25 and 26, it is there measured and expressed by the angle c. Briefly stated, it is the changing periodical space relation c, between the axis x of any coil on the primary and the axis f of the resultant unidirectional magnetization on the secondary member, brought about by changes in load or excitation, which determines and governs the inherent automatic regulating property of the new machine. The meaning of "changing periodical space relation" is this. For certain load and excitation conditions the axis of the pole S may, in its clockwise rotation, occupy with respect to the axis x of the coil 4, 5 the position shown in Fig. 8 at the time when the terminal voltage E_t passes through zero on its way from a negative to a positive maximum. This space relation is indicated by the angle c and occurs at time intervals of one period of the supply frequency. If the load is changed the angle c is changed, the periodically recurring relative position of the axes f and x is changed and the periodical space relation of the two is said to have changed. This phenomenon is common to all synchronous motors but in this one it is made use of to automatically keep the power-factor variations within bounds or, in other words, to compound the motor.

Having acquired an insight into the mode of operation and the principles governing the design of the machine under reference, it will not be necessary to do more than indicate the changes which can be made to adapt the motor to varying conditions of service. Thus, where the starting requirements are particularly severe, or the machine is large, it will be of advantage to relieve the commutator as much as possible at starting and to this end the arrangement shown in Fig. 39 can be used. Its distinguishing feature is the use of additional secondary windings 19 and 20 adapted to be closed over adjustable resistances 21 and 22. Any polyphase arrangement of secondary windings inductively responsive to the polyphase primary windings will answer the purpose and it is more economical as to stator space to displace the axes of these auxiliaries from the axes of the windings 9 and 12. The initial

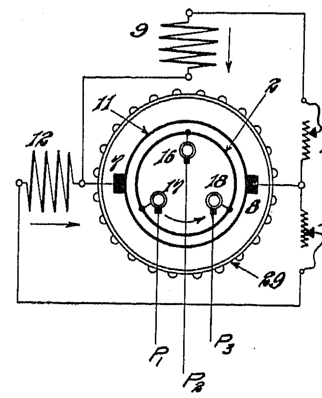

FIG. 40—SELF-EXCITED SYNCHRONOUS INDUCTION MOTOR NEW FYNN

starting effort can be secured by means of these auxiliary windings with the circuits of 9 and 12 closed over resistances of such value as to keep the current through the commutator down to a harmless figure. It is also possible to leave the circuits of 9 and 12 open during the initial starting period, closing them or reducing the resistances in circuit with them only after the motor has reached a sufficient speed.

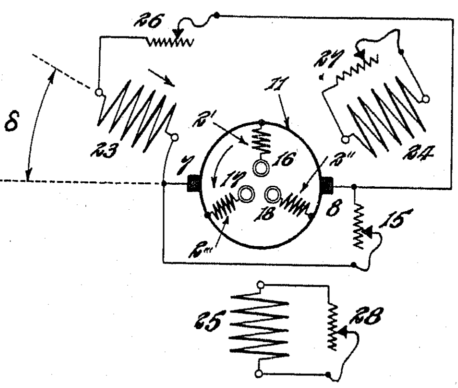

FIG. 41—SELF-EXCITED SYNCHRONOUS INDUCTION MOTOR NEW FYNN

Another way of applying auxiliary, and preferably polyaxial, secondary windings is shown in Fig. 40 where a squirrel cage 29 is located on the stator and given that resistance which will give the desired starting torque with or without the help of 9 and 12. It will be understood that all such auxiliary windings remain entirely idle in synchronous operation and it is, therefore, clear that the space utilization on the secondary member is best when the arrangement shown in Fig. 21 is employed, since in that case *all* of the motor windings are active at *all* starting and operating stages.

It is possible to combine the windings 9 and 12 into a single winding, producing a magnetization equal in magnitude and direction to the resultant of the magnetizations produced by 9 and by 12. Such an arrangement is shown in Fig. 41, where the winding 23 takes the place of the windings 9 and 12 of Fig. 21 and is displaced δ degrees from the brush axis b and against the direction of rotation of the primary.

While it may look like a simplification to combine the windings 9 and 12 into the single winding 23, yet it is not so in reality for it entails the use of at least one auxiliary winding which is idle during synchronous operation. Neither the shape nor the magnitude of the synchronizing torque is changed by the combination of 9 and 12, but the polyphase arrangement of secondary windings, capable of producing an induction motor torque at starting, a synchronizing torque near synchronism and unidirectional exciting and armature reaction opposing magnetizations in synchronous operation, is destroyed and the desirable conditions obtaining in Fig. 21 are not all re-established by the addition of one or more auxiliary windings such as 24 and 25. It should also be noted that the fewer auxiliary windings are added to 23 of Fig. 41 the less constant will the induction motor torque be at starting and at loads beyond the maximum load of the machine as a synchronous motor, for the reason that the element 23 of the polyphase arrangement of secondary windings is always in circuit with the commuted winding which has a considerable reactance. This condition can be bettered at starting by the use of the resistance 15, particularly, if this resistance is connected in parallel with the brushes, with the inclusion of the resistance 26 between one point of connection and brush 8. This is equivalent to connecting 15 directly in parallel to the terminals of the winding 23, *i. e.*, without the interposition of the resistance 26. In such case the resistance 26 should be a maximum at starting and the value of 15 set to cause 23 to contribute its fair share to the induction-motor starting torque. As the speed increases, 15 may be first diminished and then increased, or it can be left at its original value and then increased. When 15 is increased 26 is decreased and 15 is later entirely disconnected, preferably before the maximum asynchronous speed is reached. This resistance 15 can be used in this manner also in connection with Figs. 21 or 39. Whichever way the resistance 15 is connected, its function, insofar as the brushes and the commutator are concerned, remains the same—it protects them from an excessive current at starting.

The induction-motor torque can be made more constant under all operating conditions at the expense of maximum induction motor torque, by permanently including in each of the secondary windings contributing to the production of the induction-motor torque an impedance equal to that of the commuted winding. The addition of enough elements to the secondary member to constitute a complete polyphase winding independently of 23 also leads to better starting and operating conditions. These additional elements may constitute a squirrel cage of any desired resistance.

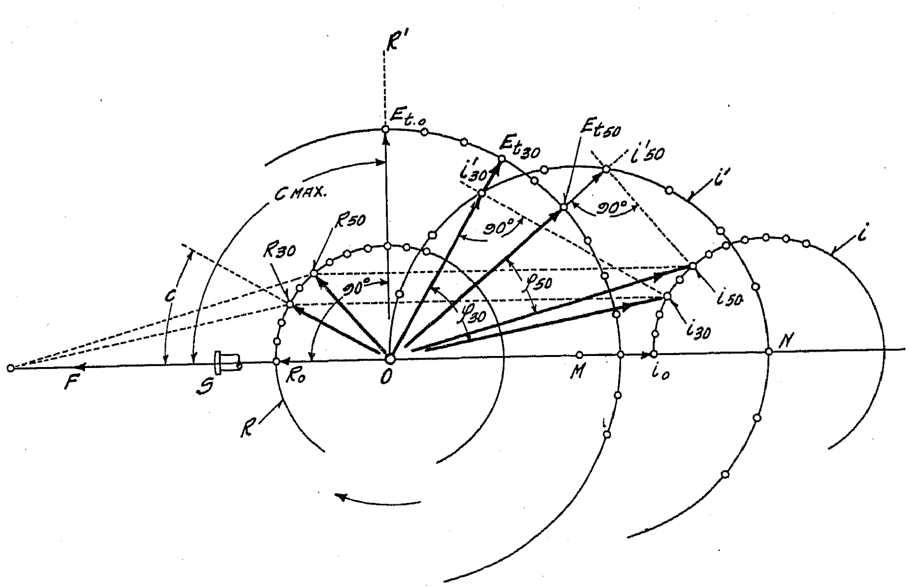

Fig. 42—Performance Diagram of a Synchronous Induction Motor with Separate and Constant Excitation

The partial or total neutralization of the armature reaction in synchronous motors or generators is by no means novel. Many of the best known electrical engineers in the United States and in Europe have repeatedly suggested and carried out different arrangements with this end in view, but the solution of this problem suggested by the writer appears to be very simple and while it may be contended that, strictly speaking, it is not a good armature reaction neutralizing device because it does not fully neutralize said reaction under all load conditions, yet it does so to a practically sufficient extent, and, in addition, permits of combinations with other elements which cooperate to

lend very desirable characteristics to a type of motor which is fast coming to the fore.

Other developments relating to synchronous-induction motors form the subject matter of a communication now in preparation and which will be published shortly.

Appendix

It is thought that a brief outline of a quick graphical method for approximately predetermining the operating characteristics of the new motor and a comparison of its performance with that of a synchronous induction motor of ordinary design will be of interest.

In order to simplify the problem, a number of partly far reaching assumptions must be made. Thus the influence of the ohmic resistance and of the reactance of the primary winding on the space position of R with respect to F and of the saturation of the magnetic circuit on the magnitude of F will be disregarded. This means that in Fig. 23, for instance, the angle c' becomes zero and the space displacement $(c - c')$ of the unidirectional magnetization F, produced by the secondary with respect to the resultant motor magnetization R, is equal to the angle c. This further means that the phase of the back e. m. f. E_r is exactly opposed to that of the terminal e. m. f. E_t. A diagram built on such assumptions will give too large a maximum primary current, too large a maximum torque and too low values for the power factor. Disregarding the effects of saturation means that at the higher values of exciting voltage the values of primary current, torque and power factor will be too high. As a first approximation and for purposes of preliminary comparisons, diagrams based on these assumptions are, however, good enough. For more accurate results the same approximate corrections must be introduced as is usual in other similar diagrams.

Fig. 42 shows the diagram for a separately excited synchronous induction motor. For no torque the magnitude of the resultant R is determined by the fact that it must, at synchronism, generate in the primary winding a back e. m. f. equal and opposed to the terminal voltage. The phase of R must lag 90 deg. behind that of E_t. If the excitation is constant and produces the unidirectional magnetization F then, in this extreme case, R must coincide with F. This position of the vector R is designated as R_o. At such time the motor will take a current i_o leading E_t by 90 deg. and producing ampere-turns equal to the difference between the ampere-turns responsible for F and for R. There will be no torque because the primary current is at right angles to the terminal and therefore to the back e. m. f. and has no component in phase opposition to the latter. The vectors $O\,F$, $O\,R$ and $O\,i$ may respresent magnetic flux, ampere-turns or current. It is merely a matter of scale.

To produce torque R must be displaced from F. For a displacement of 30 deg. the position of this resultant motor flux is designated by R_{30}. Since R is constant the locus for the end of the vector $O\,R$ is the circle R about O. The corresponding primary current i_{30} is found as one side of a parallelogram of which F is the other side and R the resultant. A similar construction yields the current i_{50}, or any other value of the total primary current. It is seen that the locus of i is a circle about N, where $O\,N = O\,F$, and with a raduis equal to $(O\,F - O\,R)$.

Since E_t is constant and always leads R by 90 deg., its locus is also a circle about O. For a 30 deg. displacement of R the terminal voltage is at $E_{t\cdot 30}$ and the torque producing component i'_{30} of i_{30} is found as the projection of i_{30} on $E_{t\cdot 30}$. The same is true of i_{50} or any other value of the primary current. The vector $O\,i'$ is proportional to the torque and the locus for i' is a circle about M with a diameter equal to F.

Maximum primary current and torque occur for $c = 90$ deg. and the power factor at the motor terminals for any value of c is the cosine of the angle φ between the corresponding i and E_t vectors.

In Fig. 43 will be found the corresponding diagram for the new motor shown in Fig. 21. In this

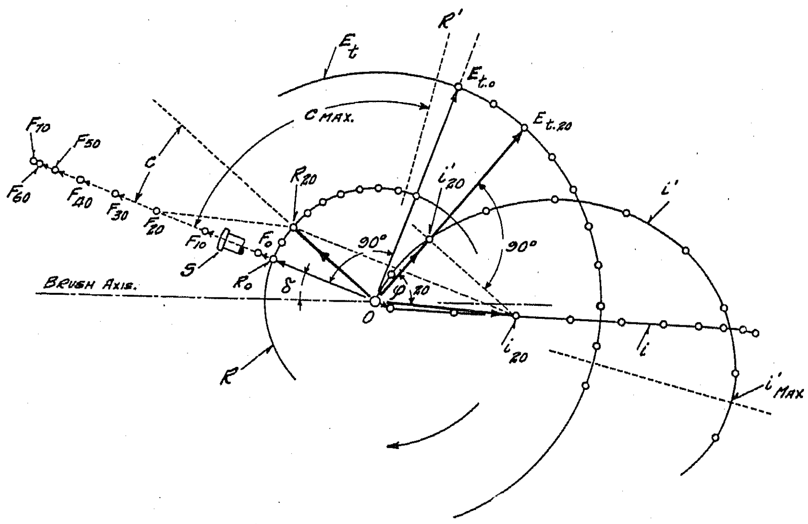

Fig. 43—Performance Diagram of New Motor

machine the ratio of ampere-turns in the windings 9 and 12 is as 1:2.75, which makes $\delta = 20$ deg. and the resistance and number of turns of the two windings are so chosen that the maximum unidirectional excitation F which they produce is equal to the constant excitation F of Fig. 42. The normal or full-load torque of the machine occurs for $c = 37$ deg. It is just about the same as or even somewhat in excess of the full-load torque of the corresponding slip-ring induction motor. At this load that component of F which is coaxial with the brush axis is in excess of the armature reaction component i. This means that the winding 12 of Fig. 21 then produces more ampere-turns than those produced by the primary or armature reaction at that load or torque. The construction is, in principle, the same as that used in connection with Fig. 42. The loci for R and E_t are circles about O, as before, but the loci for i and i' are curves. For $\delta = 20$ deg. the i curve is almost a straight line, its curvature increases as δ increases. The shape of i' does not vary so much with varying δ but approaches a circle as δ diminishes. The main difference between Figs. 42 and 43 lies in the fact that the magnitude of F changes as the angle between R and the brush axis changes, reaching a maximum when R is perpendicular to said brush axis. The exciting voltage e_b changes with this angle and is proportional to $R \times sine\,[\delta + (c - c')]$ or, in this special case, to $R \times sine\,(\delta + c)$. The value of this exciting voltage or of the corresponding unidirectional exciting ampere-turns or of the corresponding unidirectional exciting flux is given in Fig. 43 for each position of R with respect to the axis of F. Thus F_{20} corresponds to the value of e_b when the resultant is in the position R_{20} and so forth. The line current is found as one side of a parallelogram of which R is the resultant and the *corresponding* F is the other side.

The maximum torque is exerted for c equal to about 84 deg. As δ increases c decreases to some extent.

It is to be noted in Fig. 43 that e_b and therefore F first increases and then diminishes. This variation is, of course, of paramount interest in connection with the compounding characteristic or torque-power factor curve of the motor. In Fig. 44 are plotted a number of curves showing just how e_b does vary with varying torque for different values of δ and a different number of turns or a different resistance of the windings 9 and 12 of Fig. 21.

Fig. 45 shows the synchronous performance curves of the new synchronous induction motor of Figs. 21, 39, 40 or 41 and the corresponding curves of a separately excited synchronous induction motor with same maximum synchronous torque but constant excitation. The curves i_1 and $\cos\varphi_1$ show the line current and power

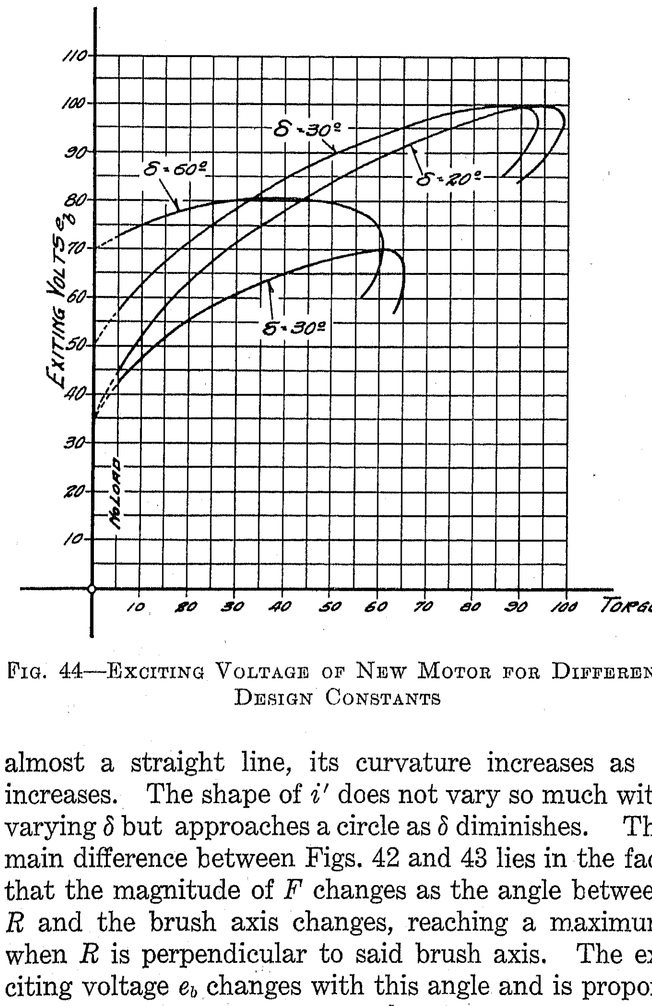

Fig. 44—Exciting Voltage of New Motor for Different Design Constants

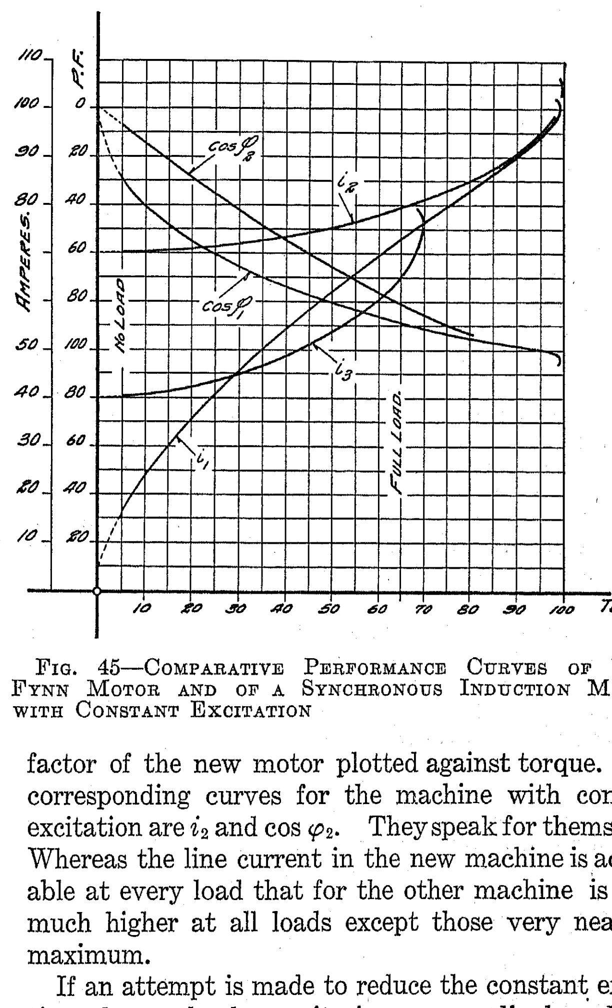

Fig. 45—Comparative Performance Curves of New Fynn Motor and of a Synchronous Induction Motor with Constant Excitation

factor of the new motor plotted against torque. The corresponding curves for the machine with constant excitation are i_2 and $\cos\varphi_2$. They speak for themselves. Whereas the line current in the new machine is acceptable at every load that for the other machine is very much higher at all loads except those very near the maximum.

If an attempt is made to reduce the constant excitation, the overload capacity is correspondingly reduced. The line current curve i_3 shows the performance with 70 per cent of the excitation corresponding to the line current curve i_2. The power factor curve for the lower constant excitation has not been plotted.

In Fig. 45 the synchronous overload capacity is 52 per cent. This is very ample in view of the fact that the non-synchronous overload capacity of the machine

is quite equal to that of a corresponding slip-ring motor and if the torque demanded exceeds the maximum synchronous capacity, the motor will slip into asynchronism without creating any disturbance whatsoever and go back to synchronism as soon as the overload has been removed.

Discussion

S. R. Bergman: I think this new motor is a courageous attempt to deal with a difficult and complex problem, namely, the problem of power-factor correction.

This motor is of the synchronous type and therefore has a constant speed over the running range. This feature, however, is of no advantage since experience has shown that the small amount of slip in the standard induction motor gives an excellent speed characteristic.

In judging a new type of motor the main question is, of course, one of economy. The motor which shows the lowest yearly operating cost to the user is the best motor. In dealing with the yearly operating cost of any electrical apparatus there are certain items which require consideration: 1st: Cost of power; 2nd: Interest and depreciation; 3rd: Maintenance; and 4th: Losses caused by interruption of service due to needed repairs.

When considering the cost of power of a motor we meet at once with difficulty due to the fact that the rates are not uniform for the whole country. Not only do different systems charge different amounts per kilowatt, but the charge due to low power factor is one that is causing a great deal of uncertainty, since no definite policy has yet been adopted. At present a number of systems have established penalizing clauses which, however, are often not enforced. Until some definite rules are established it becomes rather difficult to determine the advantage of this new motor, which possesses inherent power-factor compensation.

While this motor can be adjusted for unity power factor, or even for a leading current, it strikes me that the construction of the motor is such that it has inherently a lower efficiency than the standard induction motor. I do not hesitate to state that in my opinion, if this motor is adjusted for unity power factor the yearly cost of operation will be higher than that of a standard induction motor. This unfavorable condition is mainly due to the additional losses caused by brush losses, excitation losses, etc.

When this motor is adjusted for leading power factor, it probably has a better chance of utility since mixed with ordinary induction motors it will correct the power factor. On the other hand, there are other ways of correcting the power factor which are being successfully utilized. I mean the use of standard synchronous motors, rotary condensers and static condensers. Synchronous motors of the standard type and rotary condensers are quite advantageous in large units and the static condensers in smaller units. By a proper application of such apparatus, excellent results have been obtained. The natural evolution taking place in the electrical industry will of course, determine which of these methods is the most economical to employ to correct the power factor.

The third item referred to above was the cost of maintenance. This new machine possesses a commutator as well as slip rings and therefore, requires two sets of brushes. I also notice that it requires a starting resistance. As I understand it from the description, the armature carries two windings and the field also contains two windings. It seems to me the conclusion is obvious that this motor has a cost of maintenance far in excess of that of the standard induction motor.

Then we have the question of interruption of service caused by possible repairs. It seems that this new motor with its complicated structure would not be as reliable as the simple induction motor and therefore, would cause more lost time due to repairs which is a very serious matter to the user.

The motor industry as we know, is developing very rapidly as new water-power projects and interconnected systems are being developed in the country. The motor business and the electrical business as a whole doubles every fourth or fifth year. If the electrical industry is going to continue to be successful it is absolutely necessary that it develop along sound lines, that is, along lines which are simple so as to secure continuity of service. When judging any new piece of apparatus this point of view is of fundamental importance and with respect to this new motor its complicated structure is therefore a matter to be given serious consideration.

W. F. Dawson: I am not going to speak much about the

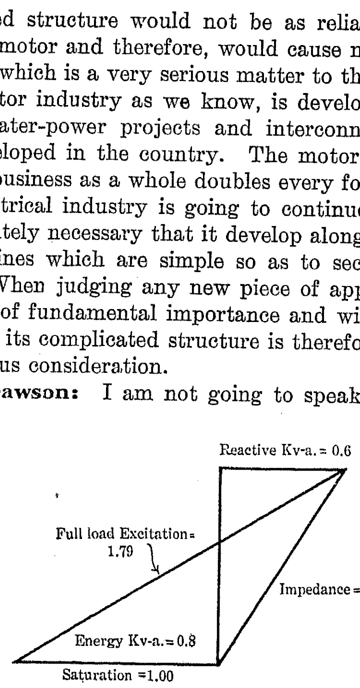

FIG. 1—EXCITATION DIAGRAM. 1.00 KV. 0.8 P. F.—0.8 KW.

motor; I think Mr. Fynn can amply defend it, but I will say a word about the effect of power-factor correction on the main generating outfit. I speak with particular feeling for the turbine alternator.

I will use the simple diagram representing the excitation of turbine alternators. Our conventional design will call for saturation 1.00 and impedance approximately equal, 1.00; 80 per cent power factor, which means 60 per cent reactive component. That gives a full-load excitation of 1.79. If the generator were operating without any reactive component and the same kw. the excitation would be 1.28; or if at unity power factor and the full kv-a. rating of the unit, the excitation would be 1.41.

The power companies pay for all that reactive component.

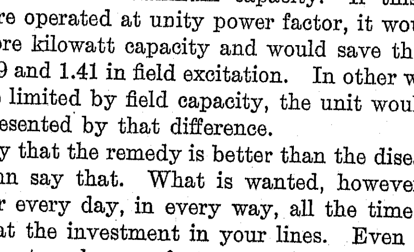

FIG. 2—EXCITATION DIAGRAM. 0.8 KW. AND 1.00 KW. 1.00. P.F.

It is the field excitation of turbine alternators, in most cases, that determines their maximum capacity. If this particular example were operated at unity power factor, it would have 25 per cent more kilowatt capacity and would save the difference between 1.79 and 1.41 in field excitation. In other words, if the output were limited by field capacity, the unit would have the margin represented by that difference.

I don't say that the remedy is better than the disease; we will let Mr. Fynn say that. What is wanted, however, is better power factor every day, in every way, all the time. Furthermore, look at the investment in your lines. Even though the turbine alternators do manufacture a 60 per cent reactive component in addition to the 80 per cent energy component, the lines do not have to carry the arithmetical sum but they do have to carry the vectorial addition.

Condensers, static or synchronous, might be placed in the power houses with the generators and thus help out the generator fields, but that would not relieve the lines of the extra load due to the reactive component. The proper place for condensers is at the point of final distribution where the power is used.

F. J. Rudd: I am particularly interested in so-called small motors, say 50 h. p. and below. To-day where individual drive is becoming more and more common, the standard mechanical construction is not always applicable. Specialization is required in many cases and it appears from the construction of this particular motor that many difficulties would be encountered when trying to fit it to various applications.

From the standpoint of certain atmospheric conditions, in many cases standard open squirrel-cage motors are satisfactory; whereas, a motor with commutator and collector rings would have to be totally enclosed. This in itself would materially increase the frame size and hence the cost for a given rating.

Another point is that where the primary voltage is higher than the normal of 550, say, for example, 2200, the problem of insulating the revolving primary winding would be much more difficult and expensive than would be required for a stationary winding, such as is employed on the usual squirrel-cage type of machine.

V. A. Fynn: The discussion brought out a point on which I have perhaps not laid sufficient stress in my paper. I was particularly interested in showing you just what theory is involved in the solution of the various problems connected with this type of motor. I think I did mention in the paper and also in my presentation that this machine could readily be inverted. This is, of course, quite simple, and when you do so, you get away from all insulating difficulties because the primary is then located on the stator. With the primary on the stator, revolving brushes must be used so long as the machine is self-excited. This revolving-brush problem has been attacked and it appears that it is capable of quite a simple solution.

But even when that is done, all of Mr. Bergman's objections are not met. I am not presenting this as a universal solution for the difficulties about which we all know, and which were so ably emphasized by Mr. Dawson. This is only one step towards a complete solution. This machine cannot compare with the squirrel-cage motor. The squirrel cage is supreme in its field, but it has a poor power factor, and the only remedy that I know of, in so far as the squirrel-cage motor is concerned, is the use of static condensers. Static condensers, theoretically, are simple enough, but they are still very expensive and have their drawbacks. If you connect static transformers to your motors, you soon run into difficulties such as have been met in Europe. Condensers are responsive to all frequencies and for that reason often exaggerate high-frequency disturbances.

The principles which I have outlined in my paper are also applicable to large separately excited machines; not only to machines of 50, 60 or 100 horse power, but to any size of machine. Just how this is done I shall have the pleasure of telling you in another paper, but in principle the solution is much the same.

While I do not claim this new motor to be a perfect machine, yet it is better than any other now available and when built with the primary on the stator and with the revolving secondary carrying the unidirectional excitation, it provides a reasonable solution in many cases.

The 65,000-Kv-a. Generator of the Niagara Falls Power Company

By W. J. FOSTER AND A. E. GLASS
Fellow, A. I. E. E.
Both of the General Electric Co., Schenectady, N. Y.

Review of the Subject:—The initial hydroelectric development of the Niagara Falls Power Company is referred to and comparisons are made with the latest development, which involves three units, each with a 65,000-kv-a. generator. The amount of material in a generator as affected by speed, periodicity and efficiency aimed at, is discussed. The electrical characteristics of the first of the 65,000-kv-a. generators are outlined. The mechanical construction is described in considerable detail with the aid of cross-sectional views of certain parts and of the generator as a whole.

A special feature of this unit is a direct-connected 650-kv-a., 25-cycle generator for furnishing excitation through a motor-generator set and for driving auxiliaries, such as pumps. Some weight data are added, showing this generator to contain over one and one-half million pounds of material—undoubtedly the heaviest electrical machine ever built.

At the close of the 19th century a notable event occurred at Niagara Falls,—the development of a plant for the utilization electrically of Niagara power. Then, as now, Niagara Falls was recognized as the finest water power in the world, a cataract of great height, fed from the Great Lakes, constituting a water storage without a rival. It was in keeping with the situation that the first plant was developed with mammoth units, much larger than had been dreamed of up to that time. They were 5000 horse power each, or, translated into electrical terms, 3750 kw., eleven of these units under one roof.

Almost exactly twenty-five years later a generator with nominal rating of 65,000 kv-a. or one capable of 50 per cent greater output than the entire row of units in the original power house, was put into service. This latest generator is the product of the experience gained during the intervening years. It is three-phase, instead of two-phase; it is 12,000 volts, instead of 2200; it is 80 per cent power factor, instead of unity-power factor; it has high internal reactance, instead of low; it has losses at full-rated load equal to approximately 2 per cent of its output, whereas the original had from 7 per cent to 8 per cent; it is of the "conventional," internal-revolving field type, whereas the original had its field revolving outside of the armature; it supports on its stator, by means of thrust bearing mounted at the top, the entire weight of its own rotor and the runner of the turbine, whereas the original had its revolving part supported from an oil-pressure step bearing located underneath; it is located so close to the turbine that it has no lower guide bearing of its own, whereas the original was some 150 ft. above the turbine with several guide bearings intervening; it is equipped with brakes to bring it to rest quickly, whereas the original had no means provided for bringing it to rest, except the shutting off of the water to the turbine; it contains approximately twenty-three pounds of material per kv-a. output, whereas the original contained nearly fifty pounds.

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

Although the quantity of material in this large generator is less than half that of the original per kv-a., it is very large as compared with a modern 60-cycle generator of large capacity at the higher speeds that are now common in hydraulic developments. There are three reasons for this generator having such great weight as one and one-half million pounds of material; first, the fact that it is low speed; second, it is low periodicity; third, it was designed for the highest economic efficiency.

Regarding the effect of rotative speed on weight, it may be said, that for the same electrical characteristics the lower the peripheral speed, the greater the weight of magnetic material and copper, and that the lower rotative speed always requires a lower peripheral speed to obtain the proper adjustment between the material that must be used for mechanical structure and that which must be used for the electrical parts. In the case of this generator, the peripheral speed is only 8200 ft. per minute, whereas many 50 and 60-cycle hydraulic generators that have been built at speeds from 200 to 600 rev. per min. have peripheral speeds of 12,000 ft. per min., or higher,—some of them as high as 15,000 ft. per min.

With regard to the effect of periodicity on quantity of material; assuming same output, same characteristics, same rotative speed and same peripheral velocity, the total magnetic flux in the air-gap must be the same at all periodicities, but the lower periodicity machine has fewer poles and the flux linked through armature from pole to pole is in inverse ratio to the periodicity, a 25-cycle machine having 2.4 times that of a 60-cycle; hence, a cross section of armature core that many times greater must be provided. Formerly, the lower periodicity permitted of higher magnetic densities in teeth and core of armature, but silicon steels have been developed with such high qualities in the matter of hysteresis losses that the lower periodicity no longer has any advantage in this respect. All periodicities up to 60 cycles are worked at as high saturation as permeability allows. Again, the smaller number of poles in the 25-cycle machine requires a

much greater radial depth of pole for heat dissipation reasons, and greatly increased cross section of the copper on the pole. For these reasons, the total quantity of magnetic material in the poles and the total amount of copper in the field-winding are greater than in the corresponding 60-cycle generator.

With reference to increase in material that was introduced in order to obtain the highest economic efficiency, it may be said, that as far as temperatures were concerned, the amount of copper in both armature and field could have been reduced at least 20 per cent, and the amount of magnetic material as much as 10 per cent. In order to obtain extremely high efficiency, it was necessary to reduce several or all of the various kinds of losses, windage, hysteresis and eddy current, $I^2 R$ and load losses. The most important factor in the windage losses is peripheral speed; hence, it is generally best to select smaller diameter, although it results in increased magnetic material and copper. Lower hysteresis and eddy losses may be obtained by working at lower densities; consequently, greater amount of material must be used in the magnetic parts. Lower $I^2 R$ losses can be obtained by increasing the

C— " " " 80 " " " "
D— " " " zero " "

quantity of copper. Load losses can be kept lower by conservative design in the matter of armature reaction, but the size of the machine is increased by reason of the lower armature reaction.

The electrical characteristics of this generator are in accord with what is regarded as best for power-producing purposes in large systems. The ampere turns at no load, 12,000 volts, are almost identically the same as required for rated current on short-circuit.

The calculated armature reactance is 26 per cent.

Unusual features in the electrical design are the low point on saturation curve at rated voltage, made necessary by the requirement of operating continuously at 13,200 volts, 68,250 kv-a., 80 per cent power factor, and the very low-current densities at which copper is working, approximately 1300 amperes per square inch in armature and 1100 in field, in order to obtain the very high efficiency.

Fig. 1 contains Curves of no load, 100 per cent and 80 per cent power factor full-load saturation.

The fact that this generator is, for the time being, the largest ever built, would in itself be sufficient justification for describing it, but in addition, it contains a few features that are entirely new, as far as the writers of this paper know. Many large vertical hydraulic units have already been built, due to the ever increasing demand for power and to the greater simplicity and economy in power houses and auxiliary apparatus thus obtained. The principal parts of such large generators may be stated as stator frame; stator core; stator winding; shaft; rotor spider; poles; field coils; upper bearings' spider; bearings; oiling system; collector rings. There are numerous detail parts in connection with every one of these major parts that are of extreme importance and worthy of description. Before taking up the major parts in order, we call attention to Fig. 3, which shows the general arrangement of the generator, the stator supported by a continuous base ring, thrust bearing carrying the total weight of the generator and water-wheel rotating elements, including water thrust, mounted on the upper bearing bracket. This bracket also carries the generator guide bearing. The water-wheel guide bearing is located directly above the turbine runner. The proximity of generator rotor to turbine runner eliminates a third, or middle guide bearing, which is often placed immediately underneath the generator.

The novel features in this generator are shown in Fig. 3, in the placing of an excitation generator with

rating 650-kv-a., the stationary part suspended from the upper bearings' bracket and the revolving part mounted on the arms of the revolving spider of main generator. The collector slip rings for supplying exciting current to this small generator, as also those for main generator, are shown mounted immediately above the thrust bearing. At the extreme top is mounted a speed limiting device. These parts are protected by a housing of pleasing design. This new generator has the same lines as the 32,500 kv-a. generators, installed in the same station about three years ago and designed in accordance with the ideas of the engineers of the Niagara Falls Power Company. Fig. 4 shows the close agreement in outlines of the two generators, the one exactly double the other in capacity, and gives at the same time a clear idea of the relative space above floor, required by the respective machines.

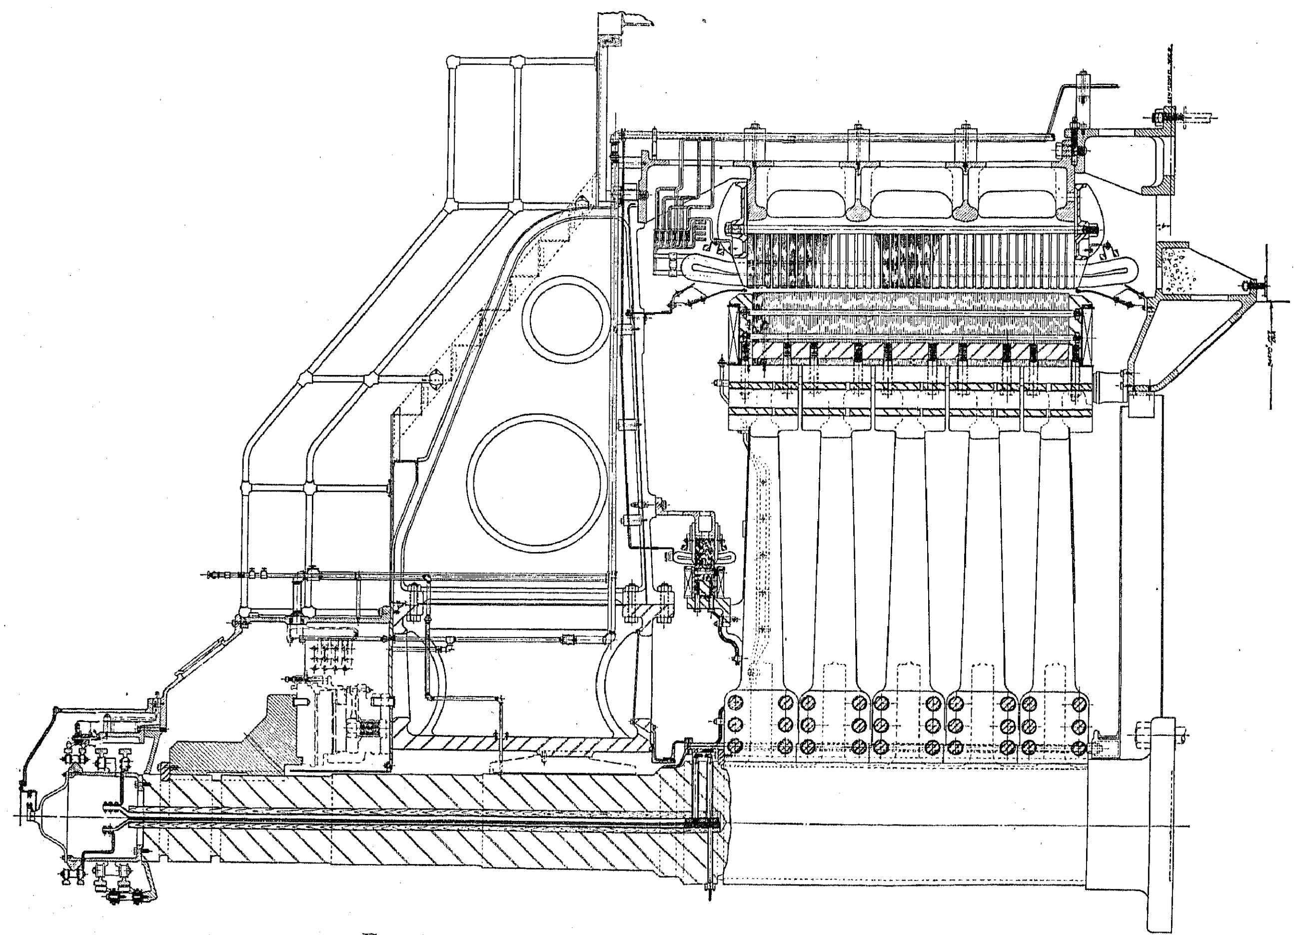

Fig. 3—Cross Section of Assembled Generator

Stator

The cast iron stator frame is made in four sections, for purposes of casting, machining, handling in the factory, transporting and erecting at power house. Each section measured 22 ft. across the arc and 10 ft. in height. The sections are keyed, doweled and put together with sufficient bolts to withstand maximum short-circuit strains. Similarly, the complete stator frame is rigidly doweled and bolted to the base ring. The final adjustments for alinment are made by means of adjusting screws in the base ring. At the top of the stator frame is a projecting flange for the attachment of ventilation housing that surrounds the machine, for the purpose of carrying away the warm air.

Stator Core

The laminations of core are assembled on keys attached to stator frame ribs by screws. The core is built up in numerous sections separated from one another by "I" beam-space blocks, so as to provide ventilating ducts. The core, by reason of its immense size, is clamped together by extra heavy cast-steel clamping flanges at top and bottom with large bolts running the entire length of the core and located between core and stator frame. By clamping the core with through bolts in this manner, the stator frame is relieved from strains which might exist if the clamping flanges were attached by bolts screwed into the stator frame, as is customary in smaller machines. Shims are provided underneath clamping flanges, in order that any looseness of core may be taken up, in case such looseness should ever develop. The core was assembled at the power house as a complete circle so that the laminations are staggered everywhere and there are

no joints in the core, which are sometimes responsible for noise, due to vibrations of the edges of the laminations immediately at the joint.

A special device for assembling and pressing the core was made for this particular installation and is shown in Fig. 5.

The laminations are of the best grade of silicon steel, of same thickness and with every sheet enamelled on both sides, in same manner and with same care as for cores of the largest and most important 60-cycle generators.

Stator Winding

The armature winding consists of 360 coils, three turns each of rectangular wire, 36 strands in multiple, spanning 70 per cent of the pole arc. The number of coils per pole is fractional, 12 $^6/_7$, to eliminate higher harmonics. The coils are connected up in four circuits per phase. All connections from coil to coil in the various phase belts, as well as the pole connections and the phase leads at beginning and endings, are made at the top of the machine. Both ends of all phase windings are carried to the busses outside frame for connecting in the differential relay protection apparatus.

The weight of one insulated coil is 186 lb. The weight of the completely insulated and connected winding is approximately 70,000 lb. The windings at heads of machine are laced back to insulated supporting bands with blocking between the coils, while the end connections are arranged in a neat and systematic manner and similarly blocked. See Fig. 6.

The insulation on turns, as also the external insula-

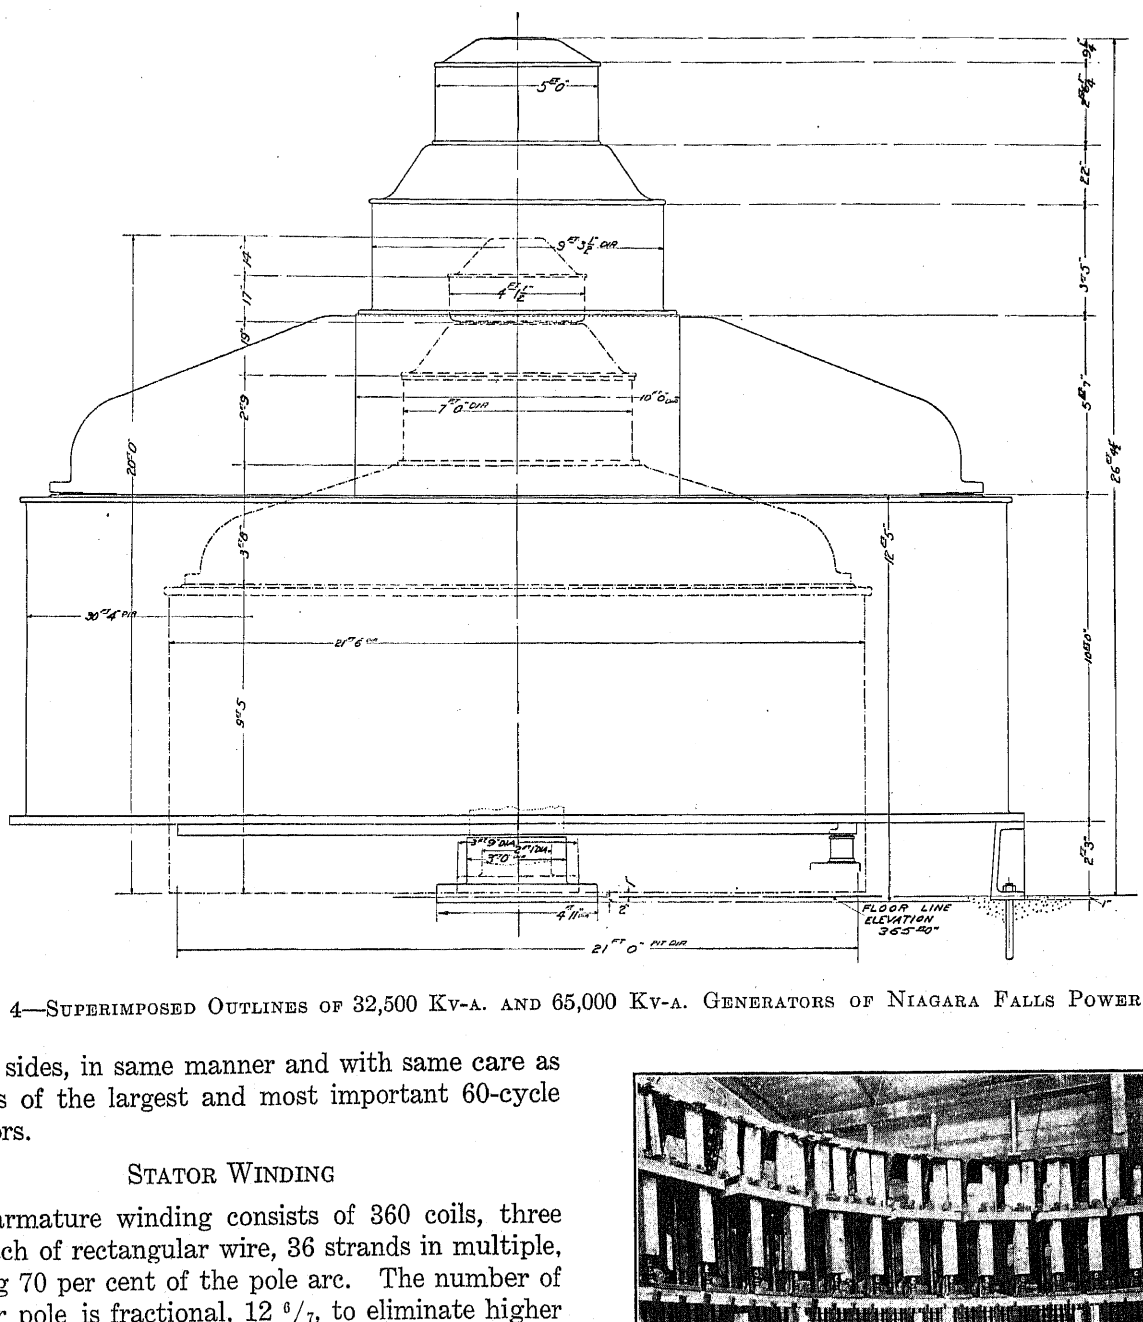

Fig. 4—Superimposed Outlines of 32,500 Kv-a. and 65,000 Kv-a. Generators of Niagara Falls Power Co.

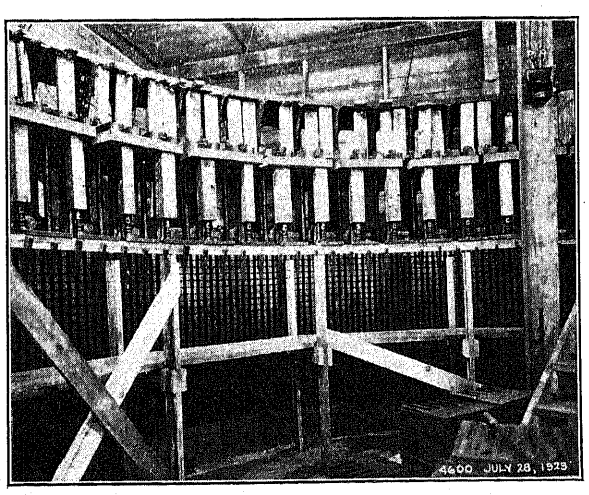

Fig. 5—Stator Core Assembling and Pressing Device

tion, consists of mica, put on in the form of tape with a specially developed varnish as sticker. The coils were subjected to vacuum treatment and moulded to size at different stages of the process. A cross section through the slot, Fig. 7, gives a clear idea of the composition of the conductor and the relative thickness of the insulation.

The insulation of such large coils has been developed with certain desirable characteristics in view, such as the elimination of all pockets for air, or other gases, to avoid internal corona and the introduction of sufficient flexibility to permit bending or yielding when coils are being assembled in deep radial slots or being removed in case repairs are ever made.

A certain amount of heat should be applied before coils are assembled, as also when taking coils out of slots. For the winding of armature of the Niagara generator in the power house a special heating oven was made—Fig. 8.

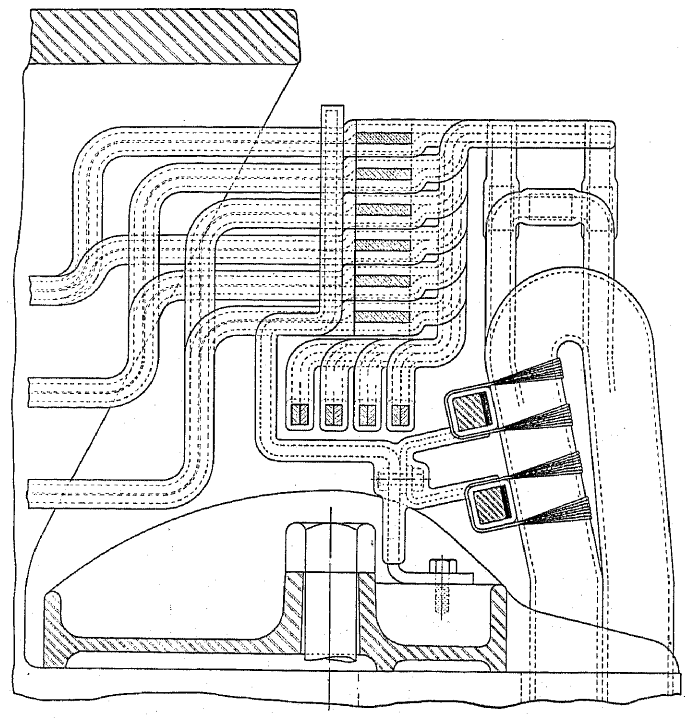

Fig. 6—Supports of Stator Winding and Connections

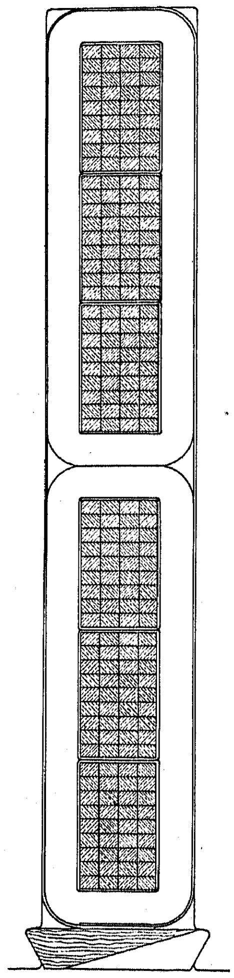

Fig. 7—Cross Section of Stator Coils in Slot

Rotor Spider

As a rule, less time is required to design the revolving field of a high-speed large-capacity generator than a low speed generator, for the reason that a laminated or plate center with dovetailed and keyed-on poles is invariably found to be the proper construction for the small-diameter, high-speed rotor. However, for a 107 rev. per min. generator of large capacity, several alternatives present themselves, requiring much study to decide which is best. Rotor spider may have laminated or plate rim, or it may be made of steel castings throughout or of steel and iron, and in various ways. Poles may be dovetailed or bolted, etc.

The rotor spider of the 65,000-kv-a. generator is cast steel throughout, made up of five sections or wheels, every wheel containing two identical castings, half wheels—Fig. 9—fastened together at each joint of the rim by two nickel steel shrink keys extending across the full breadth of rim. The half hubs are rabbeted and fastened together by numerous large nickel-steel shrink bolts. Two shaft keys, diametrically opposite and extending entire length of hub, prevent rotor turning on shaft against torque. Rotor hub at lower end rests upon a shoulder or projection of the shaft and at upper

end is held in place and kept from lifting, when brakes are applied to rim underneath, by means of a circular split ring key set into shaft and bolted to hub. This multiple-wheel type of rotor spider, with circumferential spaces at the rim between adjacent wheels, insures a supply of air for removing heat from field coils. The arms of the top and bottom wheels are

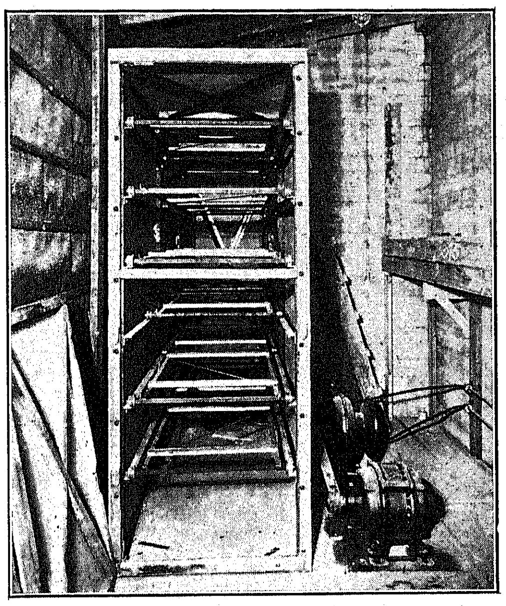

Fig. 8—Oven for Heating Armature Coils when Assembling

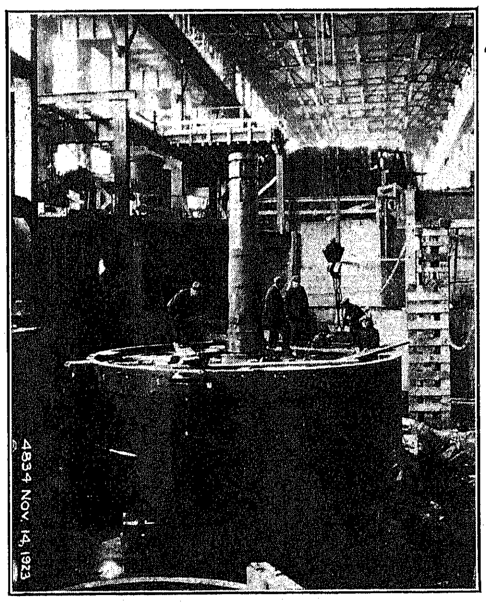

Fig. 9—Rotor Under Construction

partly covered with steel plates to reduce windage losses and increases the flow of air through the rim.

To make sure that all castings had the proper physical properties, four test coupons were cast on the rim of every half wheel. Test pieces were cut from these coupons, turned to standard size and pulled in the mechanical laboratory. The results of the tests on the forty samples from the ten castings that were used in the rotor of the first generator, were within the limit of the contract specifications.

Poles and Field Coils

The pole laminations are $\frac{1}{8}$ in. thick sheet steel, clamped between heavy cast-steel end plates and securely held by large through bolts, instead of the usual rivets. Two nickel-steel keys, running the entire length of pole, including end plates, are set into pole body and tapped to receive the bolts attaching pole to rim.

A novel feature of this design is the method of fastening pole pieces to rotor spider. Instead of the usual dovetail, keyed type of pole, twenty nickel-steel tap bolts per pole are provided, ten the length of the pole, two in parallel, or four bolts per section of rotor rim, making a total of five hundred and sixty holes drilled radially through the rotor rim. It was thought that rotor rim casting could better be "explored" for shrink holes and checks, by drilling these radial holes as against the dovetail slot, which does not cut the rim radially. Incidentally, not one shrink hole or check was discovered when drilling the five hundred and sixty holes in all ten sections.

Field Coils

Field coils are wound with copper strap 0.43 in. by 2.625 in. in cross section, which is probably the heaviest strap that has ever been used in field coils. It required from ten to twelve reels of copper for each coil, hence, about eleven brazings on an average per coil. The ordinary machines for winding copper strap on edge could not be used. Fortunately, a much heavier machine, used for forming field coils of the largest steam turbine generators, was available, although certain modifications were necessary. After forming coil, a special heating and clamping device was used to mould into shape for assembly on poles. The weight of copper in each coil is 2800 lb.

Rotor coil supporting brackets, insulated from coils are provided between each pair of poles, to prevent bulging of coils due to side thrust. On account of the size and weight of each pole, a special lifting device was made for lifting the pole into a vertical position when assembling. See Fig. 9. The revolving field, is guaranteed to withstand a runaway overspeed or speed test of 214 rev. per min., or twice normal, and such a test was made in the factory on each section of rotor spider and witnessed by customers' representatives. Special poles, each representing the weight of that part of pole over rotor spider section, were made up of laminations and end plates and attached to each section of rotor spider. Laminations, end plates and pole piece bolts, used in making test, were afterwards used in the assembly of the complete pole. All five sections of rotor spider passed double speed test successfully.

Upper Bearing Bracket

The upper bearing bracket, on which rests the thrust bearing carrying an estimated load of 1,200,000 lb.

is of the central-hub and separate-arm type. The central hub is a cylindrical steel casting, to which ten radial arms of cast steel are rabbeted, doweled and bolted, the whole when bolted together having a beveled turn lip at the ends of arm, fitting accurately into the stator frame for perfect mechanical alinment of bracket with stator frame, and securely fastened to the frame by large steel bolts. Bracket and bolts are insulated from stator frame to prevent "pitting" of the guide bearing, due to stray currents. The calculated deflection of 0.055 in. checks very closely with actual deflection of 0.063 in., obtained after generator was installed. Covers are provided between arms and are partially perforated, to allow cooling air to be taken in at top of generator. Two hand holes are provided in outer portion of each cover for the inspection of stator winding and connections at any point. A platform, supported from bearing bracket for inspection of thrust bearing, is provided, and a stairway leads to this platform from upper floor of power station.

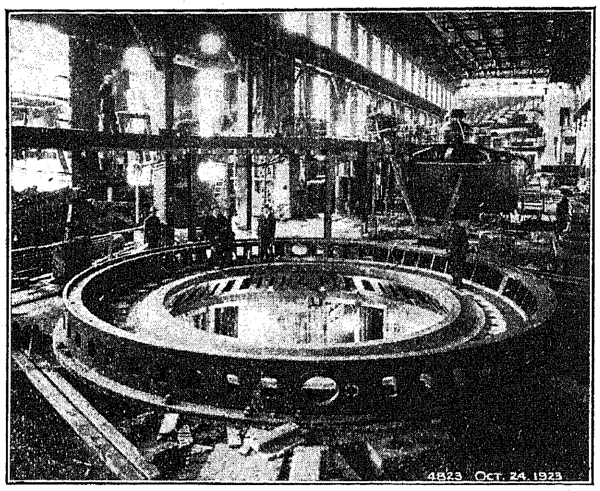

Fig. 10—Base Ring (Outer) and Brake Support (inner)

Guide and Thrust Bearing

The upper guide bearing is centrally supported, instead of having straight seat fit, as is usual in this type of generator.

Thrust bearing is of the usual Kingsbury type, with water-cooling coils, provided for cooling the oil in the bearing housing. This bearing is designed to carry a maximum load of 1,250,000 lb.

Base Ring and Brake Support

Another unusual feature of design is the segregation of the base ring, supporting the stator from the brake-supporting ring. See Fig. 10. Both rings are cast in four sections each, bolted together and separately grouted directly into the foundation. The brake supporting ring designed to take total weight of revolving elements, when jacks are applied under rotor rim to relieve weight on thrust bearing, besides supporting the brakes when used for shutting down. The base ring is provided with convenient man-holes for inspection of stator winding at bottom of generator.

Collector Rings and Connections

At the upper end of the shaft a heavy cast-iron supporting shell is bolted for the two pairs of collector rings, those of main generator and those of excitation generator. The electrical connections between rings and fields are made by means of rectangular copper strips running down from rings through a hole in shaft to a point above hub of rotor, where they are joined to cables running along arms of rotor spider to field terminals. All collector connections can be made or broken inside the supporting shell. The collector rings thus mounted with supporting shell, can be easily removed and replaced. The shell also supports the speed-limiting device, at the top of which a tachometer may be placed for taking readings of speed, if required.

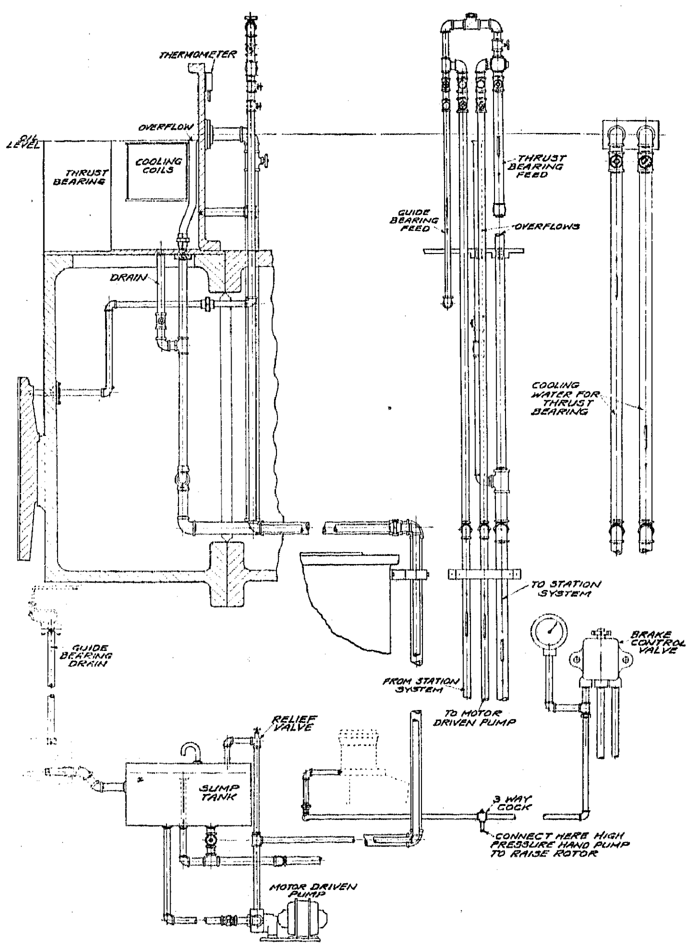

Fig. 11—Diagrammatic Plan of Piping

Oiling System

Fig. 11 shows diagrammatic arrangement of the complete piping for each generator. A feature of design in this arrangement is that generator may be supplied directly from station system, or by separate motor-driven oil pump, acting independent of the station system. Another feature is the use of the same piping

for two purposes, the application of the brakes to rotor rim to shut down (when compressed air from station system at a pressure of 150 to 200 lb. is used) and the lifting of rotor to take weight entirely off thrust bearing (when oil at a pressure of 1400 lb. per sq. in. is used). For jacking up, oil at pressure of 1400 lb. per sq. in. is supplied by a Watson-Stillman hand pump. This operation requires only a short time, and is very effective as against the more laborious method of backing off the bolts on the thrust bearing to relieve the load on bearing, when inspecting or disassembling unit.

Excitation Generators

A-c. generators, both steam and hydraulic driven, have of late been frequently provided with direct-connected exciters. In the case of the vertical units, the exciter is regularly mounted immediately above the thrust bearing at the top of the unit. In several of the largest and best known hydraulic plants excitation has been provided by individual motor-driven exciters, the motors being driven from a house generator or from the station system. As far as the writers know, this system of motor-driven exciters was first introduced many years ago into the plant of the Ontario Water & Power Co., Canadian Niagara Falls, at the suggestion of Mr. J. A. Johnson, who is now the electrical engineer of the Niagara Falls Power Co. Hence, it should not be considered strange that a new idea has been incorporated in this new 65,000 kv-a. generator by Mr. Johnson. A direct-connected alternator is used both for the purpose of driving the motor-generator set that supplies excitation, and also for supplying power to motor-driven auxiliaries.

Outside of the usual mounting of this generator, the stator being supported or "hung" from the bearing bracket arms and the rotor bolted directly to the rotor arms, no unusual problems of design are involved.

Workmanship and Installation

As a general rule, smaller generators of this type are completely assembled in the factory before shipment, to see that all parts fit together properly, and running tests are made to determine if generator comes within guarantees. Outside of assembling the rotor spider sections, without shaft, and the fitting of one or two pole pieces to determine if pole piece bolt-holes lined up with holes in rotor spider and the assembly of stairway and gallery to bearing bracket, no attempt was made to assemble this generator. Notwithstanding the fact that bearing bracket must fit stator frame accurately, that all bolt holes must line up with corresponding holes in connecting parts, that rotor spider keyways must line up accurately with shaft keyways, and all without being fitted together, when generator was finally assembled in power house for the first time, so accurately was all machine work done that, to use the words of the erecting engineer, "all parts fitted perfectly and not even one bolt had to be changed to make the assembly complete."

Weights

The $W R^2$ is 65,000,000—figures easy to remember in connection with a 65,000 kv-a. generator that has excitation auxiliary of 650 kv-a.

Discussion

R. B. Williamson (by letter): This paper is of special interest to me because I happened to be responsible for the design of one of the 32,500-kv-a. units installed in this station in 1919, and also have had in charge the design of a 65,000-kv-a. unit which will be put in the same station alongside the unit described. At the time the 32,500-kv-a. units were started, they were the largest of their kind but they had been in operation but a short time before plans were made by The Niagara Falls Power Company to install three additional units of 65,000-kv-a. output. The three 32,500-kv-a. units have now been in operation for four years or more and have given excellent service. Further, these units showed a very high efficiency, 97.5 to 98 per cent, and the larger unit was not adopted with the expectation of securing any material gain in efficiency. Neither does the large generator cost appreciably less per kv-a. output, since the speed is lower and the weight per kv-a. somewhat higher. It may be repeated here, that the 32,500-kv-a. units operate at 150 rev. per min. as against 107 rev. per min. in the case of the 65,000-kv-a. machine.

Referring to Fig. 4, it will be noted that the floor space occupied by the large generator is approximately 725 sq. ft. as compared with 365 sq. ft. for the smaller unit. Thus the floor space is almost double so that space per kv-a. is about the same in either case, so far as the generators alone are concerned. However, when all other features, such as necessary space between units, space for auxiliaries, penstocks, etc., are taken into account, it is evident that three of these large units can be put into a shorter power house than six units of 32,500 kv-a. each, and as the space available for the power house was strictly limited in this case, the larger units were chosen. In other words, it was necessary to place the largest possible generating capacity in a limited space and the 65,000 kv-a. generators in this respect were superior.

So far as the construction of the stator is concerned, it is essentially the same as that of the smaller units, though, of course, the machine is larger in diameter and higher. The chief structural differences are in the rotor which, on account of its large diameter, had to be sectionalized to a greater extent. In the unit described, the rotor spider is in ten sections, each consisting of a half wheel with the rim cast integral with the arms and half hub. The five wheels assembled on the shaft form the complete spider to which the poles are bolted. As stated in the paper, the design to be used for such a large spider is one that involves a number of considerations. Not the least of these is the ability of the steel-founder to produce satisfactory castings. Such a design has to be worked out in consultation with those who make the castings and very often the design has to be modified to conform to their requirements. Thus, designs that are quite different, may result and yet each be entirely satisfactory. In the design with which the writer has had to do, the rotor spider is in two wheels, each of which is made of seven sectors having two arms per section. The two hubs are separate castings and

the arms are bolted to heavy flanges on the hub by means of reamed bolts in the same manner as has been used for many years for large segmental engine fly wheels. The sectors are joined at the rim by heavy mild-steel tongues and dowels, and the poles are bolted to the rim. Test bars from all the rotor castings were taken from coupons and also from samples drilled from the body of the rim by means of hollow drills.

As stated in the paper, the problem of bending the field copper on edge for a field coil of this size is quite a difficult one but it has been successfully accomplished and the coils present a good even appearance. This is only one of the many problems that have to be solved in the construction and erection of such a large unit and the authors are to be congratulated on the results obtained. The writer had the pleasure of witnessing the starting of the first of these units and notwithstanding the enormous size of the machine, its operation is smooth and quiet. The third unit is now being installed and I hope at a later date to present a detailed description of it to the Institute. In external appearance and dimensions, it differs very little from the one described in the paper; in fact the engineers concerned, cooperated in every way possible to make the units present a uniform appearance and the differences are mainly in details of design which I hope to describe later.

W. I. Slichter: This paper is an important addition to the very few we have had on the subject of the design of large generators. In the PROCEEDINGS of the Institute, there was in 1914 a description of a 7500 kv-a. machine; in 1922 a description of a 32,500 kv-a. machine; in 1923, of a 45,000 kv-a. machine and this year, 1924, of a 65,000 kv-a. machine. This enumeration shows the rapid increase in capacity of water-wheel generators, as each machine described was the largest of its time. It is interesting to note that in this latest machine efficiency was given more consideration than heating, showing the effort for very high efficiency. In most large machines, if the heating is satisfactory the efficiency will also probably be satisfactory. It is well known to designers that in small machines it is difficult to get a good efficiency and if this is obtained no difficulty is experienced with heating. In large machines, particularly turbo generators, the heating is the more difficult problem and if this is satisfactory the efficiency is also satisfactory. This machine therefore marks a still further step in the development of our designs, in which the conditions have reversed themselves as the capacity increases above a certain very large figure.

The use of a fractional number of slots per pole ($12^6/_7$ slots per pole) to eliminate higher harmonics is a matter of interest as this practise, which has only been introduced in the last few years, is quite a conundrum to the engineer without experience in design, and yet it is quite a natural and desirable advance in the art of making windings to give a good electro-motive force wave-shape.

In order to compare the weight economy of this machine with others it is necessary to take into account many factors and this is best done, for purposes of comparison, by a formula, which has been applied to many lines of machines. This formula is

$$W = K \sqrt{\frac{P}{R.\ P.\ M.}}$$

in which W is the weight of the machine in pounds; P, the kv-a. rating of the machine; and $R.\ P.\ M.$, the revolutions per minute. K is a characteristic constant of a given line of machines. Thus in well known lines of sixty-cycle turbo-generators, K would run from 40,000 to 50,000 and in a line of similar machines for twenty-five cycles, K would run from 50,000 to 60,000. In the machine under discussion, K has a value of 58,000, so that this is an example of a water-wheel-driven machine of 187 rev. per min. and 8200 ft. per min. peripheral velocity which has a weight factor constant very close to that of turbo-generators which are generally understood to have a very good weight economy.

L. W. W. Morrow: One of the interesting features of this machine is the fact it has been installed at Niagara Falls; the development of hydroelectric machinery at this location has influenced the art in all parts of the world. The design of machines for this installation is unusual in that designers are given freedom to design the best possible machines and are not limited by cost values to the degree found in other locations where the units are small and the firm power is less in amount. Niagara Falls has a large and constant amount of available power which is sold largely near the development site. A fraction of a per cent gain in efficiency or in reliability on such large units and under the conditions found at this location can be capitalized for a very large sum and efficient production outweighs first cost many times.

L. P. Ferris: Mr. Foster mentioned the fact that the large 65,000-kv-a. machine described in the paper by himself and Mr. Glass has a fractional number of coils per pole, for the purpose of eliminating the higher harmonics. This is a very welcome step, from the point of view of the telephone engineer who has to deal with the effects of these higher harmonics on parallel circuits.

W. J. Foster: Mr. Dawson has asked the question about how the various losses have been determined. They have not been determined yet on the 65,000-kv-a. machine, by actual test, but they will probably be determined in about two months as soon as the second generator has been in service for a short time. The method that will be employed is the retardation method, the same as used in connection with the testing of the three 32,500-kv-a. generators. That gave most excellent and consistent results, as applied at Niagara Falls under the direction of Mr. Johnson. The retardation tests will be made on open circuit without any excitation, in order to determine the combined friction and windage losses; then under different degrees of excitation, to a considerable over-excitation. With all those curves, there isn't a shadow of a doubt as to the proper determination of the friction and windage, and of the core losses on open circuit.

Then the load losses will be determined by making similar retardation tests with the armature short-circuited, with an excitation that will give the full-load current carried during the retardation, at the 25-cycle point.

Those tests, as applied to the first generators, agreed very closely with the calculated values, showing lower figures in the case of the core losses, and practically the same as used in the calculation of efficiency for the remaining losses. But we already know from the 65,000-kv-a. machine that is operating, what its copper losses are, since we have the resistance of the armature and have determined the excitation required, which is a little lower than allowed in the calculations. So we have not much doubt that the efficiency mentioned here will be attained.

There are one or two features of that generator, that have not been brought out in the paper, and I didn't bring them out in the introductory remarks. One of these is the ventilation at the heads of the armature. The customer is very much concerned that every precaution against damage or of possible burning out of an armature coil should be taken so as to minimize the consequences of such a burn-out, and for the first time in connection with any generators that I have anything to do with, a very determined effort has been made to stop completely the swirl of air in the projecting windings of the stator. That swirl of air, especially in high-speed machines like turbine generators, once it catches fire, results as a rule in the destruction of the entire winding. In the case of slower speed machines, water-wheel machines, the damage often spreads around a considerable distance. But this particular generator, after a great deal of thought and numerous designs, has been equipped with a series of vanes at top and bottom, these vanes being made of an insulating material and also of fireproof, fire-resisting material.

Harmonics Due to Slot Openings

Review of the Subject.—*This paper represents a brief graphical-analytical exposition, followed by a mathematical development of the harmonics due to slot openings These were proved to be even and odd multiples of the number of slots plus and minus one. The modifications upon the torque speed curves of these harmonics have been discussed. A simple Fourier analysis underlies the whole phenomena.*

* * * * *

THE object of this paper is to give in Part I a graphical-analytical demonstration and in Part II a mathematical demonstration of the harmonics caused by slot openings. The description applies particularly to the field form of a rotating field motor such as the induction motor.

Part I.

Tooth harmonics affect the performance of the motor in several ways, the more important, from a practical point of view, being the low-speed counter-torques causing cusps in the speed-torque characteristic and noise.

The depth of the cusp in the speed-torque characteristic depends upon the magnitude of the low-speed counter-torque, which in turn depends upon the intensity of the harmonic field. It is, therefore, both interesting and important that the order and magnitude of the harmonics be determined for the practical case. The solid line Fig. 1 shows the speed-torque curve of an induction motor with the effect

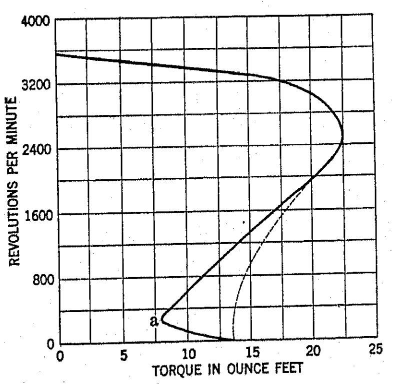

FIG. 1

of tooth harmonics shown at *a*. The dotted portion of the curve indicates the shape of the speed-torque curve if tooth harmonics were eliminated.

For the purpose of simplification, the rotating field of an induction motor only was considered and to further simplify the work involved in this anaylsis, five slots per pair of poles were assumed and the dimensions of the tooth were assumed to be in proportion to the dimensions of the teeth of a punching having the usual number of teeth. By using five teeth per pair of poles instead of the usual number in a standard motor, a large amount of unnecessary labor

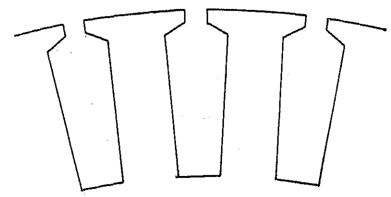

FIG. 2

was avoided. By making the shape of the teeth of the five-tooth rotor in proportion to the usual number of teeth in a standard motor, the equivalent of practical conditions was obtained. These assumptions produced a tooth of proportions shown in Fig. 2.

The air gap was of the usual size for the smaller sizes of induction motors and in this case 0.015 in. on one side.

After obtaining the normal size of tooth and slot opening of a five slot per pair of poles element, and assuming the air gap to be 0.015 in., the tooth and air gap were laid to a scale ten times normal size in order to draw in the tooth fringing as shown in Fig. 3.

The center line of the tooth was taken as the starting point and the distance from center line of slot to center line of tooth was divided into 36 equal parts and the flux paths measured at these points along the fringing lines shown in Fig. 3. Since the field strength is proportional to the reciprocals of the lengths of the paths, the reciprocals of the measured lengths were calculated and the data in the first two columns of Table I was prepared for plotting the reciprocal curve shown in Fig. 4. Since the maximum field strength is a direct function of the largest reciprocal, Column 3 of Table I was prepared on the basis of putting the per cent maximum flux equal to the largest reciprocal and other values in direct proportion. Fig. 5 was then plotted from data in Columns 1 and 3 in Table I. This curve, Fig. 5 has the same shape as Fig. 4, but the ordinates are given in per cent maximum flux instead of reciprocals which is more convenient. Curves, Figs.

*I am indebted to Mr. R. E. Hellmund for valuable suggestions.

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

4 and 5 illustrate the effect of the slot opening on a uniform field.

Since the field in the air gap of an induction motor is assumed to be sinusoidal, the curve shown in Fig. 5

TABLE I

Position in Degrees	Length from Drawing	Reciprocals of Lengths
0-29.7	0.15	6.67
30	0.3	3.33
31	0.75	1.33
32	1.2	0.833

was multiplied by the sine curve and the instantaneous field obtained as shown in Fig. 6. Two points, one at a and the other at b are calculated below to illustrate

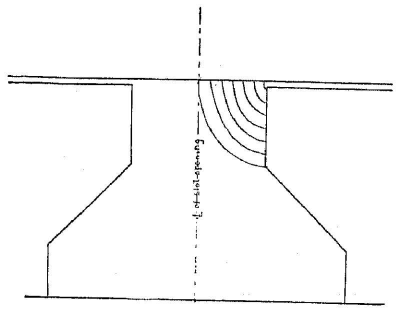

Fig. 3

the method more clearly. a is at 20 deg. on curve Fig. 5 and has an ordinate value of 100 per cent. This value is multiplied by the sine of 20 deg. to obtain the

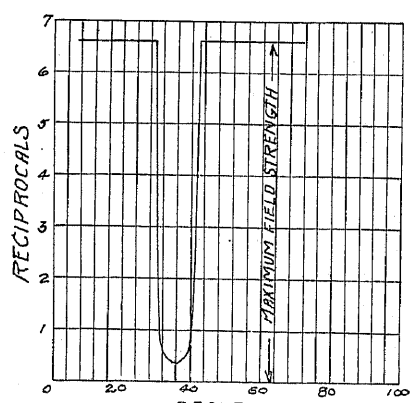

Fig. 4

corresponding ordinate for the sinusoidal field Fig. 6.

$$100 \text{ per cent} \times \sin 20 \text{ deg.} = 34.2$$

which is plotted at a Fig. 6. Likewise b at 36 deg. on Fig. 5 has a value of 5.05 per cent which, when multiplied by the sine of 36 deg., gives the corresponding ordinate for the sinusoidal field Fig. 6.

$$5.05 \text{ per cent} \times \sin 36 \text{ deg.} = 2.97$$

which is plotted at b Fig. 6.

Fig. 6 illustrates the effect of the slot openings on the

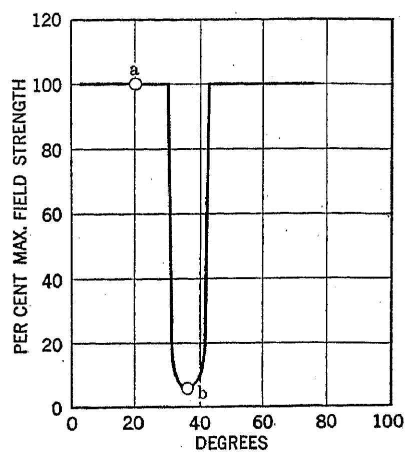

Fig. 5

field form of an induction motor. It should be noted that the indentations caused by the slot openings do not reach zero value. This, it will be understood, is due to the fringing and is what would be expected.

Since the direction of rotation of the harmonics is equally important as the kind of harmonics, it was necessary to find means for being certain of the direction of rotation of the harmonic fields as well as their order and magnitude, as compared with the direction of rotation of the fundamental. This was done by con-

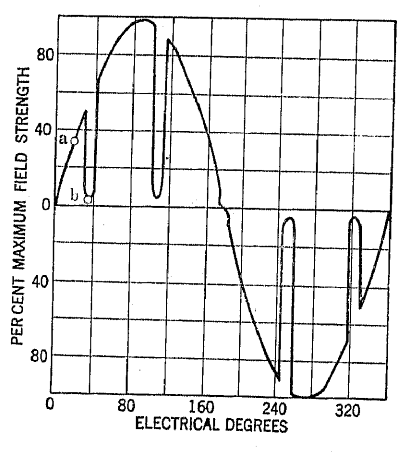

Fig. 6

sidering the fundamental as having advanced 18 electrical deg. clockwise with respect to the slotted element, which gives a new position of the indentations caused by the slot openings on the fundamental. To obtain the field form with the fundamental advanced 18 electrical deg. with respect to its former position, curve 5 with zero degrees taken at the 18 deg. point was mul-

tiplied by the sine curve in the same manner as previously explained and Fig. 7 obtained. If these two instantaneous field forms, Figs. 6 and 7 are analyzed for the various harmonics, the positions of each harmonic with respect to the fundamental in each case will give the rotation of the harmonics. This will be illustrated more fully later.

It is, of course, clear that the indentations caused

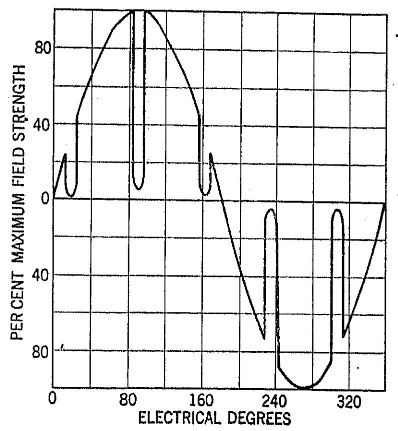

Fig. 7

by the slot openings will successively occur at all points in the fundamental in cyclical order. The task of analyzing the two instantaneous field forms, Figs. 6 and 7 for the higher harmonics was too tedious by mathematical methods and it was decided to re-plot these two instantaneous field forms on polar co-ordinates and analyze them on an available harmonic analyzer.

Figs. 8 and 9 show the instantaneous field forms Figs. 6 and 7 on polar co-ordinates. The analysis of

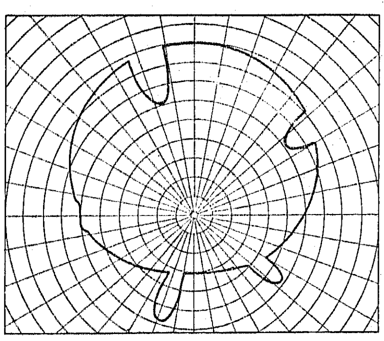

Fig. 8

these flux waves as obtained from the harmonic analyzer are shown in Table II.

An inspection of the values of the various harmonics shown in the Table brings out the fact that there are harmonics of appreciable magnitude as follows: 4th and 6th, 9th and 11th, 14th and 16th, 19th etc. . . . and that all other harmonics are zero or of negligible value. This fact may be represented mathematically as follows:

$$\text{Order of Harmonics} = k\,n \pm 1$$

where k equals any integer and n equals the number of slot openings per pair of poles.

The direction of rotation of the harmonics with respect to the fundamental was determined in the case of the 4th and 6th harmonics by plotting them on the instantaneous fields Figs. 6 and 7 from the values given in Table II as shown in Figs. 10 and 11. It will

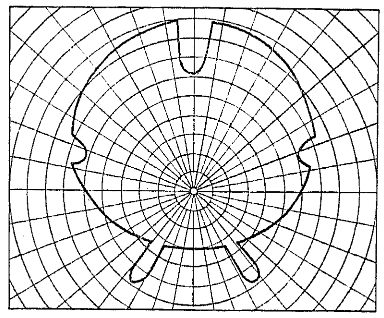

Fig. 9

be remembered that in the case of Fig. 7 the fundamental was advanced with respect to the slot openings 18 electrical deg. clockwise from its position in Fig. 6. Likewise Fig. 11 shows the conditions for the case of the fundamental having moved clockwise 18 electrical deg. from the position shown in Fig. 10. It is therefore evident that the positions of the 4th and 6th harmonics in Figs. 10 and 11 will indicate the direction of rotation of these harmonics.

In order to determine the direction of rotation of the 4th and 6th harmonics, the two instantaneous fields, Figs. 10 and 11 showing the 4th and 6th harmonics, were compared.

In the case of the 4th harmonic its maximum value occurs at 22½ deg. in the case of Fig. 10, whereas in

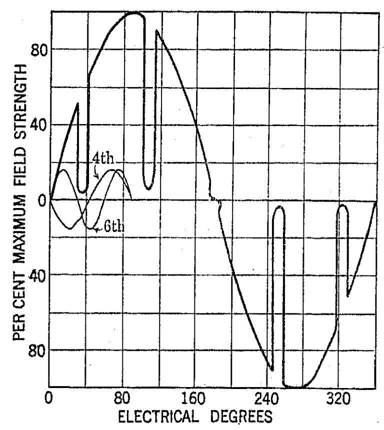

Fig. 10

the case of Fig. 11 it occurs at zero degrees. Now since the fundamental has advanced 18 electrical deg., the maximum of the 4th harmonic should be at plus 4½ deg. on Fig. 11, if the 4th harmonic did not move at all, that is, if the 4th harmonic were stationary in space. Since the maximum of the 4th harmonic on

Fig. 11 actually occurs at zero degrees it must have moved 4½ deg. contrary to the fundamental.

In the case of the 6th harmonic, its maximum value occurs at 15 deg. in the case of Fig. 10, whereas in the case of Fig. 11 it occurs at zero degrees. Since the fundamental has advanced 18 electrical deg., the maximum of the 6th harmonic should be at minus

TABLE II

	Fundamental 1st. Position		*Fundamental 2d. Position	
N	Sine	Cosine	Sine	Cosine
1	+ 93.8	0	94.1	0
2	0	− 1.1		
4	− 16.5	0	− 1.0	− 15.1
5	0	− 1.7		
6	+ 16.2	0	0	+ 16
8	0	− .8	0	− .7
9	+ 14.0	0	− 13.4	+ .6
10	0	+ .7	− .9	− .6
11	− 13.7	+ 1.1	+ 13.6	− .8
12	0	+ .8	− .6	0
14	− 10.7	− .8	+ .8	+ 10.3
15	0	0	0	+ 1.1
16	+ 10.7	− .7	− 2.0	− 10.3
17	+ .5	0	0	0
18	0	0	0	− 2.9
19	+ 7.3	0	7.5	0
20	0	0	+ .9	0

*In the second position the fundamental has moved to the right 18 electrical deg.

3 deg. on Fig. 11 if the 6th harmonic did not move at all, that is, if the 6th harmonic were stationary in space. Since the maximum of the 6th harmonic on Fig. 11 actually occurs at zero degrees, it has advanced 3 deg. with the fundamental.

Therefore, since we have assumed the fundamental to have clockwise rotation, the 4th harmonic will

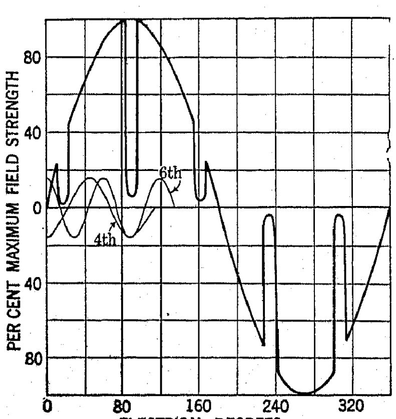

FIG. 11

rotate counter clockwise and the 6th harmonic will rotate clockwise.

The results of this graphical-analytical analysis shows that tooth harmonics are inherent and that tooth cusps are to be expected and that the tooth harmonics are of the order of an integer multiplied by the number of slots then increased and decreased by one.

After completing this investigation it occurred to the author that there ought to be a purely mathematical proof of this fact

$$\text{Order of Harmonics} = k\,n \pm 1$$

which could be obtained by a development of the series representing a rectangular wave to obtain the effect of slot openings.

This could be done by putting in place of α in

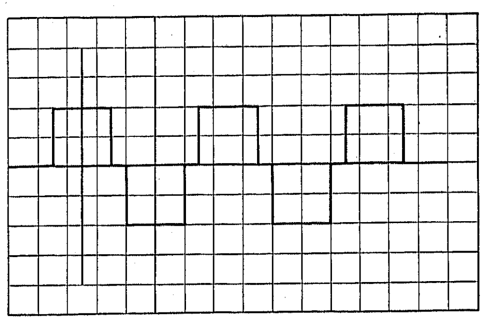

FIG. 12

Fourier's Series of the rectangular wave α plus θ and α minus θ and then adding like terms of the two series. This gives a wave as shown in Fig. 12, which can be changed to approach the form of the reciprocal wave shown in Fig. 5 by squaring the series representing this wave (Fig. 12) which gives the wave shown in Fig. 13 and which, it will be noted, is quite similar to Fig. 5. The difference between Fig. 5 and Fig. 13 is due to the

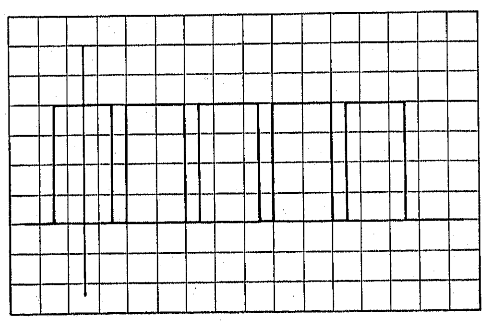

FIG. 13

fringing taken into consideration in the case of Fig. 5 which is the practical case. It will also be noted that the flux does not reduce to zero as in the case of mathematical demonstration. This difference between the mathematical case and the actual case would not affect this problem from a practical point of view.

This method of attacking the problem from a mathematical standpoint was proposed to Professor F. W. Lee, and his mathematical analysis follows in Part II of the complete paper.

Part II

While the performance of the induction motor has been discussed by Arnold, Karapetoff and Hansen[1] primarily from the point of view of the stator, little has been said upon the equally important modifications caused by the rotor. Arnold, Fritze[2], Stiel u. Ottenstein[3] have done some work upon the effect of the rotor slots in an induction motor. Now it is the purpose of this part of the paper to derive in a simple way the relations modifying the flux distribution caused by the rotor. In this exposition only the fundamental component of the static flux will be considered, since in a trapezoidal wave, under the most favorable conditions, the third harmonic is but 1/9 of the amplitude of the first, the fifth 1/25 and so forth.

From a mathematical viewpoint the flux distribution,

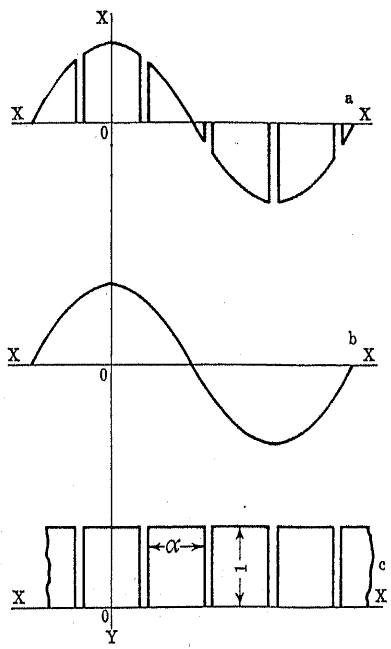

FIG. 14

as shown in a of Fig. 14, can be obtained by the product of the two curves shown in b and c.

The function of b can be considered as that of a simple cosine of unit amplitude where x is measured in electrical degrees.

$$y = \cos x \quad (1)$$

The function of c may be considered as a composite function having a rectangular Fourier series as a basis. In the previous consideration there were five fingers as indicated, and here it will be desirable to express this composite function c in terms of the angle as measured in b. For a simple rectangular wave of unit amplitude it would be

$$y = 4/\pi\,[\sin (5/2)\,x + 1/3 \sin (15/2)\,x + \text{etc.}] \quad (2)$$

1. Hansen, A. I. E. E., December 1922.
2. Fritze, Archiv für Electrotechnik, 1922.
3. Stiel u. Ottenstein, E. T. Z., 1919, page 590.

Because of symmetry it is best to choose the Y axis for this development as is shown in Fig. 15, part a, where y_1 expresses the rectangular wave of height $h/2$, and α is the tooth width in electrical degrees.

$$y_1 = (1/2)\,h\,4/\pi\,[\sin (5/2)\,(x - \alpha) + \ldots 1/n \sin^n (5/2)\,(x - \alpha)\,] \quad (3)$$

In b of Fig. 15, the same series is represented as in a except that it is displaced by $\alpha/2$ degrees to the left. Here y_2 expresses the rectangular wave

$$y_2 = (1/2)\,h\,4/\pi\,[\sin (5/2)\,(x + \alpha) + \ldots 1/n \sin^n (5/2)\,(x + \alpha)\,] \quad (4)$$

In both of these equations, n is always odd.

By subtracting the two series as is seen in c of Fig. 15, a curve is obtained which is represented by the relation.

$$\begin{aligned} y_2 - y_1 &= (1/2)\,h 4/\pi\,[\sin (5/2)\,(x + \alpha) - \sin (5/2)\,(x - \alpha) \\ &\quad + \ldots 1/n\,\{\sin (5/2)\,n\,(x + \alpha) - \sin (5/2)\,n\,(x - \alpha)\}\,] \\ &= h\,4/\pi\,[\sin 5/2\,\alpha \cos 5/2\,x \\ &\quad + \ldots 1/n \sin (5/2)\,n\,\alpha \cos (5/2)\,n\,x] \end{aligned} \quad (5)$$

If this function is squared and h is chosen unity as per part d of Fig. 15

$$(y_2 - y_1)^2 = (16/\pi^2)\,\Sigma\,\Sigma\,\frac{2}{m\,n} \cos (5/2)\,m\,x \cos (5/2)\,n\,x \sin (5/2)\,m\,x \sin (5/2)\,n\,x \quad (6)$$

This is a double manifold series, in which n has all odd values from 1 to ∞ and for each of these values of n, m has all odd values and is restricted only by the condition that $m \lesseqgtr n$.

For ease in computation of the constants, it may be expanded as the cosine function of the sum and difference of integer angles.

$$\begin{aligned} (y_2 - y_1)^2 &= (16/\pi^2)\,[\Sigma\,\Sigma\,\frac{1}{m\,n} \sin (5/2)\,n\,\alpha \sin (5/2)\,m\,\alpha\,(\cos (m + n)\,(5/2)\,x + \cos (n - m)\,(5/2)\,x)\,] \\ &= 16/\pi_2\,[A_1^1 \cos 5\,x + A_2^1 \cos 10\,x + A_3^1 \cos 15\,x + \text{etc.} \end{aligned} \quad (7)$$

By substituting values for m and n and remembering that $n - m$ is always 0 or positive, the coefficients are computed in the usual manner. Since the sum of m and n is always an even number and the difference is also always an even number, one-half of these values will give odd and even harmonics.

From the above, the coefficients enter as sine functions of odd multiples of 5/2. If now $5/2\,\alpha = 180$ electrical deg. were chosen, it would be possible to eliminate all of these coefficients. In the above case $\alpha = 2/5$ of $180 = 72$ deg. which is impossible, since it leaves no slot opening.

This indicates that from this point of view the slots should be as small as possible. However, a specific harmonic may be eliminated in the above case by choosing $5/2\,n\,\alpha = 180$, making $n\,\alpha = 72$ deg. For example, the third harmonic would make $\alpha = 24$ deg. thereby leaving a slot opening of

$$\frac{360 \text{ deg.} - 5 \times 24 \text{ deg.}}{5} = 48 \text{ deg.}$$

This would be impracticable because of the high saturation required in the teeth. It should be stated here that the starting winding which is displaced 90 deg. from the running winding will eliminate one half of the even harmonics in starting a single-phase motor where the even harmonic divided by two is odd. The respective odd harmonics on the other hand will have a cumulative action.

The function $(y_2 - y_1)^2$ may be further simplified by introducing

$$A_1 = A_1{}^1 \times 16/\pi^2,\ A_2 = A_2{}^1 \times 16/\pi^2 \text{ etc.}$$

$$(y_2 - y_1{}^2) = A_1 \cos 5\,x + A_2 \cos 10\,x + A_3 \cos 15\,x + \text{etc.} \quad (8)$$

If the flux distribution in the air gap of a machine is a simple cosine function as

$\Phi = \Phi_{max} \cos x$, if no slots were present in rotor (9)

Φ_{max} is expressed as flux per radian.

Then the resultant flux is given by

$$\Phi = \Phi_{max}\,(y_2 - y_1)^2 \cos x, \text{ if slots are present in rotor}$$
$$= \Phi_{max}\,[A_1 \cos 5\,x \cos x + A_2 \cos 10\,x \cos x + \text{etc.} \quad (10)$$

In general for k slots per 360 electrical degrees.

$$\Phi = \Phi_{max}\,[A_1 \cos k\,x \cos x + A_2 \cos 2\,k\,x \cos x + \ldots A_n \cos n\,k\,x \cos x]$$
$$= 1/2\,\Phi_{max}\,[A_1 \cos (k+1)\,x + A_1 \cos (k-1)\,x + \ldots A_n \cos (n\,k+1)\,x + A_n \cos (n\,k-1)\,x\,] \quad (11)$$

where $n = 1, 2, 3$, etc. This proves that the harmonics existing in the resultant wave are given by the relation

$$\text{Order of Harmonics} = k\,n \pm 1 \quad (12)$$

This was demonstrated by C. A. M. Weber in the first part of this paper from direct measurements of a rotor.

The above relations should be modified since the flux in the tooth slots does not reach zero but has a value $\delta\,\Phi_{max}$ as a minimum. This is shown by Fig. 16 where δ is a percentage of the flux under consideration. The flux modified by the rotor teeth is $\beta\,\Phi_{max}$. Here β is the percentage left after α has been deducted, or $\alpha + \beta = 100$ per cent. By skewing the rotor β becomes small and δ large.

With this premise the resultant flux wave in a motor is given by

$$\Phi = [\phi_{max}\,\delta + \phi_{max}\,\beta\,(y_2 - y_1)^2\,] \cos x \quad (13)$$

The modifying factor now has the curve as indicated in Fig. 17.

In a single-phase induction motor the flux varies harmonically with the time, and the equation (13) reduces to the relation

$$\Phi = [\phi_{max}\,\delta + \phi_{max}\,\beta\,(y_2 - y_1)^2\,] \cos x \cos \omega_1 t \quad (14)$$

Where ω_1 = angular velocity in electrical degrees of the supply.

If there is another winding 90 deg. displaced in space and having currents 90 deg. displaced in time the flux distribution of this winding will be given by the relation

$$\Phi = [\phi_{max}\delta + \phi_{max}\,\beta\,(y_2 - y_1)^2] \cos (x + 90) \cos(\omega_1 t + 90) = [\phi_{max}\,\delta + \phi_{max}\,\beta\,(y_2 - y_1)^2] \sin x \sin \omega_1 t \quad (15)$$

This may represent a two-phase motor or a single-phase motor with a starter winding. It is primarily the object to discuss the reaction of one winding; other windings may be added as indicated in equation (15).

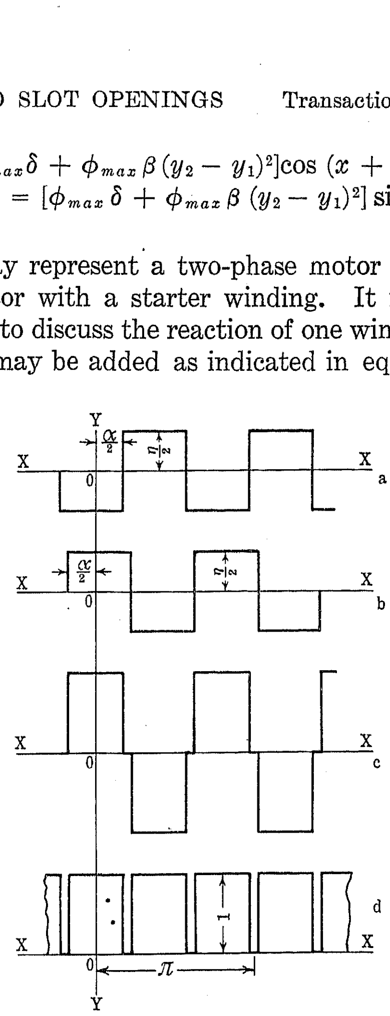

FIG. 15

Equation (14) may be expanded by introducing the sum and difference of two angles

$$\Phi = \underbrace{\phi_{max}/2\,\delta \cos (x + \omega_1 t) + \phi_{max}/2\,\delta \cos (x - \omega_1 t)}_{\text{Usual induction motor}}$$

$$\underbrace{+ (1/2)\ \phi_{max}\,\beta\,[\sum_{n=n}^{n=1} A_n \cos (n\,k+1)\,x \cos \omega_1 t + \sum_{n=n}^{n=1} A_n \cos (n\,k-1) \cos \omega_1 t]}_{\text{Modifying Factors}} \quad (16)$$

As the usual induction motor equations involve no special consideration, only the modifying factors remain

$$\sum_{n=m}^{n=1} A_n \cos (n\,k+1)\,x \cos \omega_1 t = \Sigma\,1/2\,[A_n \cos \{\,(n\,k+1)\,x + \omega_1 t\} + A_n \cos \{\,(n\,k+1)\,x - \omega_1 t\}\,]$$
$$\sum_{n=m}^{n=1} A_n \cos (n\,k-1)\,x \cos \omega_1 t = \Sigma\,(1/2)\,[\,A_n \cos \{(n\,k-1)\,x + \omega_1 t\} + A_n \cos \{(n\,k-1)\,x - \omega_1 t\}\,] \quad (17)$$

This leads to a brief examination of functions having the form

$\cos [\,(n\,k+1) + \omega_1 t]$ which may be written

$$\cos \left(\frac{2\,\pi}{\lambda}\,x + \frac{2\,\pi}{T}\,t \right) \text{ which is a traveling wave} \quad (18)$$

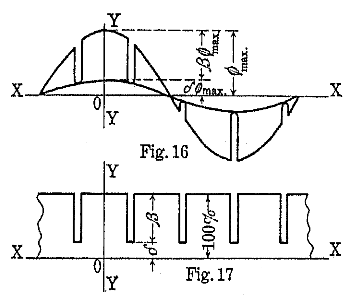
in the circumference of the air gap.

The velocity is given by $\dfrac{\dfrac{2\pi}{T}}{\dfrac{2\pi}{\lambda}} = \lambda/T$ and in the modifying factor there are the following modifying revolving fields having velocities

$$\frac{\omega_1}{n\,k+1} \text{ and } \frac{\omega_1}{n\,k-1}$$

$$-\frac{\omega_1}{n\,k+1} \text{ and } -\frac{\omega_1}{n\,k-1} \qquad (19)$$

This interpreted, means that there is a revolving flux in both directions having velocities $\dfrac{\omega_1}{n\,k+1}$ and $\dfrac{\omega_1}{n\,k-1}$ when the motor is at standstill or starting.



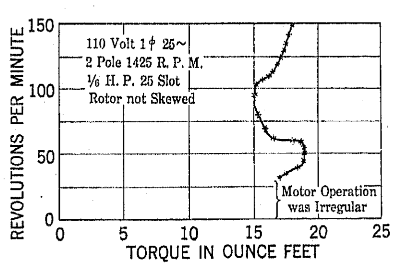


FIG. 16

Since each is exactly equal and opposite there is no tendency to start in either direction.

If the rotor rotates, the modifying function

$$(y_2 - y_1)^2 = A_1 \cos 5\,x + A_2 \cos 10\,x + A_3 \cos 15\,x \ldots A_n \cos n\,k\,x$$

rotates with it. If the angular velocity is ω_2 in electrical degrees, then this fact may be expressed in the form

$$(y_2 - y_1)^2 = A_1 \cos 5\,(x - \omega_2\,t) + A_2 \cos 10\,(x - \omega_2\,t) + \ldots A_n \cos k\,n\,(x - \omega_2\,t) \qquad (20)$$

Notice that each harmonic must have an angular velocity ω_2. The equation for the modified flux becomes

$$\sum_{n=n}^{n=1} A_n \{\cos n\,k\,(x - \omega_2\,t) \cos x \cos \omega_1\,t\} =$$
$$\sum_{n=n}^{n=1} (1/2)\,[A_n \cos \{\,(n\,k+1)\,x - n\,k\,\omega_2\,t\} \cos \omega_1\,t] +$$
$$\sum_{n=n}^{n=1} (1/2)\,[A_n \cos \{\,(n\,k-1)\,x - n\,k\,\omega_2\,t\} \cos \omega_1\,t] =$$
$$\sum_{n=n}^{n=1} (1/4)\,[A_n \cos \{\,(n\,k+1)\,x - (n\,k\,\omega_2 + \omega_1)\,t\,] +$$
$$\sum_{n=n}^{n=1} (1/4)\,[A_n \cos \{\,(n\,k+1)\,x - (n\,k\,\omega_2 - \omega_1)\,t\,] +$$
$$\sum_{n=n}^{n=1} (1/4)\,[A_n \cos \{\,(n\,k-1)\,x - (n\,k\,\omega_2 + \omega_1)\,t] +$$
$$\sum_{n=n}^{n=1} (1/4)\,[A_n \cos \{\,(n\,k-1)\,x - (n\,k\,\omega_2 - \omega_1)\,t\,]. \qquad (21)$$

Equation (21) indicates that there are for each harmonic four distinct flux waves in an induction motor. The angular velocity of these waves is

$$\left.\begin{array}{c} \dfrac{n\,k\,\omega_2 + \omega_1}{n\,k+1} \\[2ex] \dfrac{n\,k\,\omega_2 + \omega_1}{n\,k-1} \end{array}\right\} \text{ in direction of rotation} \qquad (22)$$

$$\left.\begin{array}{c} \dfrac{\omega_1 - n\,k\,\omega_2}{n\,k+1} \\[2ex] \dfrac{\omega_1 - n\,k\,\omega_2}{n\,k-1} \end{array}\right\} \text{ in opposition to rotation} \qquad (22)$$

These flux waves induce their respective voltages, and the currents due to these voltages will have torque components proportional to the cosine of the angle between the induced voltage and the current. Since the secondary reactance of a single-phase motor is high, the frequency of the currents induced by the flux in the direction of rotation is also high. The torque added because of these may be considered negligible because of the large-phase angle. The direction of these waves is always the same, irrespective of ω_2.

The last two flux waves in equation (22) are of low frequency except at the condition of starting when $\omega_2 = 0$. As soon as $n\,k\,\omega_2$ has an appreciable value relative to ω_1 the frequency rapidly decreases and the torque component of the current becomes greater until $\omega_1 = n\,k\,\omega_2$. Here the torque for this harmonic is zero because there is no induced voltage. After that the torque reverses, since the direction of the rotating flux reverses. As ω_2 becomes larger, the frequency becomes higher and after a short-speed interval its frequency will be too high to be effective for producing torque. From the equation (22) it is seen that this phenomenon usually takes place at relatively very low speeds. A typical curve which was known to be unfavorable is shown in Fig. 18, which was taken by C. A. M. Weber.

Discussion

L. P. Ferris: The paper by Messrs. Weber and Lee shows that, from the point of view of the power company, or power user, there is some advantage in the elimination of the higher harmonics which, as you all know, have a detrimental effect upon neighboring communication circuits under some conditions of association.

Some years ago, in connection with the work of the Institute Standards Committee, an effort was made to determine what effect these harmonics might have from the standpoint of the power user. This did not arouse much interest, and I have no doubt that the problem is not of large magnitude from the power man's standpoint. But it is interesting to find that, under some conditions, these harmonics—even the slot harmonics—do produce effects which it is worth while, to get rid of from this standpoint. This gives an additional incentive to the designers for a high degree of purity of wave form.

This paper comes at a time when there is being instituted a joint research, looking toward the determination of ways and means whereby the effect of harmonics may be determined and an examination made as to the practicability of improving the wave shape of machines. The manufacturers and the power companies are joining with the telephone engineers in this work, and I hope that the methods of analysis given in this paper may lend themselves to this study, in the direction of making it easier to find ways and means of improving the wave shape I have no doubt that the designers are alive to this question.

22,000-kv-a. Transformers for Niagara Falls Development

BY F. F. BRAND
Member, A. I. E. E.
General Electric Co., Pittsfield, Mass.

During the past year the Niagara Falls Power Company has put into service the first unit of an extension which will contain the three largest water wheels and generators at present in the world, each generator having a maximum rating of 65,000 kv-a. at 12,000 volts and 25 cycles.

The limited width of the right-of-way from generating station, actually only the space over an existing intake canal, necessitated stepping up to 66,000 volts to transmit 195,000 kv-a. from the complete extension.

Transformers were therefore installed on an extension of the forebay wall. These are single-phase oil-immersed water-cooled 22,000-kv-a. connected delta on the 12,000-volt side and in Y on the 39,500-volt side to give 68,500 Y.

The principal interest in these transformers is, of course, in their large size and in the construction used to obtain high efficiency. The only single-phase transformers which exceed these in output are some 60-cycle 23,600-kv-a. units of the Duquesne Light & Power Co., Pittsburg, but since the Niagara transformers are 25 cycles, the parts, if used for a 60-cycle design, would give far greater output than any existing transformers.

In these transformers it was desired to obtain the maximum efficiency at ⅞ full load, at which point the transformers would probably be loaded most of the time, as it corresponded to maximum water-wheel efficiency.

With the maximum permissible magnetic density in present-day silicon steel, to keep the magnetizing current and core temperature within reasonable limits, the loss at 25 cycles in the steel is about 1 watt per pound, while the loss in the copper in the winding is from 8 to 16 watts per pound. To obtain highest efficiency at ⅞ load it was necessary to use fewer turns and a correspondingly greater core section than would ordinarily be used and this accounts for the type of core construction used, *i. e.*, with the winding on the central leg of the core.

To meet certain specified conditions of line regulation, it was necessary that the product of per cent magnetizing current and impedance should not exceed a certain constant value. This naturally resulted in a design being used giving the minimum effective area of the leakage flux path between high-tension and low-tension windings. The spacing between high-tension and low-tension windings is ordinarily that required for insulating these windings from one another, and this distance and a fractional part of the coils themselves constitute the effective width of the leakage flux path. The magneto mechanical forces between high-tension and low-tension windings in 25-cycle transformers are usually higher than for higher frequencies. A design having a very large core area and flux and minimum area of leakage flux path would therefore be subject to higher magneto mechanical forces, both at normal load and under short-circuit conditions.

This can readily be understood when we consider that the mechanical force varies as the square of the leakage flux density between high-tension and low-tension windings and that with concentric windings the area of the leakage flux path varies as the diameter, whereas the area of the core varies as the square of its diameter, and that under short circuit conditions with sustained voltage the whole of the flux ordinarily in the core must pass between the high-tension and low-tension windings. The magneto mechanical forces would, therefore, vary approximately as the square of the core diameter.

The type of construction used is that known as th

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

concentric circular coil type, in which the low-voltage winding consists of a single circular helix, adjacent to the central core member, and the high-voltage winding a series of circular disc coils arranged in cylindrical assembly outside of and concentric with the low-voltage winding.

In this type of winding the principal magneto mechanical forces between high-tension and low-tension windings are radial. The circular coil is self-sustaining

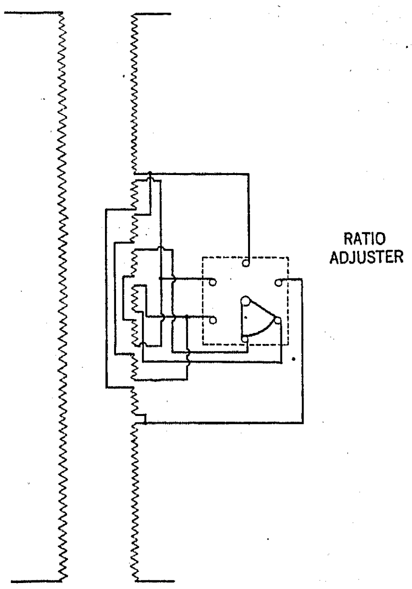

FIG. 1

against such forces, provided their value is not sufficient to exceed the elastic limit of the copper or insulation in tension or compression. If these values are not exceeded, it is only the unbalanced forces, due to the coils being assembled with the magnetic centers not co-incident, that must be considered seriously, as the coils are not self-sustaining against such axial forces.

The usual method is to provide bracing against the axial force, calculated by assuming certain definite but very conservative axial displacement of the coils to allow for variations in assembly and to add to this any displacement caused by taps which are taken off center.

To reduce the axial short-circuit forces as much as possible, the tap coils were so connected that an equal number of turns were tapped out each side of the center of the coil stack as shown in Fig. 1. Thus, the forces could only be those due to variations in assembly, which are quite small. The design calculations were based on an arbitrary displacement much greater than would be expected in practise.

Due to the self sustaining feature of circular coils against radial forces and the easy provision of bracing against axial forces, the circular-coil type of transformer can be readily designed to resist short circuit forces in all directions. In this it differs from types of transformers with non-circular coils, in which the coils tend to assume a circular shape during short circuits and which are difficult to brace against such coil distortion. In fact, this problem is so difficult that the forces, due to dissymmetry of the coils or variations in assembly, are usually neglected and no adequate bracing used to prevent distortion of this kind.

Each bank of three transformers is connected directly to one generator, so that for short circuits on the high-voltage side the generator reactance would be effective in limiting the short-circuit current to a lower value than that which would flow, if the transformer reactance alone were the limiting feature. In case of a short circuit on the low-voltage side, which is rather a remote possibility, power would be fed back from the rest of the system and the short-circuit current would be higher. To sustain the voltage under a short circuit would require a power flow of 660,000 kv-a. through one transformer bank having 10 per cent reactance.

The present system is not large enough to cause this power flow, as the voltage would fall and the short-circuit power flow be less. Conditions are, however, changing rapidly, power systems growing and it is not

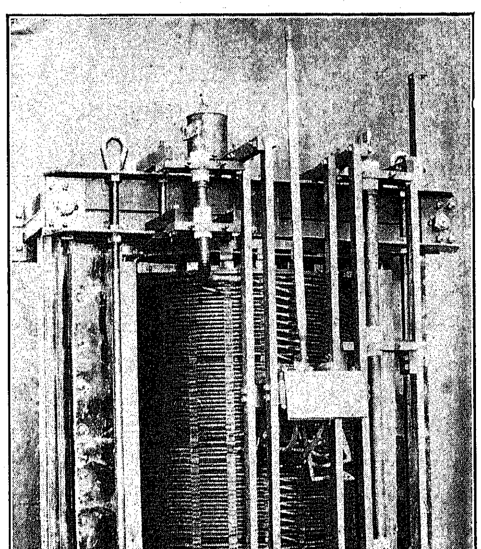

FIG. 2

good engineering to consider existing conditions as giving the limiting conditions to be met in the expected life of the transformer. No allowance, therefore, was made for any external reactance in the short-circuit calculation, the transformer being designed to withstand short circuit with fully sustained voltage.

In building transformers to stand short circuits, it is essential to consider the tremendous vibration of the

coils set up by the magneto mechanical forces, especially at 25 cycles. Tests made at Schenectady on the special short-circuit generator have shown the absolute necessity of designing the coil bracing, particularly the coil spacers, so that they will not fall out of place and thus out of alignment with each other.

A description of the spacing arrangements may therefore, be of interest. The essentials of coil bracing are:

1. To support every turn at such intervals that the short-circuit forces will not exceed the tension of compression limits on the conductor and insulation.

2. To support the turns in such a manner that a minimum amount of conductor is covered in the direction of heat flow, otherwise, the conductor covered by the spacers may heat up so much that the insulation may be damaged or the tensile strength decreased long before the conductors exposed to the cooling medium reach such limits.

3. To lock every spacer in place securely against movement by vibration.

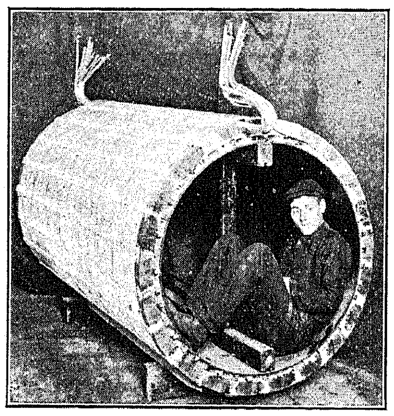

Fig. 3

4. To arrange the spacers so that they are easily inspected during and after the coils are assembled.

The coil spacers in these circular coil transformers and in others, built by the same manufacturer, are arranged radially across the face of the disc coils and the turns of the helical coils. This provides support for all conductors at approximately equal intervals.

Since the spacers are relatively narrow, two in. (5 cm.) wide as a maximum, the maximum distance of heat flow from that part of the conductor, covered by a spacer to the cooling oil, is one inch. This precludes a great difference of temperature between the part of the conductors covered by the spacers and that exposed to the oil.

The spacers between turns on the low voltage helical coil are radial. They are dovetailed onto spacers arranged axially inside the coil, which are mounted on the insulating cylinder between coil and core on which the coil is wound. The axial spacers provide a definite oil duct in a vertical direction inside the coil.

The radial spacers project out beyond the turns and are covered and held in alinment by channel pieces extending axially the complete length of the coil. The spacer extension, beyond the coil and the covering channels, provides an oil duct outside the coil.

The insulating cylinder between high voltage and low voltage is slipped over the projecting spacers and their channel pieces.

The high-voltage coil spacers are also arranged radially. Each one consists of a hair-pin type spacer placed around each coil with the open ends projecting outside the coil. It is formed of a number of parts all locked together, with the base serving to space the coil from the cylinder over which it is assembled.

The spacing of coils from cylinders is such as to provide the necessary extension of insulating diaphragms, placed between each coil to prevent creepage between adjacent coils.

The number of radial spacers in high and low-voltage coils is proportioned to the short-circuit stresses and the strength of the conductors and insulation.

The bracing against axial short-circuit forces of the low-voltage coil consists of a complete ring of bakelized insulating material of the same diameter as the coil, which abuts against the structural steel end clamps at each core yoke.

For the high-voltage coil stack similar rings are used, but in this case fibrous material is not solely depended upon. Engaging with the bakelized end rings at each end of the coil stack are square porcelain blocks, one for each line of spacers. These blocks have holes through them to contain a porcelain locking-pin, which enters the bakelized ring and into bakelized segments, placed between the porcelain blocks and the metal clamps. Adjustment of the clamps is provided by sliding one angle member on the other parts of the clamps, the pressure being maintained by adjustable studs on each clamp and tie rods between the top and bottom clamps. Adjustment in the core window is by means of a bakelized wedge.

The practise is followed in these transformers of bolting the core laminations together rigidly with re-enforcing plates on the outside of the built-up core leg and punching a large square notch at the end of each outer core leg. This notch holds an insulated square bolt which engages with the clamps and thus the core serves also as a tie rod to withstand a part of the short-circuit stresses.

INSULATION

In such moderate-voltage transformers the problem of insulating between winding or to ground is not at all difficult. The concentric-winding transformer, of course, lends itself to simplicity of insulation more than any other type. The insulation consists of cylinders of paper, treated with gums and rolled under pressure and at high temperature, forming a dense tough material which has high mechanical strength and a very high dielectric strength, both hot and cold.

These cylinders are arranged with suitable oil spaces to form the complete insulation from low voltage to core and from high to low voltage. The insulation of the high-voltage coil stack to the outer core legs consists of sheet insulation with oil spaces. The insulation from the ends of the coil stack has been described under the bracing for short circuit forces.

To reduce the potential gradient on the end high-voltage coil an electrostatic shield, connected to the line terminal of the end, is used between this coil and the core yoke. This shield and the end coil are taped to reduce the potential gradient on the oil surface and to reduce the danger from creepage to the core.

The insulation on the high-voltage conductors consists of a number of thin treated-paper tapes, having extremely high dielectric strength, and it is graded at the end coils so that the end coil will withstand line voltage between turns momentarily. This is for protection against transient voltages. The electrostatic shield connected to the line terminal modifies the distribution of transient voltages in the coil stack and reduces the concentration of voltage on the end coil to from one-quarter to one-third the value it might otherwise attain under conditions of impact of an almost vertically-fronted wave at the transformer terminals.

The electrostatic shields consist of metallic ribbons of high-resistance, wound on an insulating form of slightly less radial width than the adjacent coil. They are taped to give the same insulated radial width. The method of winding is non-inductive to the flow of the capacitance charging current. High-resistance material is used to avoid appreciable eddy-current loss in the shields, due to the high density of the leakage flux between windings.

Between each high-voltage coil is a pressboard diaphragm with an oil space between it and the coils, as protection against transient voltages. The oil spaces alone are much more than necessary to withstand the normal voltage existing between coils, due to the large number of coils and the few turns in each coil.

The pressboard diaphragm is used instead of merely increasing the oil space, due to the greater energy required to puncture such solid insulation or the time lag of the insulation against puncture by transient voltages.

The taping on electrostatic shield and line coils is additional protection against breakdown between them or the adjacent coils, due to high transient voltages, in addition to the heavier turn insulation on end coils.

The dielectric strength for one minute at normal frequency is equal to approximately line voltage between coils. Under transient stress it is much higher. Between end coils, due to the extra taping, it is much higher yet.

In the low-voltage helical winding the insulation on the conductors is principally to prevent eddy currents between the strands in parallel. The oil space between each turn serves, of course, as a cooling duct and for insulation between turns.

Cooling Arrangements

Special care was used in designing the core to arrange that all surfaces were exposed to the cooling oil. The central core leg is divided into two distinct flux paths with a large duct between them, in addition to which, there are a number of cooling ducts distributed throughout the laminations. The clamps are separated from the core by large ducts to allow the cooling oil access to all surfaces of the core yokes.

The oil for cooling the low-voltage coil is free to pass through these ducts between clamps and core yoke and to pass between the porcelain blocks used to support the high-voltage winding.

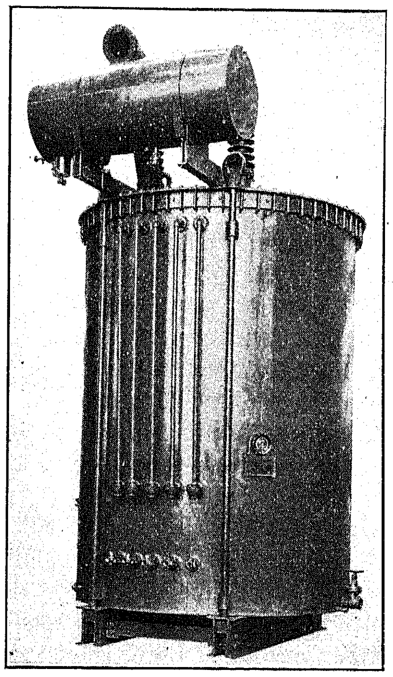

Fig. 4

The high-voltage winding is exposed directly to the oil in the tank. All coils have an oil duct on both sides and the inside edge. To provide uniform distribution between conductors in parallel, the position of these conductors is transposed. The arrangement of the tap coils in the high-voltage winding is such that this transposition is effective in them.

Due to the large number of conductors in parallel in the low-voltage winding and to the space taken up by the transpositions, it is not possible to obtain perfect equalization of current in all the strands in parallel. This fact is recognized and the average temperature rise of the low-voltage coil, as measured by resistance, is made lower than that of the high-voltage coil so that no strands will exceed the guaranteed temperature rise.

The high-voltage windings were designed to give

full kv-a. capacity continuously at any voltage from 36,000/62,300 Y to 39,500/68,500 Y, without exceeding the guaranteed temperature rise of 55 deg. cent. The rated high-voltage current was thus 611 amperes. The low-voltage winding was designed to carry a current corresponding to 611 amperes on the high voltage on any high voltage connection up to 37,600/65,120. Its rated current was therefore 1915 amperes. At 37,600/65,120 Y-volts the transformer kv-a. rating is therefore really 23,000 kv-a. The transformers are also designed to withstand 13,200 volts impressed on the 12,000-volt winding at full load.

Since the dielectric strength of fibrous insulation decreases with increasing temperature, and it is desired to obtain the maximum dielectric strength between end turns and coils, it is essential that these end coils do not attain a higher temperature than the remainder of the windings.

The cross section of the conductors in the more heavily insulated end coils of the high-voltage winding is much greater than that used in the remainder of the winding, to allow for the increased thermal drop through the extra insulation. Actually the end coils are cooler than the remaining coils.

The temperature rises of a large number of points in the coil, core and clamping structure were calculated and these calculations checked during test by insertion of thermo couples, wherever possible. These tests demonstrated that this type of design is very satisfactory for very large transformers from a thermal standpoint, as well as from a consideration of ability to resist short circuit stresses and to give great insulation strength.

It was mentioned in the early part of this paper that the design was required to give high efficiency at ⅞ full load. Actually, the efficiency at ¾ and ½ load was found to be slightly higher, as the loss per pound in the core was appreciably lower than the calculated value.

The efficiencies at various loads, based on losses measured by wattmeter at 75 deg. cent. are as follows:

Full load	99.041
7/8 full load	99.083
3/4 " "	99.11
1/2 " "	99.09
1/4 " "	98.67

The average magnetizing current at normal voltage is 2.59 per cent.

The high-voltage taps are connected to a ratio adjuster, operated from an operating handle through an oil tight stuffing box on the cover.

An interesting fact about the construction is the almost complete use of rolled steel. The tank is of cylindrical shape, of steel plate with welded seams with a flat bottom welded in place. It rests upon a structural steel truck with wheels, so that it can be rolled on a standard-gage track. The cast-steel wheels and the manhole covers are the only castings of ferrous metal. The tank cover is a pressed steel plate, with flanges for mounting of bushings, etc., extruded from it.

A cylindrical oil-conservator tank is supported from the tank cover by steel angle supports. The pressure-relief pipe is of welded steel construction and carries a relief diaphragm of glass at its upper end, designed to rupture if the pressure in the tank reaches 10 lb. per square inch.

The dimensions and weights of the transformers are as follows:

Height over Bushings	20 ft. 1 5/16 in.
Height over Oil Conservator	16 ft. 11 5/8 in.
Height over Cover	15 ft. 7/16 in.
Inside Diameter of Tank	120 in.
Floor Space over Fittings	12 ft. 10 1/4 in. by 11 ft.
Gallons of Oil	5675
Weight Complete, less Oil	117,800 lb.
Weight of Core and Coils, etc., to be Lifted from Tank	99,000 lb.
Weight of Oil	41,200 lb.
Complete Weight Oil filled	159,000 lb.

Notes on Mine Hoisting

BY F. L. STONE and F. R. GRANT
Associate, A. I. E. E. Non-Member
Both of General Electric Co., Schenectady, N. Y.

ELECTRICALLY driven mine hoists have at last come into their own. For many years manufacturers labored with prospective buyers with little results. Long and laborious calculations were made, ratings determined with great accuracy, detailed specifications drawn and presented to the customer. He usually purchased a steam hoist. The good judgment of such a decision could hardly be questioned. The steam hoists had given good and dependable service for many years. The electric hoist was a new and untried device. Power lines were not as reliable as they are today. The mine shaft is the neck of the bottle and once this becomes plugged from any cause whatsoever, the output stops and the usual trouble ensues. Operators felt they had trouble enough with most shafts and would not consider a propositon, which to them seemed to have great possibilities for trouble, the remedying of which was beyond their control.

Some small electric hoists, however, were installed inside on comparatively unimportant slopes and considering the type of equipment, gave a very good account of themselves.

These hoists were equipped with series motors usually of the railway type. The control was very crude but fairly rugged. The first electric mine hoist of which there is any record was installed at Aspen, Colorado in July, 1888 and in 1895 at the same mine a 100-kw. generator was put on a hoist and run as a motor, this equipment being (so far as can be learned) the largest of its kind in this country and perhaps in the world.

Up to the year of 1910, there are records of the installing of only a few equipments of larger than 200 horse power for mine hoists. Following the year of 1910, the sales of electric mine hoists have had a very steady and healthy growth.

Many interesting and instructive papers have been published on the calculation of mine-hoist cycles. The general method of attack is the same; *i. e.* moments of the up and down loads per turn plotted and net moments or torque derived from the algebraic sum of these moments. The friction (assumed) and the acceleration and retardation moments are added with their respective signs and the final summation moment curve changed into horse power by substitution in the well known formula: horse power $= \frac{2 \times \pi \times \text{r.p.s.}}{550} \times M$

It is not by any means the object of this short paper to enter into calculations of the cycle, but rather to show some results that have been obtained from actual installations which have been designed to meet such calculated cycles.

Many records are obtainable where the kilowatt hours per trip have checked accurately with the estimate figure given by the electric manufacturer at the time of sale. It is often very difficult to get data wherewith to check this figure as many hoists are run for other purposes than hoisting ore. In coal mines, rock is often hoisted and men and material are handled in the main shaft. So kilowatt hours taken by the hoist include much other work than actually hoisting coal.

The Lehigh Coal & Navigation Company have a water hoist which was installed some years ago. The bucket lifts 30,000 lb. of water per trip through about 865 ft. at a rope speed of 1100 ft. per min. The winder is driven by a 1200-horse power a-c. motor. An accurate record is kept of the number of buckets hoisted and nothing else is handled on this hoist.

Over a year's run, the kilowatt hours per trip on this hoist checked exactly with the figures given by the electric manufacturer, the actual figures on this hoist being 15.5 kw. hr. per trip or 1.2 kw-hr. per 1000 ton ft. This is an exceptionally good figure, better than the average. On short, fast cycles, the kw-hr. per 1000 ton ft. may run as high as 1.9.

Incidentally, it is impossible for the electric manufacturer to give a customer any positive guarantee as to the kilowatt hours per trip or per ton. This figure depends upon a number of conditions beyond the electric manufacturer's control.

The mechanical efficiency of the winding engine proper is somewhat of a guess. The rope and guide friction are variable quantities. In fast hoisting, windage must play a small part at least, and just as the sum of these quantities differs from its assumed value, so will the final result differ from the calculated.

During the last ten or fifteen years, a large number of very fast electric mine hoists have been installed, using the well-known Ward-Leonard control with or without flywheel equalization as the conditions indicate. Many of these hoists have cylindro-conical drums with very steep pitches up the cone. The duty cycles for these equipments have been calculated in the usual manner and have shown in many cases quite excessive acceleration and retardation peaks after the rotating parts had reached full speed, due to the acceleration of the up-load up the cone and the retardation of the down-load down the cone. These peaks many times produce a cycle with very jagged and irregular shape. It was, of course, fully realized that these peaks in actual practise must smooth themselves off because

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

the system, due to the flexibility of the ropes, is far from rigid.

So far as the authors know, no reliable test had ever been taken on a Ward-Leonard control system using very rapid recording instruments, such as an oscillograph so that the actual shape of the duty cycle was more or less a guess, though it was felt that the area could not differ very greatly from the area of the calculated cycle. In view of the absence of such data, it was decided to run a complete test on a fast Ward-Leonard equipment and determine how close the calculated cycle and the actual cycles were checking.

The Old Ben Coal Corporation, of Chicago, have in their Southern-Illinois mines several Ward-Leonard flywheel equipments, some of which are operating on very fast cycles. It was decided that if this Company would permit inconvenience to the extent of making a test on one of their equipments, all the data necessary would be obtained. The matter was taken up with the Old Ben officials and their hearty cooperation was very gratifying, they extending every possible courtesy and assistance in the preparation for the tests. Their No. 18 mine was selected as being a very fair example of fast hoisting.

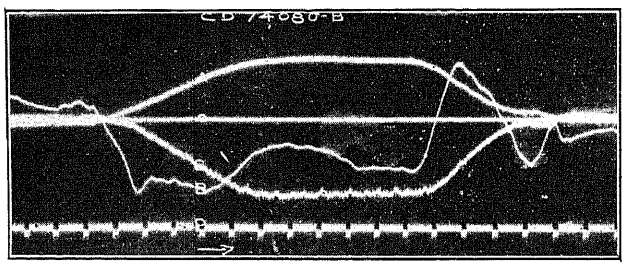

Fig. 1

The equipment at No. 18 Old Ben mine consists of the following:

1 d-c. hoist motor rated 950-horse power 40-deg. 65-rev. per min., 400-volts, direct connected to a cylindro-conical hoist drum having a small diameter of 7 ft. and a large diameter of 11 ft. with four turns up the cone.

1 Flywheel motor-generator set consisting of:

1 750-kw. 900-rev. per min., 400-volt generator

1 700 horse power 900 rev. per min. 2200-volt 3-phase 60-cycle induction motor.

1 19 kw. 900-rev. per min. 250-volt, compound-wound exciter and a steel plate flywheel, 92 in. in diameter, weighing 19,300 lb.

1 Control equipment consisting of:

1 Slip regulator with torque motor for controlling the speed and input to the flywheel set.

1 Drum controller and field rheostat for controlling the speed and direction of rotation of the hoist motor by means of varying the generator voltage.

This equipment was designed to operate under the following conditions:

Weight of coal per trip	10,000 lb.
Total distance hoisted	335 ft.
Weight of cage	15,000 lb.
Type of cage—self dumping	
Weight of mine car (open end type)	4,300 lb.
Rope diameter	1½ in.
Weight of rope per foot	3.55 lb.
Turns on small drum diameter	2.71
Turns up cone	4
Turns on large diameter	4.7
Time for acceleration	5 sec.
Time at full speed	5.5 sec.
Time for retardation	5 sec.
Rest period	4½ sec.
Trips per minute	3

From observation it was found that in adjusting the ropes on the drum, the active turns on the small diameter did not check exactly with the turns originally decided upon, the active turns on the small diameter being found to be 1.9. This, of course, materially affects the shape of the duty cycle, since the rotary acceleration and the acceleration due to climbing the cone would overlap each other slightly. Fig. 6 shows this clearly.

Using the conditions as they exist, a duty cycle was calculated in the usual manner and this cycle compared with the cycles obtained from the test. In addition to the conditions of winding the rope on the drum being slightly different from that originally calculated, the coal loads, as is always the case, differed somewhat from the calculated load in that no particular car during the actual test carried exactly 10,000 lb. of coal. The nearest approach to this, from a long series of tests, was a car containing 9,500 lb. and this value and the number of observed turns as above stated were used in making up the calculated duty cycle for checking the test results. For the purpose of simplicity, this single cycle will be discussed.

During the test, the following readings were taken:

Direct current between hoist motor and generator (oscillograph)

Voltage at motor terminals (oscillograph)

Motor speed in rev. per min. (oscillograph)

Kilowatt input to motor generator set (graphic wattmeter)

Speed of the motor-generator set (graphic volt-meter)

Time in seconds (oscillograph and timer on both graphic charts)

Weight of coal hoisted.

Fig. 1 shows the oscillograph curves as above described. The rev. per min.-curve C in Fig. 1, was obtained by a pilot generator with constant excitation belted to the hoist. The saw-tooth effect shown in this curve is undoubtedly due to the commutator bars passing under the brushes. The current curve B and

the voltage curve A were read directly on the oscillograph in the usual manner.

Fig. 2 shows the input to the motor-generator set during the cycle under discussion.

The speed curve of the motor-generator set for this particular cycle is not available, as the pilot generator belted to the motor generator set gave trouble at this particular moment. Other tests, however, showed that the slip of the motor generator set during the hoisting cycle is slightly less than that originally calculated.

From the above test readings by the application of the proper constants, it is not difficult to make up the actual horse power curve showing the horse power input to the hoist motor. Also as described early in the paper, a duty cycle was calculated, using the turns and weights as they existed. These two curves are plotted and shown in Fig. 3. The dotted line is the calculated duty cycle, and the heavy line the actual test results. more or less smoothed out in actual practise. This undoubtedly is because of the stretch in the rope. The most noticeable variations in the test cycle from the calculated cycle occur during acceleration and retardation. This may be due to quite a number of causes. The drums and rotating parts may be slightly heavier than assumed in the original calculation; and as will be seen from the speed curves, the rate of acceleration changes while the calculated duty cycle assumes a constant rate of acceleration of the rotating parts.

Fig. 4 shows the calculated torque as compared with the torque obtained from test. Here again, we find some slight differences, the most interesting among which is undoubtedly the fact that it takes a very appreciable time for the current to build up to the necessary accelerating value; whereas in the calculations, it is assumed that this current goes instantly

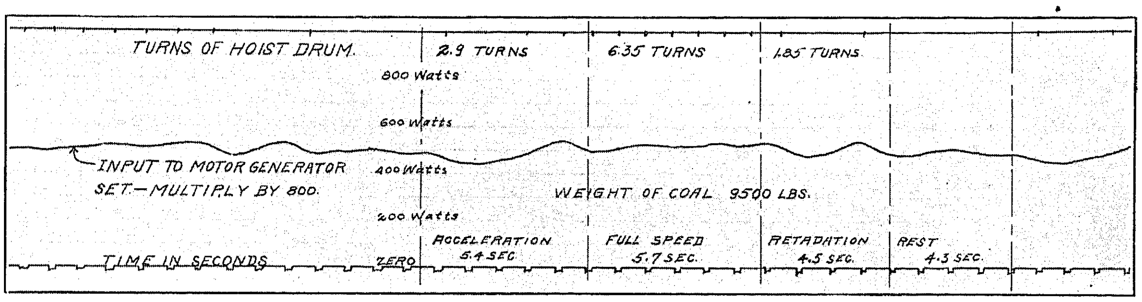

Fig. 2

The areas of the two curves check surprisingly well, the difference being less than 2 per cent.

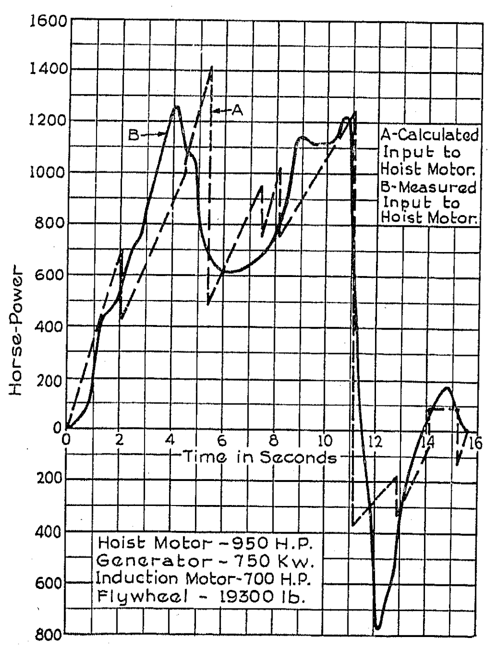

Fig. 3

It is interesting to note how the acceleration and retardation peaks, due to the effect of the cone, are to the value necessary to produce the required torque.

Fig. 5 shows speed curve of drum in rev. per min. against time and also total number of turns of drum

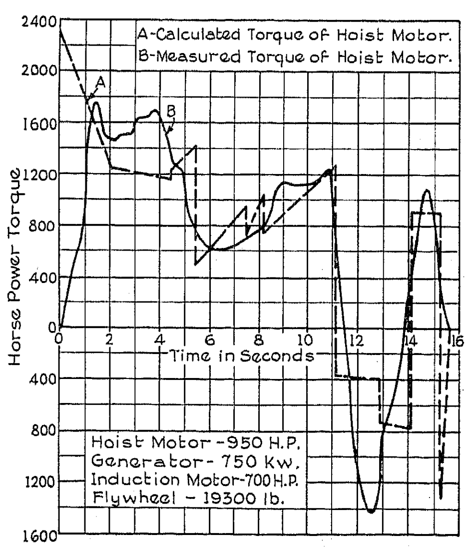

Fig. 4

against time. It is interesting to note how the rate of retardation changes, first being very high, then falling to zero and running at practically constant speed for about a second and finally retarding to rest at a high

rate. This retardation curve is not determined by any automatic devices, but is the result of the operator's experience in handling the equipment. Incidentally, curves were taken with different operators handling the hoist and in each case, the same general result is observable.

Somewhat the same general characteristics are observable during acceleration. The acceleration rate

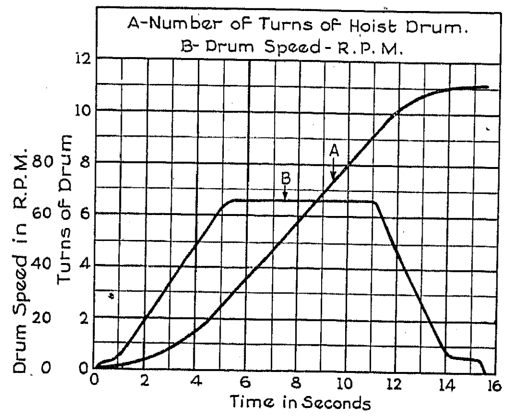

FIG. 5

in the beginning is low, then increases and remains at a practically constant rate for about four sec., then falls off somewhat gradually until constant speed is reached.

These curves are undoubtedly very interesting to a manufacturer, but what the customer is particularly interested in is the input from his line which represents to him actual expenditure. The kilowatt hours consumed in hoisting 9500 lb. through 335 ft., as indicated on the graphic wattmeter chart, amounted to 2.25

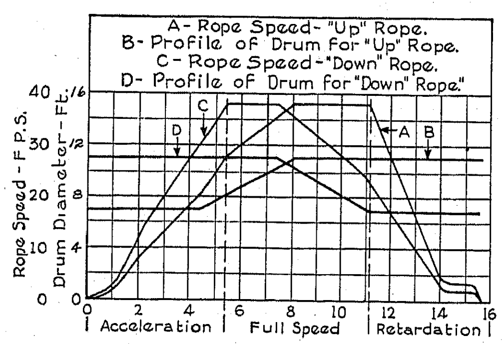

FIG. 6

kw-hr. per total trip, including the rest period or 1.41 kw-hr. per 1000-ton ft. The calculated input to the induction motor in kilowatts indicated 412 while the average reading from the graphic chart showed 402.

The calculated overall efficiency figured from actual foot pounds of energy consumed in the shaft to input to the flywheel set showed 52.4 per cent while the actual efficiency from the test showed 53.4 per cent.

Discussion

Carl Lee: The close agreement between the calculated cycle and the actual cycle of operation is very interesting and illustrates the high accuracy to which the design of electric hoists has been developed.

The smoothing out of the various curves has been noted on several hoists which have been in operation several yeras. The changes of the rope from the cone to the cylindrical part of the drum do not produce sharp changes in the load but rather gradual changes.

The efficiency of an electric hoist apparently remains very constant over a period of years as borne out by the attached figures which show the power consumption on two Ilgner Ward-Leonard hoists which have been in operation for over nine years.

This constant efficiency will be interesting to operators because with a steam hoist there is no doubt a falling off of the efficiency of the boiler plant, steam line, and steam engine after a few years use under average conditions.

W. I. Slichter: There are four important points brought out in these papers which seem to me warrant particular emphasis, as they indicate a general trend in the electrical engineering of the day.

The first point is the scientific calculation of the drum of the hoist by which the rate of acceleration is so controlled that the maximum demand on the hoist motor is limited to a reasonable peak and the load made nearly constant. This makes for economy in the size of the motor and the first cost.

The second is the use of the fly-wheel in the motor-generator set which still further reduces the maximum peak demanded of the transmission line, so that this peak is about ten per cent greater than the average. This makes for economy in the size of the transmission line and of the generator, again saving capital.

The third is the introduction of automatic control in the stations, making possible a notable reduction in the number of men required, thereby making for economy in the item of operating expense.

Finally, there is an effort to show consideration for the men, eliminating the danger of accident and enabling the men to live under more humane conditions, which illustrates the social and humane work of the engineer of the present day.

G. H. Finks: We have in Alabama quite a few electrified hoists, but no shaft hoists. The general data presented in the excellent paper of Mr. Stone and Mr. Grant does not apply in general to Alabama conditions, but the figures show that the calculated values for hoisting agree very closely with actual values obtained on tests. We have made some studies in the Alabama Power Company in connection with that, and find that that is true.

Most of the hoists in Alabama are slope hoists and they vary in length from a few hundred feet to some eight thousand. The grades vary from possibly 60 per cent down to very light grades. Also the grades found in the average mines vary.

In connection with the slope of the long-haul hoist, the trip is unbalanced in the pulling of cars. The return of the empty trip into the mine is usually done with a break. I would be interested in a discussion on the question of regeneration in such cases. We have found that such regeneration is possible and it returns appreciable percentages of power to the line.

In connection with the conduction of peaks on hoists, that becomes a matter usually to be determined between the consumer and the power company, if it happens to be purchased power, or in the case of a small power plant used to operate the hoist, a matter of not overloading a small plant; but particularly in the case of a power company, the demand applies, that is, a time limit, or in the case of almost all Alabama mines, a fifteen-minute demand period. You will have a certain number of

cycles during that period, and the momentary peaks do not usually influence the total demand.

F. L. Stone: I think I may be able to throw some light on the question of regeneration. It is entirely feasible to regenerate with an induction-motor hoist, provided you let it go a little above synchronism. Many slope hoists are operating under those conditions, but strange to say, many power companies put a ratchet on the meter.

G. H. Finks: In connection with the regeneration, you say the power company might put a ratchet on the meter. Well, that is true. A mine usually has additional load to carry which can be carried on a hoist and the meter will tend to come to a standstill as the mine load is picked up by the regenerated hoist. We have noted that a meter will not reverse until the total load is carried on the hoist. Most mines have a large amount of pumping, fans, and stuff of that kind, which has to be carried before energy can be put back into power lines, but the energy that is used for operating ventilating fans and pumps must be paid for and puchased from the power company.

Automatic Substations for Industrial Plants

BY CHESTER LICHTENBERG
Member, A. I. E. E.
General Electric Company, Schenectady, N. Y.

THE automatic electric power station is a new development in the art. It was conceived by a central station engineer and developed by a railway engineer. It is natural, therefore, for automatic stations to be more widely used in these branches of the electric art than in industrial power applications. Nevertheless, the most promising field for automatic substations seems to be for the transformation and supply of electric power for all sorts of industrial purposes.

Electricity supply for factories, mills, mines shops and other industrial enterprises usually lends itself quite readily to automatic operation. The kind of automatic switching equipment and its application, however, depends to a large extent on the particular requirements of the industry served.

Generally, some form of power-transforming equipment is utilized for these enterprises. It may be rotating equipment such as motor generators, synchronous converters or synchronous condensers, or it may be static equipment such as transformers, static condensers or mercury tube converters. All of these have been equipped with automatic switching and control for central station and railway service and can readily be adapted to electrified industrials.

Primary power plants where water is the source are particularly well-suited for automatic control, but steam-operated stations have not yet been added to the rapidly growing list of automatic station installations.

Synchronous condensers form one of the simplest classes of rotating machines to which automatic station control equipment has been applied. They also form a class of power conservers which industrial organizations seem hesitant to adopt. It may be that heretofore the need to provide them with an operator has retarded their location at strategic points on the power network, or forced their location in existing attended stations which were remote from the preferred point for best performance. Whatever the reason may have been, the successful automatic operation of these units has very widely extended their field of application, particularly to electrified industries.

The first automatic synchronous condenser was a 3000-kv-a. unit installed by the Interstate Light & Heat Company at Hazel Green, Wisconsin. It was started in March, 1917, and is still in successful operation. It is located at a point on the power company's transmission lines where regulation had previously been quite poor. It more than paid for its cost in the first two years' operation. The latest automatic synchronous condenser is a 7500-kv-a. unit being installed by the New England Power Company at the Worcester, Mass. mills of the American Steel and Wire Company. In the meantime there have been a number of installations of automatic synchronous condensers but invariably by the power companies, although in most cases the condensers have been utilized for the correction of power-factor conditions caused by the industrial enterprises using the electricity.

The automatic control of a synchronous condenser is relatively simple. The starting impulse is given by any one of several familiar devices. A voltage relay, a power-factor relay, a time clock or simple tumbler switch may be used to start the set. The synchronous condenser is usually provided with an amortisseur winding and is brought up to speed as an induction motor. A compensator or Y-delta starting scheme may be used, either being readily adapted to automatic control. Usually during the period of acceleration, the synchro-

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

nous condenser field remains disconnected from the source of exciting current and is bridged by a field-discharge resistor. This aids in giving the required starting and pull-in torque. After its field is excited, the unit has been connected to the line and full pressure applied to its windings, it begins to function as a power-factor corrector. A power-factor regulator or a voltage regulator which forms part of the automatic switching equipment adjusts the field current automatically to maintain either fixed power factor or fixed pressure within the limits of operation of the unit. Automatic synchronous condensers are provided with the usual automatic station protective devices. The bearings are equipped with bearing temperature relays which will cause the set to be shut down if the bearings tend to overheat and before damage results. The machine armature is provided with current-operated thermal relays having a time-temperature characteristic similar to that of the condenser. These automatically shut the machine down if the armature current exceeds a safe value for a given time. They also permit the unit to re-start automatically after a shut-down of a sufficient time duration to cool the windings. These thermal devices are of the integrating type and are self-adjusting for ambient temperatures. A grounding protective relay is also provided which causes the set to shut down in case of any leakage to ground in excess of 50 amperes. This cares for any insulation failures

Fig. 1—United Railways of St. Louis, Franklin Ave. Substation, St. Louis, Mo. for Synchronous Converter 600-Volts, 2-Kw. 25-Cycle 6-Phase and Portion of 6 Stub End and Multiple D-C. Reclosing Feeders 600-Volts 2000-Amperes for Reclosing from Either Side

and prevents undue damage. Single-phase starting, harmful single-phase running, reverse phase, loss of field, too low line pressure, short time a-c. overload, etc., are also cared for by the usual automatic station relays.

Synchronous motor generators form the next general class of rotating electrical machines which have been successfully equipped with automatic switching. Units of 150 kw. in capacity are now operating in many sections of the coal mining district and are typical of the smaller sizes. A 2000-kw. set is in operation on the 666-volt d-c. electrification on the main line of the New York Central Railroad and is typical of the larger sizes applied to very severe operating conditions. These units may be started on load demand or at a predetermined time or by a tumbler switch or its equivalent. The automatic switching equipment proceeds to function immediately the starting impulse is given. First, it checks the line pressure to be sure it is ample to start and run the set. Next, it checks the supply to be sure all the phases are intact and are of the

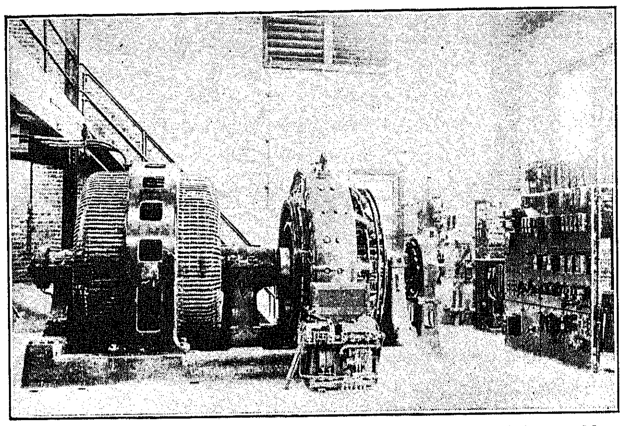

Fig. 2—Automatic Railway Substation, New York Central Railroad Co. 110th St. General View of Station Showing 2000-Kw. Motor-Generator, High Speed Circuit Breaker and Automatic Control Panels

correct sequence. Then, it checks the bearings, machine windings, and ambient temperatures, to be sure these will permit the machines to run if and when started. Next, it connects the motor to the source of power, either through a compensator or to taps on the transformer, or through the transformers direct if Y-delta starting is used. Then the set starts to rotate and increases in speed. At synchronous speed, the automatic switching equipment again takes hold and connects the field circuit to the source of the exciting current. When field current has been established, the set is transferred from the starting combination to the running combination. During the accelerating period the motor field remains disconnected from the source of exciting current and is bridged by a resistor in the same manner as is the synchronous condenser during its starting cycle. This permits individual adjustment of each motor so as to obtain a complete start under practically all conditions which can be found in service.

In the larger sets, a low value of field is applied while on the starting tap, and the final value after the machine is transferred to the running connections. In the smaller sets, the final value is applied in one step while on the starting tap. The smaller sets having 250-volt or 275-volt generators are usually excited directly from the generators. Those rated for higher pressures or arranged with voltage regulators are usually fed from an exciter either separately operated or direct connected.

The synchronous motor has the usual automatic

station protection to prevent runaway, operation without field, harmful single-phase operation, leakage to ground, short-time and long-time continued overload, bearing temperature, etc. Some of these devices, such as the bearing temperature relays, are hand reset where continued operation of the machines under any circumstances might lead to their destruction. The number of such devices, however, is a minimum so as to insure continuity of service under all conditions, excepting where the machine might fail and thus interrupt such continuity for a long time. Most of the other protective devices, such as the long-time delay overload relays, phase-checking relays, etc., are automatically reset and permit the equipment to resume normal operation as soon as the unusual conditions have been corrected.

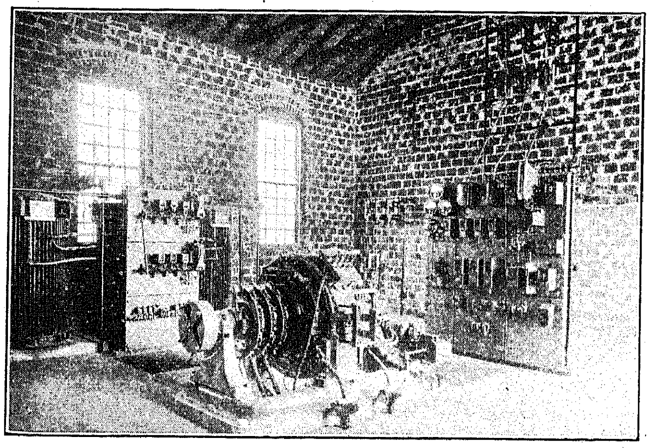

Fig. 3—Clearfield Bituminous Coal Corp., Grass Flat, Pa., Pleasant Hill Mine. Interior View of Station Showing Automatic Switching Equipment and Synchronous Converter 275-Volts 200-Kw. 6-Phase 60-Cycles and Combined Stub End and Multiple D-C. Reclosing Feeder 275-Volts 1090-Amperes

The d-c. generator is provided with protection and adjustment, depending upon the service requirements to which it will be subjected. The simpler equipments, which may be shunt or compound wound, are usually operated with a fixed shunt-field setting. This setting is chosen to give the desired terminal pressure, and in the case of multiple-unit sets, must be carefully adjusted to give the correct loading of the machines. Multiple-unit stations also require careful compounding of the units to permit the successful multiple operation of "hot" and "cold" machines.

The d-c. generators of larger sized sets are frequently provided with automatic load regulation. One type is provided with a shunt-field bucking scheme. This has been successfully applied to shunt-wound generators for multiple-pressure booster service. The shunt-field current is normally furnished by the generator itself. The current is then passed through the armature of a tiny motor-generator continuously rotating. This set, by a suitable raising or lowering of its field current, bucks or boosts the shunt-field current of the generator the correct amount and gives the desired regulation. In one example, using this method of control, load swings of from 300 per cent normal to 200 per cent reversal are successfully handled.

Another modification is a compound-wound d-c. generator with the series field connected to oppose the shunt field. This type of generator is usually operated with the series field shunted by a circuit breaker which allows only a fraction of normal current to flow through the field when it is closed. Under heavy overload conditions, the circuit breaker is automatically opened and the series field carries the full line current. Under this condition it tends to oppose the shunt field. Now by suitably proportioning the shunt and series fields, the d-c. generator can be made practically a constant-current machine and service may be maintained at a reduced pressure during emergency load conditions. As soon as the overload condition ceases, the circuit breaker automatically recloses and shunts the series field. A number of such equipments is operating on the Edison three-wire networks of many of the large electricity supply corporations, and their use is being very rapidly extended. Their judicious application to electrified industrial establishments would insure continuity of service under the most severe conditions short of complete and sustained interruption of primary electricity power supply.

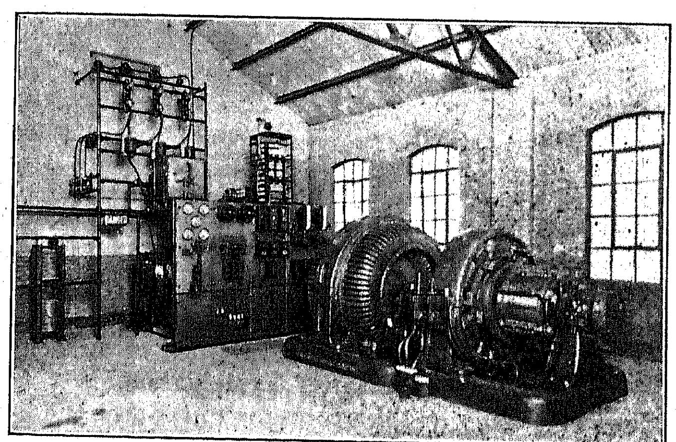

Fig. 4—300-Kw. 250/275-Volt D-C. 6000-Volt 3-Phase 60-Cycle Synchronous Motor-Generator with Automatic Control Equipment, Clearfield Bituminous Coal Corporation, Rossiter, Pa.

Synchronous converters form without exception the largest single class of rotating electrical machines which have been successfully provided with automatic switching equipment. In fact, they were the first electrical machines to be so equipped, notwithstanding the fact that with a single exception they are considered the most difficult electrical machines to operate. This is principally because of the almost universal application of synchronous converters for interurban railway service where automatic stations were first widely adopted.

The automatic switching and control of synchronous converters assumes the a-c. supply to be available

before any starting operations are performed. Consequently, all automatically-controlled synchronous converters are a-c. starting. Also, with one or two minor exceptions, the starting is accomplished with the aid of an amortisseur winding on the field.

The starting indication for an automatic synchronous converter may be any one of the usual devices, such as a pressure relay, a time switch, a tumbler switch, or their equivalent. Immediately the starting impulse has been completed, the synchronous converter is connected to the starting taps on the power transformer. One-third taps or one-half taps, depending on the design of the synchronous converter and transformers, will usually furnish sufficient torque to start the converter armature and pull it into step. Then the converter is automatically transferred from the starting taps to the running taps.

During the starting operation, the shunt field is usually opened. After the machine has reached synchronous speed, its field is either flashed with the correct

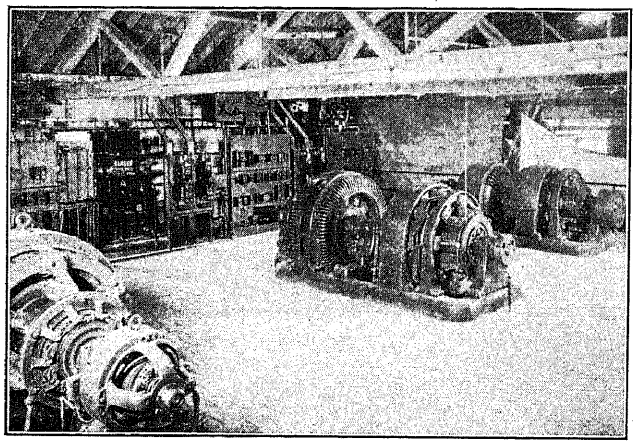

Fig. 5—Automatic Station Control Equipment, Mobile Electric Company, Mobile, Alabama. Synchronous Motor Generator Set and Control Equipment

polarity before it is made self-exciting, or its field is reversed until correct polarity is established.

The next step in the process is to connect the synchronous converter to the d-c. network or feeder, and here the inherent characteristics of the converter require a different series of operations than do motor-generator sets. The d-c. terminal pressure of a synchronous converter is regulated largely by the a-c. pressure-supply. Only a relatively narrow range of d-c. terminal-pressure adjustment is possible by field adjustment. This then requires some arrangement for safely connecting the synchronous converter to the d-c. network, even though that network may be operating at a pressure quite different from the terminal pressure of the synchronous converter. This condition is most usually encountered in all sorts of electric haulage installations, since here the wide swings in power demand are very large compared with the feeding capacity of the a-c. supply. For electric railways and commercial electric power service generally, and sometimes for industrial electric power supply, synchronous converters are equipped with load-limiting resistors. These are connected between the d-c. terminals of the synchronous converter and the d-c. network or feeder after the synchronous converter has been placed in complete running condition in so far as the a-c. side is concerned. These resistors are then usually shunted out in two or three

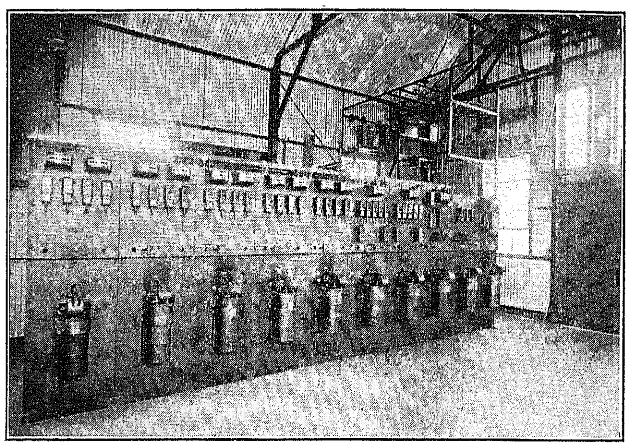

Fig. 6—Automatic Switching Equipment, Long Island Lighting Co., Port Washington, L. I. For Five 2-Phase and Two Single-Phase, 2200-Volt, 60-Cycle Reclosing Feeders and Automatic Transfer Apparatus for Two Incoming Lines

steps thus gradually loading the synchronous converter from the d-c. network. The shunting contactors or circuit breakers used for this service are usually provided with current relays having interlocks so that the synchronous converter cannot be loaded beyond its

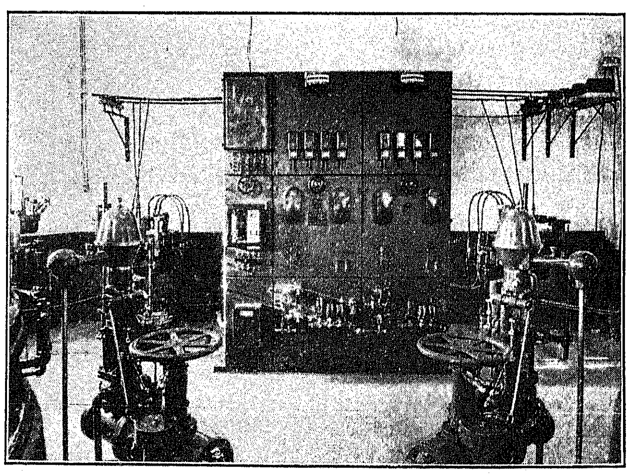

Fig. 7—Automatic Generating Station Control Board and Generator. Fairbury Mill and Elevator Company. Two 40 150-Kv-a. 180 Rev. Per Min. 2300-Volt Generators

thermal capacity. Other devices such as thermostats, located near the load-limiting resistors, permit the synchronous converter to supply current to the d-c. system within safe heating limits until the load is reduced or the resistors and converter tend to dangerously overheat. Under these conditions, the converter

is automatically shut down until it and the resistors cool. After the equipment has cooled sufficiently, a fresh start is automatically made. In some cases the load-limiting resistors are shunted out in only one step where economy in design and manufacture permit *Y*-delta starting. With this combination and with suitable transformer design, the *Y*-delta arrangement may be used to take the place of one step of the load-limiting resistors.

The load-limiting combination available for, and used with, synchronous converters permits their wide application to all sorts of electrified industries as well as to electric railway and electric power supply systems. It permits the use of the economical synchronous converter in many places where motor-generator sets were formerly considered supreme. For certain few applications, they were excelled only by specially designed motor-generators with automatic load-regulating features.

Synchronous converters for automatic operation are provided with the usual automatic station protective features such as bearing and resistor temperature relays, short and long-time continued a-c. overload relays, single-phase starting preventive and harmful continued single-phase running preventive relays, low a-c. pressure starting or operating preventive relays, overspeed switches in combination with a shunt trip circuit breaker, leakage to ground relays, etc.

Other electric power-transforming machines, such as balancers, mercury tube converters, and static transformers have been made completely automatic and are now in successful operation. Their design usually takes pattern after the best manual operation scheme, except that the time for the switching is generally reduced from a matter of minutes to a matter of seconds.

The automatic hydroelectric plant is one of the outstanding applications of automatic switching equipment to industrial enterprises. Consider, for example, the many streams of moderate size but relatively uniform flow which are found in the upper Middle West. They have been used for many generations to drive grist mills of quite good size, as well as performing many other industrial functions of varied natures. The hydro equipment which has heretofore been used is fast becoming antiquated and the output of the mills is suffering in consequence. The recent installation of automatic hydroelectric equipments in a number of these mills has wrought an important change in this section of the country. The same streams now permit not only a greater mill output in combination with the electrification of the mills, but also provide an inexpensive power supply to adjacent towns and villages. More important even is the fact that the electrified mill can now be connected to the large electric power supply system covering the country, and can either take power from this system during times of low water or can feed power into the network during times of high water.

Automatic hydroelectric stations almost invariably use synchronous generators since they can be provided with their own exciters. They almost always have a waterwheel equipped with either an oil pressure governor, a servo-motor, or motor-operated gates. The synchronous generator is usually provided with an amortisseur winding to assist in pulling the machine into step. The starting impulse is given by any one of the familiar relays or by a push button, or may be given by making alive the station feeder from an a-c. network. Immediately after the starting impulse is completed, the waterwheel gates are opened and the waterwheel started. Then the gates are shut until only enough water passes through to bring the machine up to about 95 per cent normal speed. At this point the armature is connected to the a-c. network, either directly or through transformers and immediately thereafter the field is excited. This brings the generator into phase with the network and places load on the machine.

Automatic hydroelectric stations are usually provided with automatic voltage regulators and these, in combination with the hydraulic regulating equipment, adjust and maintain the desired load on the equipment.

Automatic hydroelectric stations are provided with only such protective features as are needed for the quite simple machinery involved. Excess speed, excess electric pressure, insufficient oil pressure, bearing and machine heating, short and long-time, continued overloads, together with loss of field, each has its protective devices, which make the automatic hydroelectric station economical and safe in sizes up to 8,000 or 10,000 kw.

Feeders for a-c. and d-c. networks and supply are now not only automatic tripping on overload, but also automatic reclosing. Many forms are available, each being particularly designed for its individual application.

Discussion

C. S. Butcher: One of the earliest installations of automatic equipment in industrial plants was in the motor car industry in Detroit, where two 1,500 kw. motor generators are used to augment the power supplied by a steam plant. The steam plant is located at one end of the manufacturing aisle, which is some 600 ft. or so long, and a very heavy bus runs through a tunnel from the power house to the load, which is distributed along the bus quite uniformly. It was found, in making a study of the power plant, that the steam costs were very high, however, in the wintertime the exhaust steam is used for heating, and in working out the economics of the problem it was found that if substations were located along the bus, the steam plant, during the summer months could be shut down and considerable saving realized by purchasing power.

The first machine was installed in the summer of 1920 and consists of a shunt generator provided with a constant-voltage regulator. This very materially improved the voltage on the bus at that point, since it was more nearly in the center of distribution. As the plant grew, the next year a similar substation was added, and in that case we ran into our first difficulty of parallel operation. The machines, while being built for shunt

operation, were, as I say, equipped with constant-voltage regulators and it was quite difficult for a time to get the machines to share the load. This was done by rather an ingenious device attached to each regulator. By the use of this device, the machines were given somewhat the characteristic of a straight shunt machine not provided with voltage regulation. The installation has been entirely successful and has since been followed by a great number of installations in the industrial field generally.

Mr. Lichtenberg starts out with the power plant, quite naturally, in the development of our natural resources. However, I don't like to think that we are going to limit automatic operation to the smaller sites; in fact, we haven't done so. We now have about ready to go into operation an 8000-kv-a. hydroelectric station, completely automatically operated, equipped with two 4000-kv-a. generators. That is not large in a sense, but in proportion to the capacity of that system, that really represents quite a large operation.

Previous to that, on the same system we installed a generating station equipped with two 2000-kv-a. water-wheel generators. On that particular property 4000-kv-a. would represent about 25 per cent of the total system capacity. However, inasmuch as all of that was not connected to the load, there were times when the automatic station would represent perhaps 50 per cent or better. of the total connected capacity.

The machines are of the older type and are not equipped with damper windings, and it was necessary to find some means for synchronizing the automatic machines with those already connected with the load. Most of you are familiar with the automatic synchronizers which were first used with the old engine-driven units. With the machines of larger capacity, no one liked to depend on the automatic synchronizer. However, with that as a foundation, we started out to make an automatic synchronizer. With that, we combined an automatic speed-adjusting device, which consists of nothing more than two little synchronous motors, one connected to the line and the other connected to the incoming machine; the two motors driving together a differential which operates to regulate the speed of the incoming unit by the operation of the speed adjustor on the governor mechanism. That, in combination with a modification of the old synchronizer, worked out beautifully, and that station has now been in operation for six or eight months and has been entirely successful.

In connection with hydroelectric plants we are accustomed to thinking of large developments. Large developments often involve the condemnation of considerable portions of land in order to create the necessary storage capacity and to get the necessary head. That is done for the reason that by concentrating our power at any one point, operating cost is kept down to a minimum. If we eliminate the operating cost; that is, the labor of attendants, and develop that same head at a number of smaller sites, the same can be all automatically operated and connected to a common distribution system and operated with considerably greater economy.

Passing from the automatic hydroelectric station, we of course come to the automatic operation of a-c. feeder circuits. That equipment also is practically standardized and practically ordered by style number. The periodic reclosing equipment is perhaps the most common that is used. There are other special applications, but I will not mention those. The duty cycle on the breaker for periodic reclosing is more severe than the standard duty cycle; even the new one that has been adopted. For example, the power companies ordinarily apply this type of equipment to radial-type feeders and require that the first reclosing following an outage shall be on the order of thirty seconds. In case the feeder does not remain closed, it is closed again at the end of perhaps a period of a minute; the third reclosing taking place at the end of a period of approximately two minutes. At the end of that time, if the circuit is not closed definitely, the feeder is locked out of service. If, following any of these reclosures previous to the last one, service remains normal for a predetermined length of time, the equipment is automatically reset to zero. Therefore, the equipment is restored to complete service.

Coming down to the application of automatic substations for supplying direct-current load, we have the railway, light and power, and industrial. They perhaps pretty well cover the industrial; but just taking the railway, which has perhaps seen the greatest development in automatic switching equipment. That is where we started with the synchronous converter, which is probably the most difficult to control. I think most of us are quite familiar with some of the earlier developments which were applied particularly to interurban railways. A great many people at that time said, "Well, that's all right for small interurban roads where continuity of service is not required, but you will never see it on the larger systems." Well, it hasn't worked out that way.

At first we were forced to show a considerable saving in order to justify the installation of automatic switching, but it has been definitely proven that the operation of automatic substations is so much more satisfactory than the operation of manual stations, that automatic switching equipment is being installed now where continuity of service is of prime importance. The application of automatic substations to heavy networks, whether they are railway or light and power, is made not so much on what can be saved in operators' wages and the like, but what can be saved in distribution losses.

I have in mind our first application to Edison's load which was made in the City of St. Paul in 1920. There, a large theatre and office building was built on the very edge of the Edison three-wire, 250-volt network. To run cables to this point would have meant a large investment in ducts and in copper. It was absolutely essential, however, that they have good voltage regulation at this building, so they compared the cost of cable and ducts with the cost of an automatic substation. The economics were decidedly in favor of the automatic substation, but they were not quite sure that it would give them just the service they wanted. However, it was tried out. The inspection has been weekly, with a man visiting the station approximately twenty minutes each day, and all of the little things which might have caused a shut-down have been caught on inspection. So that station has never caused an interruption of service to that building. Several times the network has been lost and the station has automatically isolated itself from the system and supplied the isolated load.

F. M. Nash: In our concern we had occasion once to consider an automatic outdoor generating station, and I would like to ask if there are any here who know of, or can give any account of, the installation of automatic outdoor generating stations. In this particular instance we had to consider the replacing of three 1000-kw. machines with one automatic generator, outdoor type. The change was not carried out, partly because of the cost and partly because of the uncertainty of such an undertaking.

C. A. Butcher: So far no automatic switching equipment; that is, complete automatic switching equipment, has been applied to an outdoor generator, and to my knowledge there has been built only one generator for that type of service. I am pretty sure that the Allis-Chalmers Company built that.

That problem came up a number of years ago and a study was made to determine whether or not it was feasible. It was determined quite definitely that it was feasible and also practical, but uneconomical, for the reason the protection which must be afforded the generator and the generator housing would have to be of special design. The fact that there are very few applications for this class of machine, thus necessitating placing all the development costs on very few, made it an uneconomical proposition on the very few that we considered.

Effect of Certain Impurities in Storage Battery Electrolytes[1]

BY G. W. VINAL, and F. W. ALTRUP

Member, A. I. E. E.

Both of the Bureau of Standards

Review of the Subject.—*A new method for measuring the rate of sulphation of storage battery plates was recently devised at the Bureau of Standards by Vinal and Ritchie (Technologic Paper 225). This consisted of periodic weighings of plates suspended in electrolyte. The present paper is an extension of this work. Detrimental impurities when present in the solution may (1) corrode the plate, (2) accelerate the formation of lead sulphate, or (3) be deposited in the pores of the plate. In any case, the weight of the plate changes and this affords the most sensitive and exact means which we have for estimating the extent and nature of the reaction. A physical meaning can be given to the rather vague term "local action." It was found that electrolyte, containing only one part of platinum in ten million parts of the solution, increased the local action at the negative plates by 50 per cent. Copper, like platinum, deposits on the negative plates, but produces less effect. Iron is of unusual interest because it greatly accelerates the formation of lead sulphate at the negative plate. The reaction of the positive plates is slower, which mitigates its detrimental effects to some extent. Manganese is particularly destructive to the positive plates. The results of our experiments indicate that the reactions of manganese compounds in the battery are somewhat different from the previously accepted theories. Manganese in the form of manganese dioxide is deposited on the positive plates covering the active material, closing the pores and causing a part of the charging current to be wasted. The work is being extended to include the effect of other impurities.*

CONTENTS

INTRODUCTION

THE importance of obtaining exact information about the effect of impurities in storage battery electrolytes arises from the detrimental effects which many of them produce on the operating characteristics and life of the storage battery, and such information is necessary as a basis for the preparation of specifications for sulphuric acid to be used in the batteries. Engineers have recognized for a long time the necessity for maintaining a high standard of purity in the electrolyte, but within recent years millions of small batteries have passed into the hands of non-technical users who must depend upon the manufacturer and his subsidiaries for satisfactory service. The information hitherto available on this subject has been fragmentary and in some cases contradictory.

The most recent systematic research on this subject is that of Helen C. Gillette.[2] Her experiments were carried out by the method used by several previous experimenters, *i. e.*, by poisoning the cells after their electrical characteristics had been determined. This method, while valuable from the standpoint of operation does not permit us to determine quantitatively the effects produced on the positive and negative plates or to determine definitely the chemical reactions which take place.

A new method for measuring the rate of sulphation of storage battery plates was recently devised at the Bureau of Standards. A description of this method with experimental results for measurements on positive and negative plates suspended in pure sulphuric acid solutions has been published.[3] The same method and apparatus have been employed in the present investigation but with some modifications necessitated by the conditions of our experiments. In this paper the effects of small amounts of iron, maganese, platinum and copper are described.

II. PRINCIPLE AND METHOD

The discharge of either the positive or negative plates in sulphuric acid solutions results primarily in the formation of lead sulphate. A certain amount of lead sulphate is formed as the result of local action when the plates are immersed in even the purest acid solutions obtainable. Detrimental inpurities may (1) corrode the plate, (2) accelerate the formation of lead sulphate, or (3) be deposited in the pores of the plate. In any case the weight of the plate changes and this change affords the most sensitive and exact means which we have for estimating the extent of the reaction. In order to obtain comparable results it is necessary that the temperature be maintained at a constant value. This was usually accomplished by immersing the glass jars containing the electrolytes in a large water bath thermostatically controlled at 25 deg. cent. (77 deg. fahr.).

1. Prepared under the Auspices, and published with the approval of the Bureau of Standards.

2. TRANSACTIONS American Electrochemical Society 41, p. 217, 1922.

Presented at the Spring Convention of the A. I. E. E., Birmingham, Ala., April 7-11, 1924.

3. Vinal and Ritchie, Bureau of Standards, Tech. Paper 225. *Chem. & Met.*, v. 27, p. 1116; *Electrical World*, v. 80, No. 26, p. 1383.

This temperature was maintained constant to within about 0.01 deg. cent. Two positive plates or two negative plates, suspended on glass hooks were placed in each jar. As a preliminary step the plates were given several cycles of charge and discharge following which they were fully charged and then submerged in the electrolytes to be tested. Each jar contained a solution of chemically pure sulphuric acid having a specific gravity of 1.250. The electrolytes were saturated with lead sulphate because the previous work showed this to be necessary.

A sensitive balance mounted on a marble slab above the thermostat bath was used for weighing the plates while they were immersed. Any plate could be brought

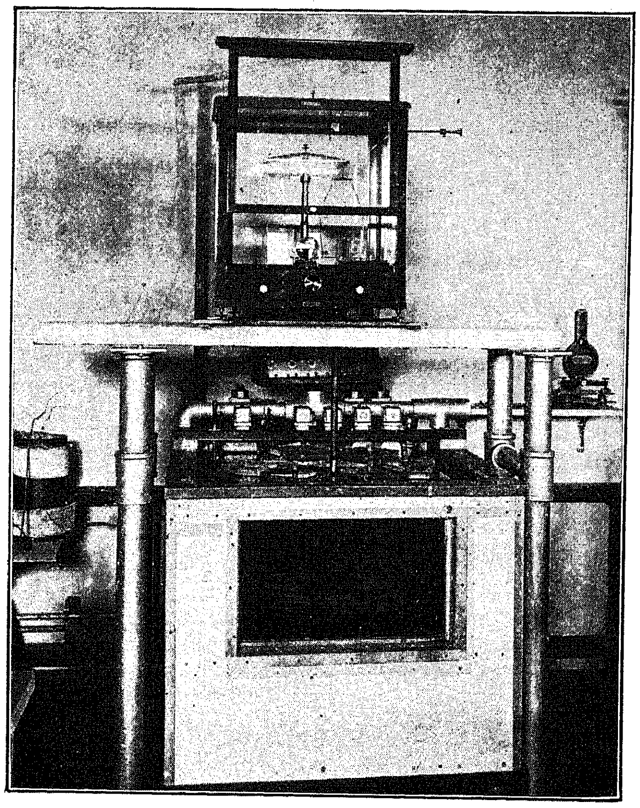

FIG. 1—APPARATUS FOR TESTING BATTERIES

directly under the arm of the balance, as the jars containing them were carried on a revolving frame. The arrangement of the apparatus is shown in Fig. 1.

A carefully measured quantity of the impurity was added to the electrolyte in each case before the plates were immersed. Simultaneously with the tests to determine the effect of the impurities, measurements were made of the rate of sulphation of the plates in pure solutions. The results of the experiments are shown by means of curves relating the total change in weight of the plates to the time in hours. Weighings of the plates were taken immediately after placing them in the solutions and they were weighed at frequent intervals during the first day because the rate of the reaction was generally the greatest at this time. As the reaction slowed down weighings were made at less frequent intervals.

A distinction must be made between the rate and the total extent of the reactions produced by the impurities. In the case of impurities such as platinum and copper, the rate of the reaction is of interest because the reaction, if allowed to proceed indefinitely, will be terminated only by the complete exhaustion of the plates. On the other hand with an impurity such as iron the total extent of the reactions is limited by the amount of the impurity added and any spontaneous oxidation or reduction which may occur. In such a case, therefore, the total reaction is of more interest than the rate of the reaction since it permits us to verify the chemical equations for the reactions that occur.

The concentrations of the impurities are expressed as percentages by weight.

III. EFFECT OF COPPER

Copper was added to the solutions of sulphuric acid saturated with lead sulphate in the concentrations shown in Table I. The solutions initially had the characteristic blue color of copper sulphate. When the two negative plates were immersed in the solutions the copper began to deposit upon the plates and the solutions gradually lost color. An analysis of the solutions after the experiment was completed showed only a small trace of copper. This shows that practically all the copper had been deposited upon the plates. Since the amount of solution in which they were immersed greatly exceeded the amount of solution that would ordinarily be present in a battery, the amount of copper deposited on each plate was in excess of that which would be found in ordinary practise. The quantity of solution was approximately ten times the amount that would be contained for the same number of plates, in a starting and lighting battery. To obtain equivalent conditions, therefore, in the case of those impurities which deposit upon the plates, the concentrations should be multiplied by a factor of 10.

TABLE I

LOCAL ACTION PRODUCED BY COPPER AT NEGATIVE PLATE

Concentrations of copper are shown in the box headings. Results are calculated as ampere-hours of equivalent discharge for one plate.

Time in Hours	Copper Concentration. 0.4	0.08	Per Cent Pure Acid
10	0.8	0.1	0.0
20	2.1	0.2	0.1
30	2.9	0.3	0.2
40	3.6	0.5	0.3
50	4.1	0.6	0.4
75	5.2	0.9	0.5
100	6.0	1.2	0.7
150	7.4	1.7	1.0
200	8.7	2.2	1.4
300	10.9	3.4	2.0
400	13.1	4.5	2.6

The deposition of the copper upon the negative plates could be easily seen. An illustration of one of these

plates, together with a similar plate taken from a pure acid solution, is shown in Fig. 2.

The local action which occurred at the plate as the result of the deposition of copper was accompanied by the evolution of hydrogen. The changes in weight of the plate during the process are shown in the curves of Fig. 3, and from these has been computed the equivalent of the local action in ampere-hours as the average value per plate. The results of the calculation are

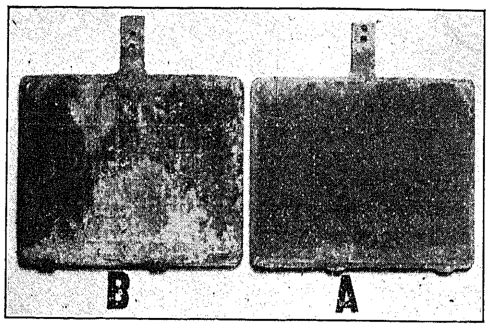

Fig. 2—Negative Plate (B) Contaminated with Copper —Plate (A) was Taken from a Pure Solution

given in Table I. The ultimate capacity of the plate has been calculated from the amount of active material contained in the plate allowing for 60 per cent sulphation. Since the plate contained 148 grams of the active negative material the ultimate capacity is calculated to be 22.9 ampere-hours.

Table I shows that during the first part of the experiment the extent of the local action produced by the

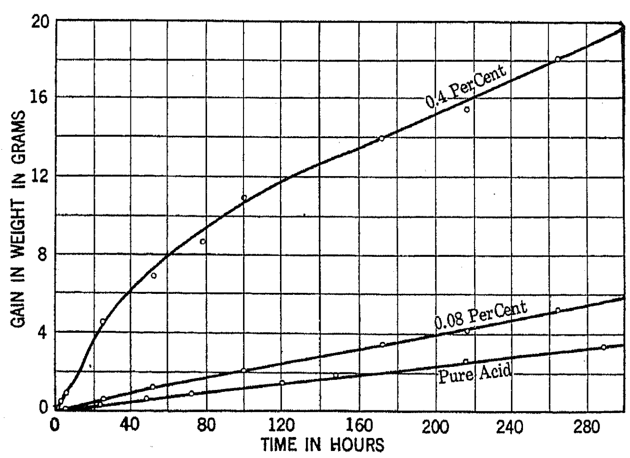

Fig. 3—Effect of Copper on Negative Plates

copper is not as great as might be expected. This is probably due to the rather high overvoltage for hydrogen on the surface of copper. The solution which contained 0.08 per cent of copper produced approximately double the amount of local action that was observed in the case of the plates immersed in the pure solution. The total number of ampere-hours of equivalent discharge at the end of 400 hours, however, was only one-fifth of the ultimate capacity of the plates. The solution containing 0.40 per cent copper produced an equivalent discharge of 13 ampere-hours per plate in a period of 400 hours. This is about half of the ultimate capacity of the plates.

IV. Effect of Platinum

Platinum has always been considered one of the most deleterious impurities. The results of this investigation amply justify this conclusion. Platinum, however, is not as common an impurity at the present time as it has been in the past, because comparatively little sulphuric acid is now concentrated in platinum vessels during the process of manufacture.

Platinum was added to the sulphuric acid solutions, as in the case of copper, in the percentages shown in Table II. The experimental results are given in Fig. 4.

The platinum evidently began to deposit upon the negative plates very quickly as they began to gas almost

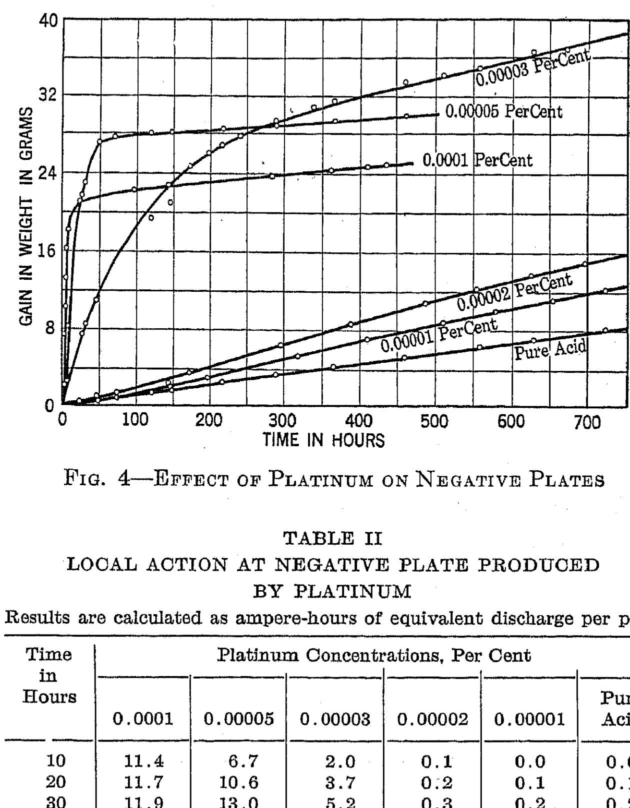

Fig. 4—Effect of Platinum on Negative Plates

TABLE II
LOCAL ACTION AT NEGATIVE PLATE PRODUCED BY PLATINUM

Results are calculated as ampere-hours of equivalent discharge per plate

Time in Hours	Platinum Concentrations, Per Cent					
	0.0001	0.00005	0.00003	0.00002	0.00001	Pure Acid
10	11.4	6.7	2.0	0.1	0.0	0.0
20	11.7	10.6	3.7	0.2	0.1	0.1
30	11.9	13.0	5.2	0.3	0.2	0.2
40	12.0	14.5	6.4	0.4	0.3	0.3
50	12.0	15.3	7.4	0.5	0.4	0.4
75	12.2	15.6	9.3	0.8	0.6	0.5
100	12.4	15.7	10.8	1.1	0.8	0.7
150	12.8	15.9	13.1	1.7	1.2	1.0

400	13.9	16.4	18.1	5.0	3.8	2.6
500		16.5	19.1	6.2	4.7	3.2
600			19.8	7.3	5.7	3.7
700			20.5	8.3	6.6	4.3
800			21.0	9.3	7.4	4.8
900			21.4	10.2	8.2	5.4
1000			21.8			5.9

immediately. The plates in solutions containing the greatest amount of platinum gassed violently and increased in weight very rapidly. The gassing was so

violent that the surface of the plates was apparently blasted off and most of the platinum thereby eliminated. With the highest concentration the plates became about 60 per cent discharged within eight hours, but after this the rate of their discharge was comparatively slow. The reaction was not quite so violent in the solutions containing the next lower percentage of platinum but it is significant that the reaction proceeded farther. At the end of 48 hours the plates were 72 per cent discharged. The solution containing 0.00003 per cent of platinum produced a reaction which was much slower but produced 95 per cent of the ultimate discharge in 1000 hours. The lower concentrations produced smaller effects but the gain in weight was appreciably greater than with pure acid. One part in ten million, or 0.00001 per cent platinum produced an increase of 50 per cent in the local action over that in pure acid solutions, which shows that the effect of extremely small amounts of platinum may be detected by this method. Chemically, it is possible to determine platinum in solutions to the extent of about one part in two million, but it is estimated that by this method the effect of as little as one part in fifty million may be determined. The local action calculated as ampere-hours of equivalent discharge for the solutions containing platinum is contained in Table II.

The curves of Fig. 4 make possible an estimate of the local action in terms of the equivalent current that would be discharged by the plate normally for the same rate of sulphation. The equivalent currents are proportional to the slopes of the lines. The curve for plates in pure acid shows the average equivalent current of the local action to be 0.0059 amperes. With this as a basis the equivalent currents during the first part of the experiment for the other curves have been calculated to be as follows:

Platinum Concentration	Current Equivalent of Local Action
Per Cent	Amperes
0.00001	0.0093
0.00002	0.0113
0.00003	0.107
0.00005	0.345
0.00010	1.71

By this calculation a physical meaning is given to the rather vague term "local action."

The plates which gassed most vigorously and from which the original lead surface was blasted off were black for the most part but showed portions covered by the white lead sulphate. The black coloration was probably due to the lamp black which was mixed with the paste when the plates were made. An illustration of one of these plates as compared with one immersed in a pure sulphuric acid solution is shown in Fig. 5.

V. Effect of Iron

Iron may exist in the sulphuric acid solutions in two states of oxidation. Iron in the ferric condition is reduced to the ferrous condition at the negative plate and then in turn oxidized to the ferric condition at the positive plate, and also to some extent by the air.

(a) *Effect on positive plates.* When iron in the ferrous condition is added to the solution, it is oxidized by the active material of the positive plates to ferric sulphate accompanied by the formation of lead sulphate and water. Assuming the following equation for the reaction

$$Pb\,O_2 + 2\,Fe\,S\,O_4 + 2\,H_2\,S\,O_4 \rightarrow Pb\,S\,O_4 + Fe_2\,(S\,O_4)_3 + 2\,H_2\,O \qquad (1)$$

The lead sulphate which is formed permits an accurate calculation to be made of the extent of the reaction from the gain in weight of the plates. The gain in weight of the positive plates must, however, be calculated as $Pb\,S\,O_4$: $(Pb\,S\,O_4 - Pb\,O_2)$, because the plate gains the sulphate radical $S\,O_4$ as the result of the reaction but loses simultaneously two oxygen atoms for each

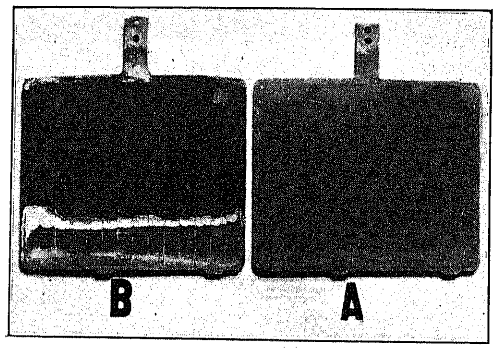

Fig. 5—Negative Plate (B) Contaminated with Platinum —Plate (A) was Taken from a Pure Solution

molecule of lead sulphate which is formed. The reaction expressed by equation (1) proceeds to completion if sufficient time is allowed. That is to say, all of the ferrous sulphate is oxidized to the ferric condition and beyond this point the rate of formation of lead sulphate is essentially the same as for plates in pure acid solutions. The results of these experiments are given in Fig. 6, which shows that the curves representing data obtained from the iron solutions become parallel to those for the pure acid solutions toward the end of the experiment. We may, therefore, calculate the amount of lead sulphate which should be formed and compare it with the amount determined by the weighings. Such a comparison is made in Table III.

The agreement is as good as can be expected. The curves shown in Fig. 6 show the average gain in weight per plate and the figures given in Table III represent the sum total of the lead sulphate formed on both plates in each jar.

Since the reaction expressed in equation (1) came to

TABLE III
COMPARISON OF CALCULATED AND OBSERVED VALUES FOR POSITIVE PLATES IN SOLUTIONS CONTAINING IRON

Amount of Iron Added		Equivalent Ferrous Sulphate	Calculated Equivalent Lead Sulphate	Observed Amount of Lead Sulphate
Per Cent	Grams	Grams	Grams	Grams
0.4	22.5	61.2	61.2	60.2
0.08	4.5	12.2	12.2	11.8
0.012	0.675	2.7	2.7	3.4

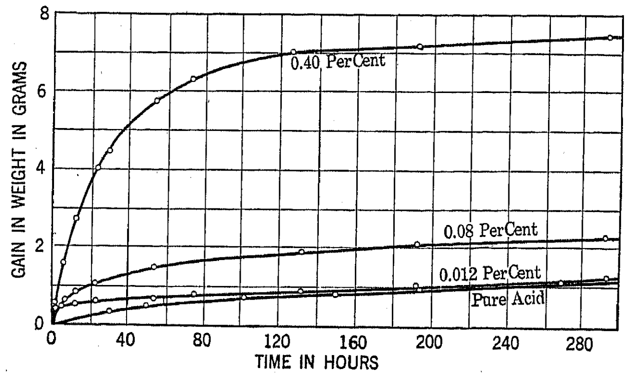

Fig. 6—Effect of Iron on Positive Plates

a definite termination this afforded an excellent opportunity to determine what the effect of introducing negative plates into the solution would be. This case represents the condition of a battery containing both positive and negative plates. One charged negative plate was immersed in each solution at the conclusion of 360 hours. These plates were not in electrical contact with the positive plates. The reduction of the iron to the ferrous condition began immediately and the

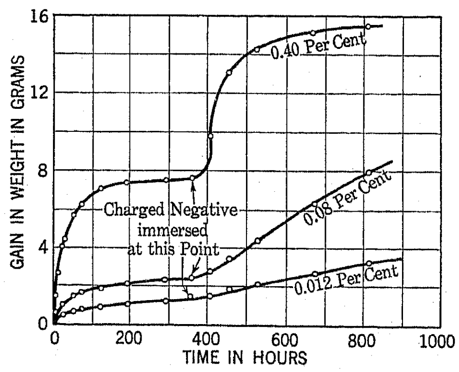

Fig. 7—Gain in Weight of Positive Plates in Solutions Containing Iron

product in turn was reoxidized by the positive plates accompanied by a further discharge. Curves showing the observations which were made are given in Fig. 7, the experiment being continued until 820 hours had elapsed.

(b) *Effect on negative plates.* The action of iron on the negative plates is much more pronounced than on the positives and the local action produced is in excess of the amount which would be calculated from the reduction of the ferric sulphate. The effect is probably the result of two simultaneous reactions that may be represented by the following equations:

$$Pb + Fe_2\,(S\,O_4)_3 \rightarrow Pb\,S\,O_4 + 2\,Fe\,S\,O_4 \qquad \textbf{(2a)}$$

$$Pb + H_2\,S\,O_4 \rightarrow Pb\,S\,O_4 + H_2 \qquad \textbf{(2b)}$$

The amounts of iron added to the solutions were 4.5 g. and 0.675 g. These are equivalent to 16.1 g. and 2.4 g. of ferric sulphate. On the basis of equation (2a) these amounts will account for 13.4 and 2.0 grams of lead sulphate respectively.

The curves, Fig. 8, show the gain in weight of the plates in terms of the sulphate $S\,O_4$ taken from the electrolyte. This gain in weight calculated to lead sulphate $P\,b\,S\,O_4$ is greatly in excess of what may be accounted for by the reduction of the iron salt from the ferric to the ferrous condition. The curves show also that the gain in weight of the plates in the solutions to which iron had been added is in excess of the sulphation of similar plates in the pure acid. This indicates clearly that the presence of iron accelerates the action

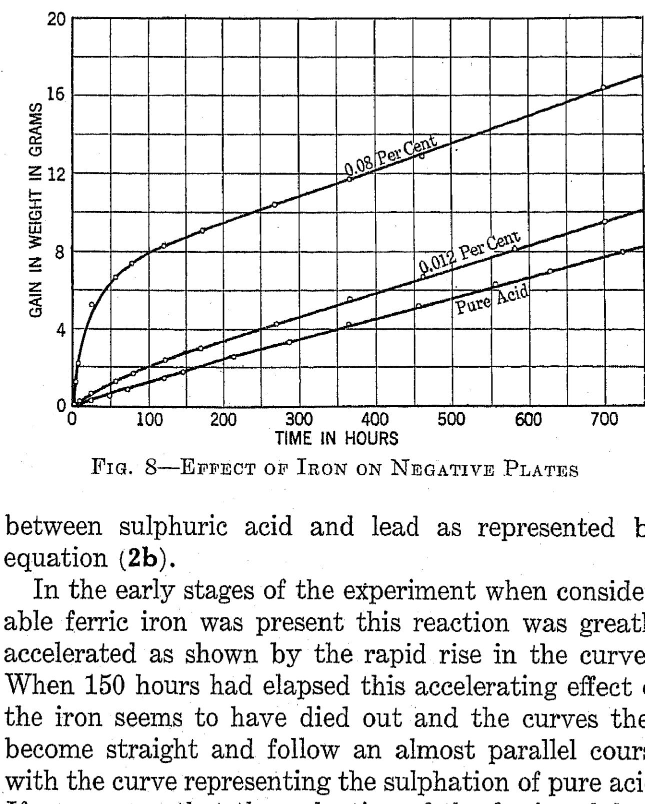

Fig. 8—Effect of Iron on Negative Plates

between sulphuric acid and lead as represented by equation (**2b**).

In the early stages of the experiment when considerable ferric iron was present this reaction was greatly accelerated as shown by the rapid rise in the curves. When 150 hours had elapsed this accelerating effect of the iron seems to have died out and the curves then become straight and follow an almost parallel course with the curve representing the sulphation of pure acid. If we assume that the reduction of the ferric sulphate according to equation (**2a**) has become complete at this point, we may calculate an average value for the amount by which the reaction between lead and sulphuric acid has been accelerated. In the solution containing the greater concentration of iron the increase over the normal sulphation in pure acid is about 7 times and in the other solution about 3 times.

After 150 hours the curves shown in Fig. 8 are all approximately straight, but they diverge slightly which shows that sulphate was being formed at a slightly

greater rate on the plates in the solutions to which iron was added than in the pure acid. This effect is probably to be accounted for by the well known slow spontaneous reoxidation of the ferrous sulphate by the air and its subsequent reduction by the negative plates during the long time that the experiment lasted.

Table IV shows the gain in weight of the plates in the solutions to which iron had been added in comparison with the gain in weight of similar plates in pure acid solutions. There were two plates in each jar and the total gain of each pair of plates is shown in the table. Fig. 8 shows the average values.

TABLE IV
EFFECT OF IRON ON NEGATIVE PLATES
The weights are the total gain of the two plates in each case, expressed in grams

Hours	Iron Concentration, Per Cent 0.08	0.012	In Pure Acid
10	4.36	0.60	0.20
20	8.80	1.10	0.48
30	10.80	1.58	0.76
40	12.00	2.00	1.00
50	12.94	2.40	1.24
75	14.26	3.26	1.94
100	15.80	4.04	2.50
150	17.60	5.48	3.64
200	19.00	6.86	4.72
300	21.70	9.58	7.12
400	24.30	12.00	9.30
500	27.00	14.24	11.44
600	29.64	16.62	13.46
700	32.40	18.80	15.40
800	35.00	20.84	17.26

In addition to the above experiments a third concentration of the iron, 0.004 per cent, was used. The results were about the same as for 0.012 per cent and as the curves would lie so near together only one of them has been plotted in the figure. The reason that the smaller amount of iron produced the same amount of sulphation as the larger amount is probably to be attributed to the spontaneous reoxidation of the ferrous sulphate.

The results of this experiment show that the presence of iron is more detrimental to negative plates than to positives because of the acceleration of the reaction between lead and sulphuric acid. Further, the ferrous sulphate which is formed suffers a slight reoxidation by air, in addition to that which would be caused by the positive plates present in a battery.

VI. Effect of Manganese

(a) *Effect on negative plates.* The experimental results obtained when negative plates were immersed in solutions containing manganese are shown in Fig. 9. The lowest curve represents the sulphation of the plates in pure acid solutions. The three curves above this are for similar solutions to which were added respectively 0.04 per cent, 0.08 per cent, and 0.40 per cent of manganese as potassium permanganate.

It is at once apparent that the effects produced are not proportional to the amounts of manganese added. The reason for this is a reaction between the sulphuric acid and the potassium permanganate which is independent of the reaction at the plates. The reaction between the permanganate and the 1.250 sp. gr. acid may be expressed by the equation

$$4\, K Mn O_4 + 6\, H_2 S O_4 \longrightarrow 2\, K_2 S O_4 + 4\, Mn S O_4 + 6\, H_2 O + 5\, O_2 \qquad (3)$$

This is a slow reaction that may be demonstrated by a simple laboratory test, several hours being required to collect enough of the oxygen to make a satisfactory test. During the experiments the gas (oxygen) given off appeared in small amounts over the entire surface of the liquid. It was not localized at the plates.

The reactions which take place at the plates in contradiction to the above reaction, which occurs whether the plates are present or not, results in decolorizing the permanganate and in the formation of lead sulphate and manganese dioxide. The reactions are not fully understood, but the following equation, which

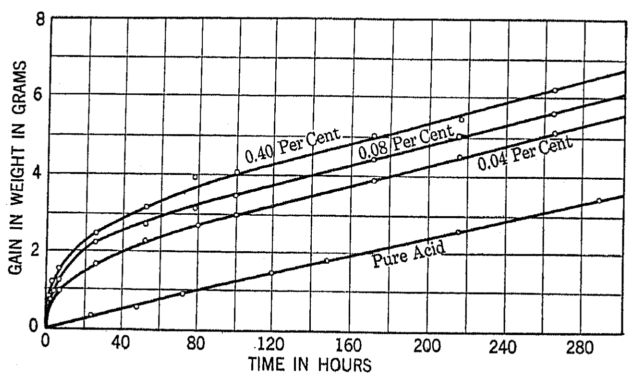

Fig. 9—Effect of Manganese on Negative Plates

is in accordance with the observed facts is believed to represent the reaction:

$$2\, K Mn O_4 + 4\, H_2 S O_4 + 3\, Pb \longrightarrow K_2 S O_4 + 2\, Mn O_2 + 3\, Pb S O_4 + 4\, H_2 O \qquad (4)$$

There are probably several intermediate reactions which take place before the end products are reached. A sludge fell to the bottom of the jar which was tested and found to be hydrated manganese dioxide. Possibly some of the manganese was converted into manganous sulphate. No gassing was visible at the plates. The equation indicates that three molecules of lead sulphate result from the reduction of 2 molecules of permanganate. The data given by the curves in Fig. 9 do not account for the amount of lead sulphate that would be expected. This is because of the spontaneous reaction expressed by equation (3) above. The permanganate in our experiments was added 18 hours before the plates were put in since we did not anticipate this reaction. The curves show a rapid sulphation of the plates for about 50 hours. Then the solution became decolorized and the curves became parallel to the curve representing the sulphation of the plates in

pure acid. The curves continued parallel during the remaining 250 hours of the experiment. The parallelism of these curves indicates that the reaction has become complete and that the manganese has been reduced to manganese dioxide and precipitated.

(b) *Positives in solutions containing manganese.* The manganese was added to the solutions as manganous sulphate, $M\,n\,S\,O_4$. The solutions were initially colorless but began to show a purple coloration almost

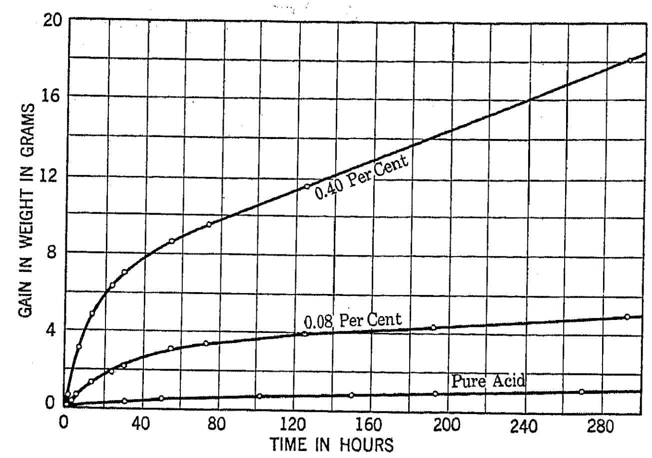

FIG. 10—EFFECT OF MANGANESE ON POSITIVE PLATES

immediately after the positive plates were immersed. This indicates the formation of permanganic acid, $H\,Mn\,O_4$, probably according to the equation

$$5\,Pb\,O_2 + 2\,Mn\,S\,O_4 + 3\,H_2\,S\,O_4 \rightarrow 2\,H\,Mn\,O_4 + 5\,Pb\,S\,O_4 + 2\,H_2\,O \quad (5)$$

The solutions containing 0.4 per cent of manganese became so dark within one hour after the plates were immersed that the plates were no longer visible.

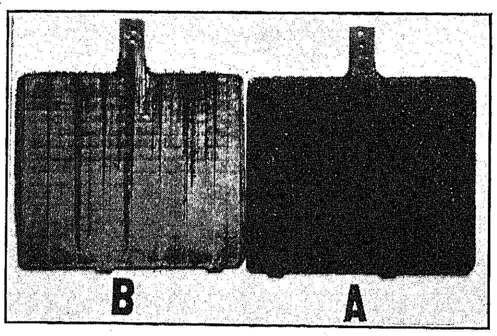

FIG. 11—POSITIVE PLATES SHOWING DEPOSIT OF MANGANESE DIOXIDE

A rapid gain in weight of the plates was observed as shown in Fig. 10. Comparing the results for both positives and negatives obtained in solutions with 0.08 per cent of manganese it was found that the gain of the positives was much larger as a result of the oxidation of the manganous sulphate than the gain of the negatives resulting from the reduction of permanganate in the same length of time. After the rapid gain during the first 50 hours, the plates continued to gain in weight at a rate somewhat more rapid than for similar plates in the pure acid solution. The rate of the gain, however, steadily decreased indicating that the reactions were becoming complete.

A deposit was formed on the plates, the sides of the glass jar, and to some extent on the surface of the liquid. The deposit on the plates after drying was a dull sooty black which filled the pores of the plates and the excess formed a rough spongy layer over most of the plate surface also. Two plates are shown in Fig. 11. Chemical analysis showed that this deposit was manganese dioxide, $Mn\,O_2$. It seems probable that the gain in weight of the plates during the first period of perhaps 50 hours is largely the lead sulphate formed as a result of oxidizing the manganous sulphate, but an important part of the total gain in weight is due to manganese

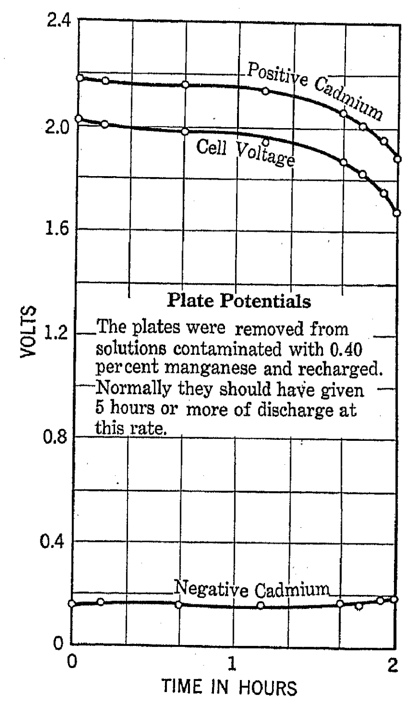

FIG. 12

dioxide deposited in the pores and on the surface of the plate. Our experiments do not permit us to estimate the relative amounts of each.

Since the tendency of the negative plates is to throw the manganese out as a sludge, it might appear that the effects of manganese would gradually disappear. This, however, is not the case as the experiments of Helen C. Gillette[4] have shown. The reason for the destructive effects of manganese are to be found in the reactions at the positive plates.

The manganese dioxide deposited upon the positive plates fills the pores of the active material and covers the plate with a non-conducting hard film in a highly oxidized state. The authors took two of the plates, a positive and a negative upon which weighings had been made

4. *Loc Cit.*

and immersed them in pure acid solution of specific gravity 1.250 and passed a charging current through them beginning with a rate somewhat below the normal finishing rate of charge. The positive began to gas immediately. Raising the charging rate to the normal value increased the gassing and the electrolyte, initially clear, began to show a purple coloration indicating the re-formation of permanganic acid. The reaction at the positive during charge might be expressed by the equation

$$2\,Mn\,O_2 + 3\,O + H_2\,O \rightarrow 2\,H\,Mn\,O_4 \qquad (8)$$

This reaction at the positive occurred more rapidly than the reduction at the negative as shown by the increasing coloration of the electrolyte due to permanganic acid. With the re-formation of permanganic acid by the charging process the battery is again put in condition for a repetition of the reactions represented by the equation (5). It should be noted that the equation for charging makes no provision for the oxidation of the lead sulphate at the positive plate. Plates that are heavily coated with $Mn\,O_2$ can receive but little charge. The pores are stopped and part of the energy is expended in the reaction on the manganese dioxide and part in the liberation of excess oxygen which normally would oxidize the lead sulphate.

After the plates had been charged, a discharge of them was made using a cadmium electrode to measure the plate potentials. These are shown in Fig. 12. These plates were discharged at the normal 5-hour rate. The positive plates, however, gave out at the conclusion of two hours. It is quite evident from an examination of the plates that the pores were stopped and that the plates could not be fully charged.

VII. Conclusion

In the case of four impurities, copper, platinum, iron, and manganese, it has been possible to determine quantitatively the effects produced by various concentrations of the impurities and to indicate to a fair degree of certainty the nature of the chemical reactions produced. In interpreting these data, particularly with reference to the drafting of specifications for sulphuric acid, two factors must be borne in mind. One of these relates to the extent of the deleterious effects produced by the impurities and the other to the amounts of the impurities which are present in the acid as produced under normal manufacturing conditions.

In the case of platinum it was shown that the presence of one part in ten million increases the local action 50 per cent over that which is found in the case of pure acid. This amount is below that which can be determined by ordinary chemical methods. The obvious conclusion, therefore, is that no platinum whatever should be allowed by the specifications. This condition can be met by the acid manufacturers at the present time.

Copper by itself produced less effect than was anticipated. It is not desirable, however, that the amount of copper to be permitted by the specifications should be raised to as large a figure as the results of these experiments might indicate to be permissible; because (1) such an amount would be unnecessarily large and in excess of the amount found in acid of good quality, (2) because copper in combination with certain other impurities is believed to be very detrimental.

Iron presents unusual interest because of its accelerating effects on the reactions at the negative plate. These experiments show that the presence of iron affects the negative plate more severely than the positive. Iron will, therefore, tend to exist in the ferrous condition in the battery and its activity is limited by the rather slow rate at which it is oxidized to the ferric condition by the positive plate and by air. Since the negative plates ordinarily exceed the positive plates in capacity the effect of iron may be minimized. Iron is, therefore, in the same category with copper in that the maximum amount to be permitted by the specifications should be determined by manufacturing conditions rather than by the effects which it produces in the battery.

Manganese deposits upon the positive plates and produces serious effects. It covers the active material of the plate, closes the pores and causes a large amount of charging current to be wasted as gas. Although the manganese is deposited on the positive plate it does not remain there, since during the charging process part of it is thrown back into the solution as permanganic acid. The results show that manganese in the electrolyte must be kept at the lowest possible figure.

This work is being extended to include the effect of other impurities. We are indebted to Drs. Blum and Lundell of the Bureau of Standards for valuable suggestions about the chemical reactions involved in this work.

Discussion

H. M. Gassman: I would like to ask a question as to whether any experiments, including the effect of uranium salts in electrolyte, have been made?

G. W. Vinal: We have not as yet made any experiments with uranium salts. We have made experiments with some of the unusual impurities, such as tungsten. We hope to include quite a wide variety of these impurities later.

H. M. Gassman: The reason I asked that question was because I understand that is the active component of some of these revivifying solutions of electrolyte.

Mr. Vinal: I have seen some of them that are supposed to contain uranium, but I don't know that uranium really does much.

These advertised solutions may really be classified under three heads, so far as our experience goes. The first is ordinary sulphuric acid, to which is added some coloring matter. The second class contains substances which are supposed to retard sulphation. Some people still have the idea that sulphation is an unmitigated evil. As a matter of fact, if the battery didn't sulphate, there would be no discharge. The third class of impurities are those which are active corrosive agents and eat into the plate and grids.

Repeated Thermal Expansions and Contractions
Their Effect on Long Armature Coil Insulations

BY T. S. TAYLOR
Member, A. I. E. E.
Research Physicist, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

THERE has been considerable discussion among engineers interested in the operation of large turbo-generators as to the possible effects of expansion and contraction on armature coil insulation. During the past ten years, generators have increased in core length from less than 100 in. to 160 in. and generators approaching 200 in. in core length are being discussed. With increasing length of cores, it has become more important to settle this question and the tests described in this paper were undertaken three years ago with this object in view. Preliminary tests were started on May 5, 1921, in order to work out some of the details of the procedure. The investigations herein described were actually started on June 2, 1922, the test coils having been prepared just previous to that time.

That some differential effect may reasonably be expected in long-core generators arises from the fact that the coefficient of thermal expansion of built-up mica and paper insulation is practically the same as that for iron[1] while the coefficient of copper is roughly 50 per cent larger. With a core length of 150 in. and an average temperature difference between copper and core teeth of 40 deg.—a usual value for high voltage windings—the difference in linear expansion between core and insulation, on the one hand, and the copper of the coils, on the other hand, will be roughly 1/32 of an inch.

Description of Apparatus and Procedure

A set of four slots was made up from punchings such as is shown in the upper part of Fig. 1. The slots were of sufficient depth to permit two insulated coils to be placed and wedged in each slot. The punchings were assembled in two sections each 54¼ in. in length including the two ⅛ in. end plates. These two sections were then placed end-on and bolted tightly together so as to constitute four slots 109¾ in. long and having the imitation vent ducts as indicated in the lower sketch of Fig. 1. There were six ½-in. imitation vents at the one end of the assembled slots; another six ½-in. vents near the middle, and three 1¼ in. vents near the middle. The positions of these vents are given on Fig. 1.

The experimental coils each had 8 square brass tubes ¼ in. by ¼ in. for conductors. Six sets of these 8 tubes were assembled into coils and insulations for a length of 118 in. with standard Westinghouse insulation for 13,200 volts according to the standard Westinghouse practise. Slight variations were made in applying the insulation in certain cases, in that the quantity of mica was varied and also in impregnating the assembled conductors before applying the insulation so as to produce a sort of slip joint. The other two coils were insulated with mica tape instead of with the regular turbo-coil insulation.

Eight thermocouples were placed with their junctions adjacent to the various conductors on each coil. There was one couple placed on each tube. There were two of these couples placed at the mid-point of the length of the coil and others at intervals of 17 in. in either direction from the middle towards the ends. These couples were

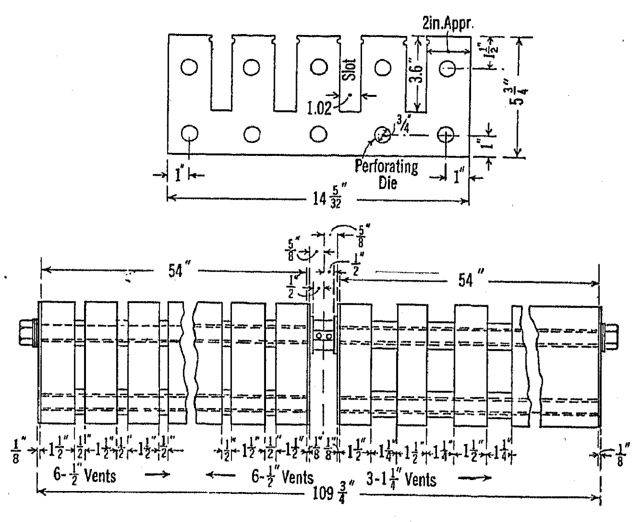

Fig. 1—Experimental Punchings for Expansion Test

made of 0.005 in. advance and copper ribbon being insulated with mica tape.

The coils after being insulated were inserted into the slots and wedged into place by the standard methods. Two coils, one over the other, were placed in each slot. The conductors of the coils were joined electrically in series. They were also joined by means of rubber tubes in parallel to air reservoirs, which were connected in series with a blower and valve. It was possible by means of the blower and valve to cool the coils by air circulation and to reverse the direction of the air through the tubes during the cooling period. The general set up is shown in Fig. 2. Some of the auxiliary apparatus used is indicated by letters on Fig. 2 and noted on the description below the figure.

The heating of the coils was produced by means of alternating current supplied by a suitable transformer.

1. This coefficient was determined by O. H. Gish of the Westinghouse Research Laboratory for Westinghouse micarta folium insulation during the early part of 1921.

Presented at the Northeastern District Regional Meeting of the A. I. E. E., Worcester, Mass., June 4-5, 1924.

The time the current was on, the starting of the blower, the reversals of the air stream or operation of the air valve, and the stopping of the blower were all controlled by means of a time contact-making device. This was so adjusted that one complete heating and cooling cycle occurred in one hour in the early experiments. In the latter part of the tests this cycle was completed each 50 min. This was the case as a result of the characteristics of the contacting device. In the early part of the tests the length of the times of heating, and cooling, and the magnitude of the heating current were so adjusted that the temperature of the conductors would reach 150 deg. cent. at their mid-points during the heating cycle, and would be cooled to approximately 100 deg. cent. during the cooling part of the cycle. The temperature of the iron stampings constituting the slot formation was so adjusted that it was approximately 100 deg. cent. This was accomplished by means of placing insulating materials over the form. Two sheets

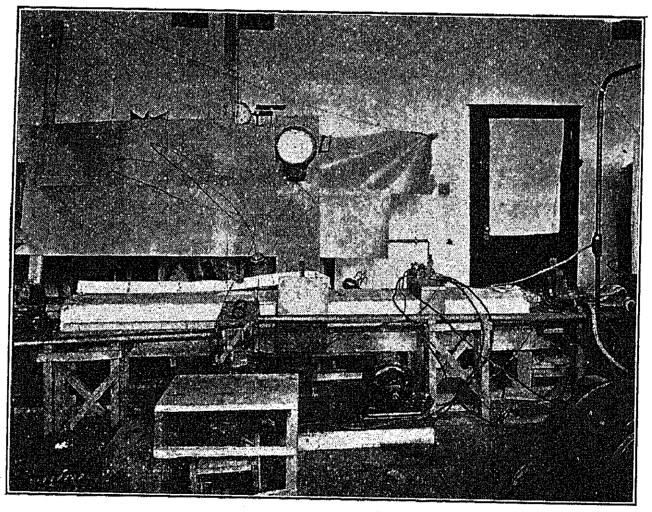

FIG. 2—LONG COIL INSULATION EXPANSION CONTRACTION DESTRUCTIVE TESTS

A —Blower
B-C—Air Valve for Reversing Direction of Air Flow
D —Recording Thermometer Used to Check Air Reversals

of regular thin sheet asbestos were found to be sufficient for this purpose.

The temperature distributions along the stampings and along the conductors before and after cooling are shown in Fig. 3. This curve shows an average temperature drop of the conductor during the cooling cycle of approximately 50 deg. cent.

The heating current was then adjusted so that this average drop in temperature of the conductors was 75 deg. cent. This particular change of temperature was such as to produce as much differential change in expansion and contraction as would be produced when a machine having coils of the length used in these tests would cool from maximum operating temperature to room temperature. The average change of 75 deg. cent. in temperature of the conductors of the coils was continued for approximately 7800 heating and cooling cycles. The insulations of the coils then still having withstood an insulation voltage test for one minute of 23,000 volts, the heating current and cycle were so changed as to obtain an average temperature change of 100 deg. cent. in the temperature of the conductors. This temperature change was continued for approximately 2500 more cycles, thus making a total of 10,300 heating and cooling cycles since the beginning of the

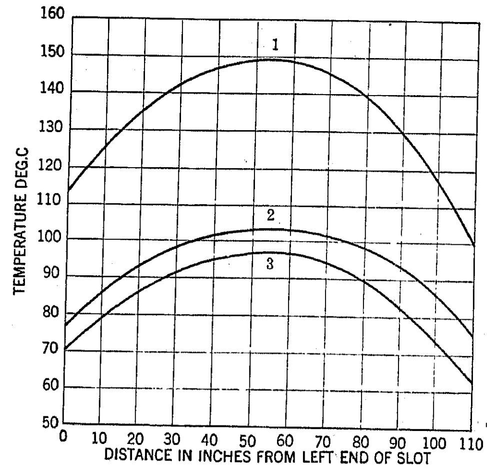

FIG. 3—TEMPERATURE DISTRIBUTION CURVES

1—Along Conductor before Cooling
2—Along Slot or Iron Stampings
3—Along Conductor after Cooling

test. The insulations still standing a voltage test of 23,000 volts for one minute, it was decided to still increase the temperature change of the conductors during the cooling cycle. To do this it was necessary to substitute water-cooling in the conductor tubes in place of the air-cooling. For this substitution, a magnetically-operated water valve was substituted for the magnetically-controlled air valve used up to this time.

Conditions of heating and cooling were so adjusted

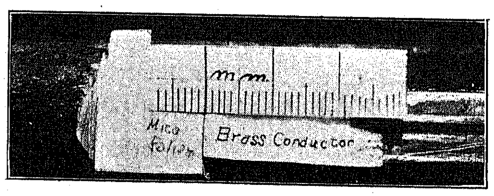

FIG. 4—RELATIVE POSITIONS OF CONDUCTOR AND INSULATION AT CLOSE OF COOLING CYCLE

that an average temperature change of the conductors of 130 deg. cent. was produced during the cooling part of the cycle. Such a change in conductor temperature was continued for approximately 825 cycles. The range of temperature change of conductors was then further increased to approximately 160 deg. cent. and was continued for approximately 400 cycles. At this point in the tests, the transformer furnishing the heating current failed on Feb. 8, 1924. The coils were tested for breakdown and after removing several inches of the

stampings from the ends of the form constituting the slots, in order to prevent sparking over the ends, it was impossible to break down the insulation of any one of the 8 coils with a voltage of 37,000. So much difficulty was encountered in preventing sparking over the ends for any higher voltage, that 37,000 was as high as was used in testing the insulation at the completion of the test.

An idea of the relative change in length of the coil insulation and the conductors during a heating and cooling cycle can be obtained by referring to Figs. 4 and 5. Fig. 4 shows the positions of the brass conduct-

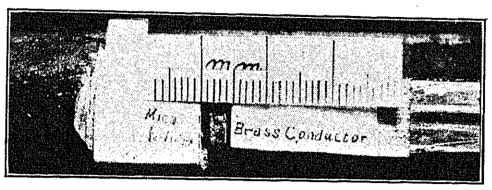

Fig. 5—Relative Positions of Conductor and Insulation at Close of Heating Cycle

ors and insulation at the close of a cooling cycle, and Fig. 5 at the close of the heating part of the cycle. These show a relative change in length of conductor and insulation of almost 5 millimeters (0.197 in.) at each end of the coils. These illustrations were made during the latter change of 160 deg. cent. of the conductors during the cooling cycle.

The following summary gives the number of cycles, the corresponding temperatures of coils at end of heating periods of each cycle, and the temperature change in the conductors during the cooling part of the cycle,

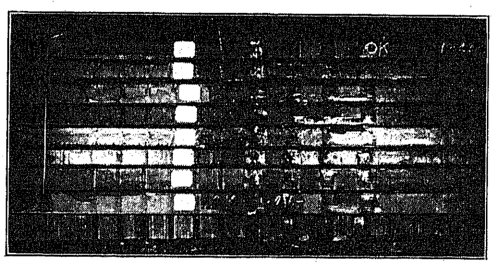

Fig. 6—Illustration of Middle Portion of Coils After Completion of Tests and Removal from Slots. Also Showing Imitation Vent Ducts in Stamping Form Constituting Slots

as well as the temperature of the iron stampings constituting the slots.

Tem. of Coil at end of heating Cycle	Temp. Drop during Cooling of Conductors	Tem. of Stampings	No. of Cycles for Temp. Range	Total No. of Cycles
150 to 160 deg. cent.	75 deg. approx.	100 deg. approx.	7800	7,800
160 to 170 deg. cent.	100 deg. "	100 deg. "	2512	10,312
150 deg.	130 deg. "	100 deg. "	825	11,137
180 deg.	160 deg. "	100 deg. "	400	11,537

After the completion of the 11,537 heating and cooling cycles and the failure of the transformer supplying the low-voltage heating current, the coils were removed from the slots and examined. Fig. 6 shows the eight coils after their removal from the slot. It is quite evident from this illustration that the paper cells which were put around the coils are completely carbonized at the middle portion of all the coils. The two coils insulated with mica tape were naturally more difficult to remove from the slots. In fact, the others were removed with considerable ease as they only bound slightly at the imitation vent ducts where the insulation had swollen slightly.

Discussion of Results

The eight samples of long coil insulation have successfully withstood the severe tests resulting from long continued heating and repeated heatings and coolings of the conductors. The range of temperature change was at first made such as would be equivalent to the differential effect produced as a result of the different coefficients of expansion of iron stampings, insulation, and brass conductors. This range of temperature change was continued for 7800 cycles, which would be as many such changes as the machine would possibly have in practise by warming up and cooling down once each day for almost 22 years. The coils were subjected to a one-third greater relative change for an equivalent of some 7 years possible heating and cooling changes. The cooling by means of water for 825 cycles and 130 deg. cent. change in conductor temperature, and for 400 cycles and 150 deg. cent. was extremely severe treatment, in that the relative changes were approximately twice as much as would be experienced in practise. These tests having extended over a period of about 20 months and the coils having been subjected to such severe treatment without failure even at 37,000 volts at the completion of the tests, indicate that all the samples of insulation were of excellent quality from both a mechanical and an electrical standpoint. Inspection of the coils after removal from the tests disclosed no places where the insulation had been sufficiently bent or folded at any vent duct so as to produce any cracking of the insulation. If such had been the case, a voltage of 37,000 would have broken down the insulation at any such points.

It might be well to mention the fact that these samples of insulation were even subjected to more severe treatment on several occasions than is to be inferred from the discussion thus far. These cases arose when the contacting device failed to operate properly at some 8 or 10 different times and thus permitted the heating current to be left on the circuit continuously and no cooling to be produced for some six or eight hours before it was discovered. At such times the temperatures of the conductors may have reached values as high as 250 deg. cent. and the iron stampings a temperature of 135 deg. cent. By looking at the coils,

it is apparent that quite high temperatures have been reached at times on account of the darkened, in fact blackened, condition of the paper, in particular at the vents in the external part of the wrappers. The discoloration was much more pronounced naturally at the middle point of the coils than at the ends. The discoloring seemed to be more pronounced on the coils which were in the lower portion of the slots as might reasonably be expected. While the paper in the insulation had very little mechanical strength left, the insulation as such was sufficiently strong mechanically to retain its form about the conductor and suffer no apparent additional destructive effect during the removing of the coils. The deterioration was very much more marked at imitation vent ducts than where it was in contact with the stampings. The paper was only just browned instead of blackened where the coil was adjacent to the stampings. The deterioration was much more pronounced also at the 1¼-in. vent ducts than at the ½-in. ducts. This is what might be expected since the wider the duct, the more readily could the air reach the paper and thus produce the effect.

Short-Circuits of A-C. Generators-II

BY C. M. LAFFOON

Associate, A. I. E. E.

Power Engineering Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—*At the mid-winter convention of the A. I. E. E. in February, 1924, the writer presented a paper on the maximum instantaneous values of the currents delivered by alternating-current generators under different short-circuit conditions. A summarized table was given for the maximum values of the short-circuit currents for different winding combinations of an ideal generator on the basis of a constant field flux, and that the short-circuit occurs at the instant the axis of the field winding coincides with the axis of the particular portion of the armature winding under consideration.*

In the present paper, a similar analysis is given for the magnitude and variation of magnitude of the short-circuit currents during the transient period, that is, during the time the currents vary from the maximum to the sustained values.

Magnitude of Short-Circuit Currents During the Transient Period

In the previous analysis of the maximum instantaneous values of the short-circuit currents delivered by a-c. generators, the shape and maximum value of the armature and field current-waves were determined, first, on the assumption that the respective circuits had zero resistance; and finally it was shown that resistance in the electric circuits of either member tends to decrease the instantaneous values of the currents, for resistance in the electric circuits necessitates a change in the flux interlinkages of the respective circuits, in order to produce at any instant electromotive forces equal to the corresponding resistance drops. The physical interpretation of the effect of resistance on the rate of decay of the short-circuit currents can be greatly facilitated by assuming that:

(1) The resistance of the armature circuit is appreciable but that of the field circuit is negligible;

(2) The resistance of the field circuit is appreciable but that of the armature circuit is zero; and

(3) The resistances of both circuits are appreciable.

Effect of armature resistance:—If only the armature circuit has appreciable resistance, the net flux interlinkages of the field circuit will be maintained constant at its initial value, but the flux interlinkages of the armature circuit must change a sufficient amount at each instant to generate an electromotive force equal to its resistance drop. In considering the case in which the armature short-circuit current wave has the maximum displacement from the zero reference axis, the total change in the initial flux interlinkages of the armature circuit will be proportional to $\int_0^{t_0} i_a \, r_a \, d\, t = K\, i_{a\,max}\, r_a\, t_0$, when the armature current has decreased to zero value, and the rotor is in the angular position $(2\,\pi - \alpha_1)$ where,

i_a = instantaneous value of the armature current;

$i_{a\,max}$ = maximum value of the armature current.

r_a = resistance of the armature circuit;

t_o = time interval in seconds corresponding to an angular change of the rotor position from 0 to $2\,\pi - \alpha_1$, *i. e.* $t_0 = K^1\,(2\,\pi - \alpha_1)$; and,

K = ratio of average to maximum value of the armature current over the portion of the wave under consideration.

Presented at the Northeastern District Regional Meeting of the A. I. E. E., Worcester, Mass., June 4-5, 1924.

Since the armature current is zero at this rotor position, the flux interlinkages of the armature circuit, due to the normal field flux will be $I_1\, M_{1a} \cos\,(2\,\pi - \alpha_1)$ or $I_1\, M_{1a} \cos \alpha_1$, and must be equal to the initial flux interlinkages of the armature circuit, minus total change required to overcome the resistance drops for this portion of the wave; that is,

$$I_1\, M_{1a} \cos \alpha_1 = I_1\, M_{1a} - \int_0^{t_0} r_a\, i_a\, d\, t = I_1\, M_{1a} - K\, i_{a\,max}\, r_a\, t_0$$

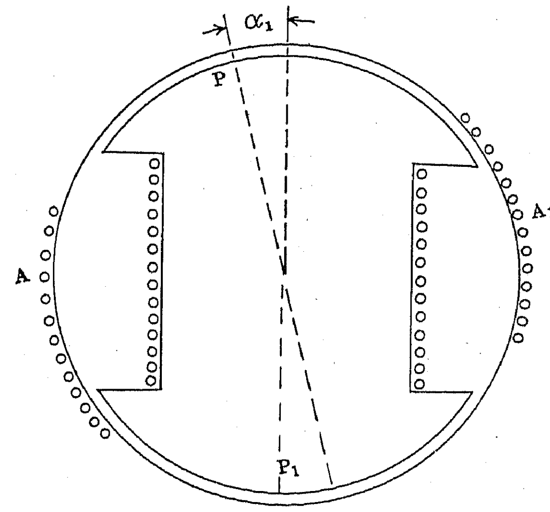

Fig. 40 a

This equation determines the approximate angular position of the rotor at the instant the armature current reaches zero value; and starting from this position, the magnitude and polarity or direction of flow of the armature current will be determined on the basis of initial flux interlinkages of $I_1\, M_{1a} \cos \alpha_1$, instead of $I_1\, M_{1a}$. As the rotor moves toward the angular position of $2\,\pi$, the field winding tends to increase the flux interlinkages of the armature circuit from $I_1\, M_{1a} \cos \alpha_1$ to $I_1\, M_{1a}$, consequently a current of opposite or negative polarity will flow in the armature circuit and resist any change in its flux interlinkages. When the rotor reaches the angular position, $2\,\pi + \alpha_1$, the mutual

flux interlinkages of the armature circuit from the field circuit are $I_1 M_{1a} \cos \alpha_1$, consequently, the armature current will again be zero. Further rotation of the rotor tends to decrease the flux interlinkages of the armature circuit and causes a current of positive polarity to flow in it. Hence, in order to offset the resistance drop, it is evident that the net flux interlinkages of the armature circuit must decrease during the positive loop, and increase during the negative loop of the current wave for each complete cycle.

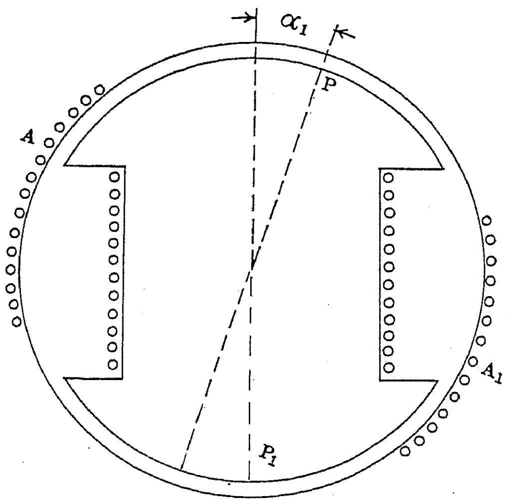

FIG. 40 B

Since the integrated flux-interlinkage change of the armature circuit is greater for the positive loops than for the negative loops, the net flux interlinkages of the armature circuit will continue to be reduced in magnitude at the end of each cycle, until the wave becomes symmetrical with respect to the zero reference axis. After the symmetrical conditions are reached, the zero values of the armature current will occur at rotor positions which correspond to odd multiples of $\frac{\pi}{2} + \theta_1$, at the instants; that is, the axis of the field winding is approximately at right angles to the axis of the armature winding. Since the initial flux interlinkages of the field winding are maintained constant, the sum of the maximum values of the positive and negative crests will be constant for any complete cycle of the current wave. When the armature current wave becomes symmetrical, the maximum values of the positive and negative loops will be one-half of the initial value that was reached at the end of the first half-cycle, and the same as the initial peak value that was reached when the short circuit occurred at the instant the axis of the field winding was at right angles to the armature winding.

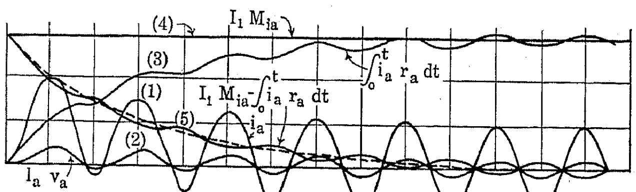

FIG. 41

In Fig. 41, the variation of the respective current and flux interlinkage quantities with respect to time are shown graphically by the following curves:—

(1) Instantaneous value of the armature current.

(2) Instantaneous value of the resistance drops in the armature circuit.

(3) Total integrated change in the armature flux interlinkages due to the resistance drops.

(4) Initial flux interlinkages of the armature circuit.

(5) Instantaneous value of the flux interlinkages of the armature circuit.

The pulsation or indentations in Curve (5) which represents the instantaneous values of the flux interlinkage of the armature circuit are of practical importance only in so far as they assist in the physical interpretation of this phenomenon. However, the average curve drawn through the points which represent the armature flux interlinkages at the beginning of each cycle is of prime importance, for it represents the rate of decrease of the flux interlinkages of the armature circuit sufficiently close for all practical purposes. This average curve does not decrease according to a straight line law, but varies according to an exponential law on account of the fact that the total integrated flux-interlinkage change is not constant but decreases for each successive cycle.

Since the sum of the peak values of the positive and negative crests of the armature current wave is constant for any cycle, it is convenient from an analytical standpoint to consider the armature current wave as being composed of a constant alternating wave super-imposed on a d-c. component, which decreases in value according to an exponential law. At the end of the first-half cycle, the d-c. component is equal to the maximum value of the alternating component and from one-quarter to one-half second later the d-c. component totally disappears. The d-c. component can be considered as produced by the rate of decay of the initial flux interlinkages of the armature circuit. Then from Helmholtz's Law, the flux interlinkages and d-c. component of the armature current will decrease according to the exponential function $E^{-\frac{r_a}{N_a} t}$ where

r_a = resistance of circuit;

N_a = equivalent leakage induction coefficient of the circuit with respect to adjacent closed circuits; and,

t = time in seconds after closure.

Effect of resistance in the field circuit:—If only the field circuit has appreciable resistance, it is evident from the previous analysis, that its total flux interlinkages at any time t_1 after the short circuit occurs, will be

$I_1 L_1 - K \int_0^t i_1 r_1 \, d t$ and in the case of polyphase alternators will continue to decrease until its mutual flux interlinkages with the armature circuit are equal to the leakage flux interlinkages of the armature circuit. Hence, for any angular position of the rotor, the change (due to rotation) in the normal field flux interlinkages will also be decreased and the maximum values of the armature current, which occur at rotor positions that are odd multiples of π, will decrease in the same ratio. When the rotor is in the angular position that are even multiples of π, its mutual flux interlinkages with the armature circuit will continually decrease in value. Since the resistance of the armature circuit is zero, currents of positive value will flow in the armature circuit at these rotor positions, in order to maintain its flux interlinkages constant at the initial value. The curves in Fig. 42 show:

(1) Initial value of field flux interlinkages.

(2) Instantaneous value of the flux interlinkages of the field circuit.

(3) Instantaneous values of the circulating current in the field circuit.

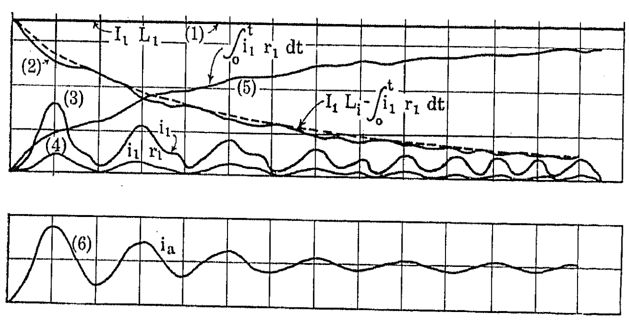

FIG. 42

(4) Instantaneous values of the resistance drops in the field winding.

(5) Instantaneous value of $\int_0^{t_1} i_1 r_1 \, d t.$;

(6) Instantaneous values of the armature current.

Then from Helmholtz's Law, the average curve which shows the flux interlinkages of the field circuit at the beginning of each cycle varies according to $I_1 K (1 + A E^{-\frac{r_1}{N_1} t})$ where

$I_1 L_1 = I_1 K (1 + A)$ = initial flux interlinkages of the field circuit.

$I_1 K_1$ = final flux interlinkages of the field circuit.

Y_1 = resistance of the field circuit.

N_1 = equivalent induction coefficient of the field circuit.

In this case the armature current can be considered as being composed of an alternating component, which decreases in value, super-imposed on a constant d-c. component. The alternating component, which has a maximum value $i_{a max} = I_a (1 + A)$, at the end of the first half-cycle after the short-circuit occurs, decreases according to the above exponential function, $(1 + A E^{-\frac{r_1}{N_1} t})$, until it reaches a final or sustained value, I_a, a few seconds later. The d-c. component remains constant, for there is no change in its initial flux interlinkages.

Effect of resistance in armature and field circuits:— If both armature and field circuits have appreciable resistance, the flux interlinkages of the armature circuit will decrease from their initial value at the instant of the change from short-circuit to zero, according to the exponential law $E^{-\frac{r_a}{N_a} t}$, and the field flux interlinkages will decrease from the maximum value before the short circuit occurs, to a final or sustained value according to the exponential law $(1 + A E^{-\frac{r_1}{N_1} t})$. Then at any instant, the d-c. component of the armature current can be represented by $I_{dc} E^{-\frac{r_a}{N_a} t}$; the peak values of the alternating component will be on the curve determined by the exponential function $I_{acs} (1 + A E^{-\frac{r_1}{N_1} t})$ and the total peak values of the armature current will lie on the curve, which is determined by the sum of the two exponential functions, $I_{dc} E^{-\frac{r_a}{N_a} t} + I_{acs} (1 + A E^{-\frac{r_1}{N_1} t})$ where,

I_{dc} = maximum value of the direct current component.

I_{acs} = maximum value of the armature current under sustained conditions.

$I_{acs} (1 + A)$ = maximum value of the alternating current component at the end of the first half cycle; and all other symbols are as previously defined.

If the instantaneous values of the alternating component vary sinusoidally with respect to time, the r. m. s. value of the armature current for any given cycle will be

$$I_{r.m.s.} = \left\{ \frac{1}{2 \pi} \int_0^{2\pi} [I_{dc} E^{-\frac{r_a}{N_a} t} + I_{acs} (1 + A E^{-\frac{r_1}{N_1} t}) \cos \omega t] \, d t \right\}^{1/2}$$

$$= \left\{ [I_{dc} E^{-\frac{r_a}{N_a} t}]^2 + \left[\frac{I_{acs} (1 + A E^{-\frac{r_1}{N_1} t})}{2} \right]^2 \right\}^{1/2}, \text{ approximately.}$$

Hence, for any given initial short-circuit conditions, instantaneous peak and r. m. s. values of the armature currents can be calculated, provided the resistance and equivalent-leakage induction coefficients of the respective circuits are known. In the preceding analysis, which covered the maximum possible value of the short-circuit currents, it was shown that the combined equivalent-leakage inductance coefficient of the armature circuit was approximately constant and equal to

$L_a - \dfrac{M_{1a}^2}{L_1}$ when the rotor was provided with a damper winding, but this induction coefficient pulsated at double frequency between maximum and minimum values,

L_a, and $L_a - \dfrac{M_{1a}^2}{L_1}$ respectively, if the rotating element did not have a damper winding. It is obvious, from analogy, that the similar induction coefficient of the field winding will be approximately constant and equal

to $L_1 - \dfrac{M_{1a}^2}{L_a}$ when the stator member is provided with polyphase windings, but will pulsate at double frequency between maximum and minimum values, L_1, and

$L_1 - \dfrac{M_{1a}^2}{L_a}$ respectively, for an a-c. generator with a single-phase armature winding. It can be shown mathematically that, so far as the rate of decrease of the short-circuit currents is concerned, the double-frequency pulsating equivalent-leakage inductance coefficients for either the armature or field circuits can be replaced by an effective coefficient which is constant

and equal to $K\left(L_{1 or a} - \dfrac{M_{1a}^2}{L_{a or 1}}\right)$ where the value of

the constant K is between 1 and 2[1]. Table II shows the relative values of the time constants for the armature and field circuits for polyphase and single-phase generators when the rotors are constructed with and without damper windings.

In the above table the actual value of the constant K depends on the effectiveness of the material and construction of the rotor or stator as a partial damper winding. It is obvious that the time constants for the different electric circuits of actual generators can be calculated with only an approximate degree of accuracy. However, the most important and definite conclusions to be drawn from the above data are:

(1) In the case of either single-phase or polyphase alternators, the addition or presence of the damper winding on the excitation element increases the rate of decrease of the d-c. component of the armature current.

(2) The presence of the damper winding does not affect the rate of decay of the alternating component of the armature short-circuit current for polyphase alternators.

(3) The rate of decrease of the a-c. component of the armature short-circuit current delivered by a single-phase alternator either with or without a damper winding is lower than that of a polyphase alternator.

TABLE II

Permanent or Sustained Value of the Short-Circuit Current

Sustained Short-Circuit Current of Polyphase Alternators. In the case of polyphase alternators the armature currents reach final or sustained values a few seconds after the short circuit occurs and the excess circulating current in the field winding totally disappears. The sustained armature current waves are symmetrical with respect to a zero reference axis and are equal in amplitude, but displaced in phase with respect to each other. Since the resistance of the armature circuit is very small in comparison to the reactance, the armature currents lag approximately 90 deg. behind the induced voltages and the resultant armature m. m. f., which is approximately constant in shape and magnitude, is directly opposed to the m. m. f. of the field circuit. Consequently, the net field flux that interlinks the armature windings is just sufficient to neutralize the leakage flux interlinkages of the armature circuits. Then the magnitude of the sustained armature currents will be such that the total flux interlinkages of the armature circuits are equal to the total mutual flux interlinkages supplied to them from the field circuit.

In the case of a two-phase alternator the magnitude of the resultant armature m. m. f. wave is approximately equal to the m. m. f. of one phase acting alone when the current in this phase is at its maximum value. When the rotor is in such angular position that the axes of the field winding and phase A of the armature winding coincide, the induced voltage in phase A is zero and the current flowing in it is at its maximum value. Similarly, the current in phase B is zero and the voltage is at its maximum value. Consequently, the flux interlinkages of phase A due to ${}_{2\phi}I_a$ must equal the total mutual flux interlinkages that are supplied to it by the field winding. That is,

$${}_{2\phi}I_a\, L_{a_{2\phi}} = I_1\, M_{1a}\,, \text{ or}$$

$${}_{2\phi}I_a = \frac{I_1\, M_{1a}}{L_{a_{2\phi}}} \qquad (47)$$

If the reluctance of the magnetic circuit does not change for different rotor positions and the m. m. f. waves of the armature circuits are sinusoidal with respect to space and time, the r. m. s. value of the armature current is

$${}_{2\phi}I_a = \frac{I_1\, M_{1a}}{\sqrt{2}\, L_{a_{3\phi}}}\,.$$

In the case of a three-phase alternator, the sustained short-circuit current is a maximum in phase A, and at one-half of the maximum value in phases B and C when the axis of the field winding coincides with the axis of phase A of the armature winding. The mutual flux interlinkages of the armature windings, due to the field circuit, are $I_1 M_{1a}$ for phase A, and $\frac{1}{2} I_1 M_{1a}$ for phases B and C respectively or a combined value of $2\, I_1 M_{1a}$ for all three phases. If the maximum value of the current in phase A is ${}_{3\phi}I_a$, the total flux interlinkages of the armature winding, due to their own currents, are approximately ${}_{3\phi}I_a\,(2\, L_{a_{3\phi}} + 2\, M_{ab})$ where $L_{a_{3\phi}}$ is the total inductance coefficient of one leg of the armature winding and M_{ab} is the mutual inductance coefficient between any two legs of the armature winding. Since the total flux interlinkages of the armature windings must be equal to the total mutual flux interlinkages from the field circuit,

$${}_{3\phi}I_a\, 2\,(L_{a_{3\phi}} + M_{ab}) = 2\, I_1\, M_{1a}\,, \quad \text{or}$$

$${}_{3\phi}I_a = \frac{I_1\, M_{1a}}{L_{a_{3\phi}} + M_{ab}}$$

But $M_{ab} = \frac{1}{2} L_{a_{3\phi}}$, approximately and then

$${}_{3\phi}I_a = 0.667\, \frac{I_1\, M_{1a}}{L_{a_{3\phi}}} \text{ approximately} \qquad (48)$$

$${}_{3\phi}I_a = \frac{0.667}{\sqrt{2}}\; \frac{I_1\, M_{1a}}{L_{3\phi}} \text{ approximately} \qquad (48a)$$

In comparing the ratios of the sustained short-circuit currents to the full-load currents for two and three-phase generators which have the same rating, terminal voltage, and constant field flux per pole, the armature conductors per inch for the two-phase winding must be 122.5 per cent of those for the three-phase winding. If $I_1 M_{1a}$ = maximum mutual flux interlinkages of armature phase A due to the field current,

$\sqrt{3}\, I_1 M_{1a}$ = maximum mutual flux interlinkages of two legs of the three phase winding connected in series for the star type of winding.

$\sqrt{3}\, I_1 M_{1a}$ = magnitude of mutual flux interlinkages of one phase of two-phase winding in order to give the same voltage as a three-phase star type of winding.

If both windings had the same armature conductors per inch, the total inductance coefficient of one leg of the two-phase winding would be twice that of one leg of the three-phase winding, as shown by Curve (1) of Fig. 19. Since the conductors per inch for the two-phase winding are 122.5 per cent of those for a three-phase winding, the total inductance coefficients of one leg of the two-phase winding will be three times that of one leg of the three-phase winding. That is,

$$L_{a_{2\phi}} = \overline{1.225}^2 \times 2\, L_{a_{3\phi}} = 3\, L_{a_{3\phi}}$$

Then from equations (47) and (48) the sustained short-circuit currents will be

$${}_{3\phi}I_a = 0.667\, \frac{I_1\, M_{1a}}{L_{a_{3\phi}}}$$

for the three-phase winding, and

$${}_{2\phi}I_a = \frac{\sqrt{3}\, I_1\, M_{1a}}{3\, L_{a_{3\phi}}} = 0.577\, \frac{I_1\, M_{1a}}{L_{a_{3\phi}}}$$

for the two-phase winding. The maximum values of the full-load currents for the two windings have the following relation,

$${}_{2\phi}I_{aF.L.} = 0.866\; {}_{3\phi}I_{aF.L.}$$

Then the ratios of the sustained short-circuit currents to the corresponding full-load currents for the two windings will be,

$$\frac{{}_{3\phi}I_a}{{}_{3\phi}I_{aF.L.}} = \frac{0.667\,\dfrac{I_1\,M_{1a}}{L_{a_{3\phi}}}}{K\,I_1\,M_{1a}} = \frac{0.667}{K\,L_{a_{3\phi}}}$$

for the three-phase winding,

$$\frac{{}_{2\phi}I_a}{{}_{2\phi}I_{aF.L.}} = \frac{0.577\,\dfrac{I_1\,M_{1a}}{L_{a_{3\phi}}}}{0.866\,K\,I_1\,M_{1a}} = \frac{0.667}{K\,L_{a_{3\phi}}}$$

for the two-phase winding.

In the construction of actual machines, it is very improbable that the two and three-phase generators, designed to deliver the same terminal voltage, would be identical in every respect except armature conductors per inch, consequently, it is to be expected that ratios of sustained to full-load current will be slightly different for the two cases.

Sustained Short-Circuit Current of Single Phase Alternators. The magnitude of the sustained short-circuit current is more difficult to determine analytically for a single-phase generator than for a polyphase generator, on account of the fact that the leakage and mutual induction coefficients of the armature winding are neither constant in magnitude nor position with respect to the field winding. If the rotor of the single-phase generator is provided with a polyphase damper winding, then under either stable load or sustained short-circuit conditions, double-frequency currents will flow in the damper winding, the armature current wave will be practically sinusoidal in shape, and there will be no appreciable variations in the field flux or pulsations in the field current. A simple physical and quantitative analysis can be obtained by making the usual assumption that alternating flux, flux interlinkages and m. m. f. of the single-phase armature winding can be resolved into two components which are of constant shape and equal magnitude, but rotate in opposite directions at synchronous speeds. The component of the armature m. m. f. which has the same direction of rotation as the rotor, maintains a fixed space relation with respect to the field winding and produces a demagnetizing action on the field circuit just as in the case of a polyphase alternator under similar load conditions. The backward rotating component of the armature m. m. f. moves at double speed with respect to the rotor and consequently induces double-frequency currents in the damper winding. The m. m. f. produced by the double-frequency currents in the damper winding rotates synchronously with and directly opposes the counter-rotating component of the armature m. m. f. and the resultant flux interlinkages are the equivalent leakage flux interlinkages of the two windings, due to the two corresponding and opposing m. m. f's. Hence, under sustained short-circuit conditions, the magnitude of the armature current will be such that the total flux interlinkages of the forward rotating component, plus the total equivalent combined leakage flux interlinkages of the armature and damper windings, due to the backward rotating components, will be equal to the mutual flux interlinkages supplied by the field circuit.

When the rotor is in such angular position that the axes of the armature and field windings coincide, the armature current will be at its maximum value and can be readily calculated, if the proper induction coefficients are known for this rotor position.

If,

I_a = maximum value of the sustained single-phase short-circuit current;

L_a = total self-induction coefficient of the armature circuit;

M_{1a} = mutual induction coefficient of the armature and field circuits;

L_b = total self-induction coefficient of the damper winding;

M_{ab} = mutual induction coefficient of armature and damper circuits;

$L_a - \dfrac{M_{ab}^2}{L_b}$ = total equivalent leakage induction coefficient of the armature and damper circuits;

$I_1\,M_{1a}$ = total flux interlinkages of the armature circuit supplied by the field circuit;

$I_a\,L_a$ = total flux interlinkages of the single-phase armature winding;

$\tfrac{1}{2}\,I_a\,L_a$ = total flux interlinkages of the armature circuit due to the forward rotating component;

$\tfrac{1}{2}\,I_a\left(L_a - \dfrac{M_{ad}^2}{L_d}\right)$ = total combined leakage flux interlinkages of the armature circuit, due to the backward rotating component;

Then,

$$\tfrac{1}{2}\,I_a\left[\,L_a + \left(L_a - \frac{M_{ad}^2}{L_d}\right)\right] = I_1\,M_{1a}$$

$$I_a = \frac{2\,I_1\,M_{1a}}{L_a + \left(L_a - \dfrac{M_{ad}^2}{L_d}\right)} \tag{49}$$

$${}_{1\phi}I_{aW.D.} = \frac{1}{\sqrt{2}}\;\frac{2\,I_1\,M_{1a}}{L_a + \left(L_a - \dfrac{M_{ad}^2}{L_d}\right)}$$

If the rotating element of a single-phase generator is not provided with a damper winding and the construction of the rotor is such that the rotor material does not act as a squirrel cage winding, the field winding will act as a single-phase damper winding. Oscillographic records show that the odd numbered harmonics are very pronounced in the armature current wave and the

even numbered ones in the field current, when operating under either stable load or sustained short-circuit condition. A qualitative analysis of the phenomenon can be obtained by making the assumption as in the previous case, that the single-phase alternating armature flux and m. m. f. waves can be replaced by two equal and oppositely rotating waves of constant shape and magnitude. The forward-rotating component maintains a fixed space relation with respect to the field winding and reacts on it as in the case of a polyphase winding. The backward rotating component produces double-frequency currents in the field winding. This double-frequency flux or m. m. f. wave of the field winding can in turn be considered as being produced by two equal waves of constant magnitude which rotate in opposite directions at twice synchronous speed. The backward rotating wave of the field winding maintains a fixed space relation with the backward rotating wave of the armature and the resultant flux interlinkages are the combined leakage flux interlinkages of the two windings, due to the two opposing m. m. f. waves. The forward rotating wave of the field winding moves at three times synchronous speed with respect to the armature winding and consequently, produces triple-frequency currents in it. The triple-frequency alternating flux and m. m. f. waves of the armature winding can be considered as produced by equal waves which rotate in the opposite direction at three times synchronous speed. The forward rotating component maintains a fixed relation with the forward-rotating double-synchronous-speed wave of the field winding and exerts a polyphase reaction on it. The corresponding backward-rotating component of the armature triple-frequency wave moves at four times synchronous speed with respect to the rotor and produces a quadruple-frequency current in the field winding. It is evident from the foregoing analysis that all of the odd harmonics will be reflected into the armature circuit and the even harmonics into the field circuit, but the amplitude of the harmonics of both circuits rapidly decreases as the frequency increases.

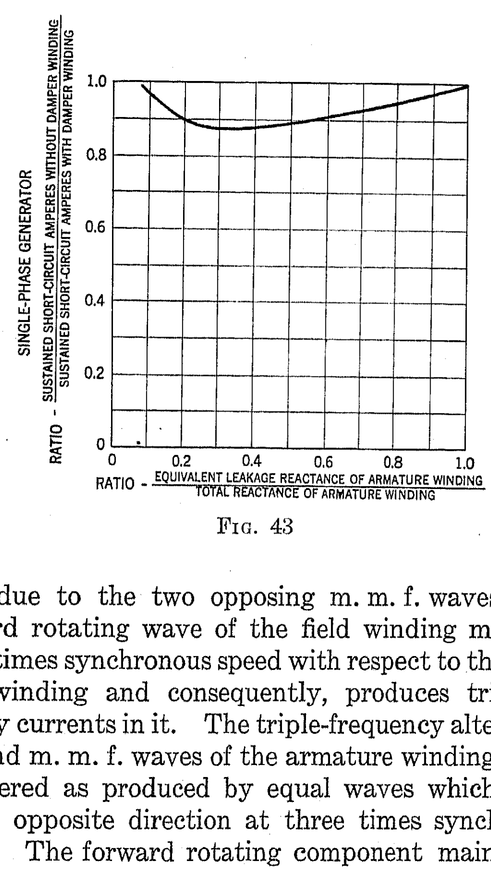

FIG. 43

A less involved quantitative analysis of the magnitude of the currents can be obtained by solving the two simultaneous equations of the flux interlinkages for the two circuits.

$$\left.\begin{aligned} I_a{}^1 L_a + (l_1 + I_1)\, M_{1a} &= 0, \text{ for the armature circuit,} \\ I_a{}^1 M_{1a} + (i_1 + I_1)\, L_1 &= I_1 L_1 K, \text{ for the field circuit} \end{aligned}\right\} \qquad (50)$$

The solution of these equations and the determination of the value of the quantity K gives[2]

$$I_a{}' = \frac{I_1 M_{1a}}{L_a} \sqrt{\frac{L_a}{L_a - \dfrac{M_{1a}{}^2}{L_1}}}$$

for the maximum value of the armature current,

$$_{1\phi}I'_{aN.D.} = \frac{I_1 M_{1a}}{\sqrt{2}\, L_a} \sqrt[4]{\frac{L_a}{L_a - \dfrac{M_{1a}{}^2}{L_1}}}$$

for the effective value of the armature current. The curve in Fig. 43 shows, graphically, the variation of the sustained current ratio $\dfrac{_{1\phi}I_{aN.D.}}{_{1\phi}I_{aW.D.}}$ as a function of

$$\frac{L_a - \dfrac{M_{1a}{}^2}{L_1}}{L_a}$$ where,

$_{1\phi}I_{aN.D.}$ = the calculated effective value of the sustained current for a single-phase generator without a damper winding;

$_{1\phi}I_{aW.D.}$ = the calculated effective value of the sustained current for a single-phase generator with a damper winding;

$L_a - \dfrac{M_{1a}{}^2}{L_1}$ = equivalent leakage induction coefficient of the armature and field windings;

L_a = total self-induction coefficient of the armature winding;

$L_a - \dfrac{M_{1a}{}^2}{L_1} = L_a - \dfrac{M_{ad}{}^2}{L_1}$, assumed relation used in this comparison.

The value of the sustained current of the single-phase generator without a damper winding is only 12½ per cent less than that of a generator with a damper winding, at the point of widest variation over a wide working range, 0.1 to 0.5, of the inductance ratios. In actual manufacturing practise it is practically impossible to construct a generator with a perfect damper winding or one without partial damping action, consequently there should be only a small expected difference in the sustained r. m. s. current values of

2. See paper on Electromagnetic Phenomena resulting from the sudden short-circuiting of an Alternator by P. Boucherot, 1912 *Atti del Congresso Internationale delle Applicazioni Elettriche.*

similar single-phase generators, when equipped either with or without a definite damper winding. Hence, in estimating the r. m. s. values of the sustained short-circuit current for a single-phase generator, it is sufficiently accurate for all practical purposes to use the formula which was developed for the care of the generator with a damper winding, namely:

$$ {}_{1\phi}I_{aW.D.} = \frac{1}{\sqrt{2}} \times \frac{2\, I_1\, M_{1a}}{L_a + L_a - \dfrac{M_{ad}^2}{L_d}} $$

$$ = \frac{\sqrt{2}\, I_1\, M_{1a}}{L_a\,(1 + K)}\ , \text{ Where } K = \frac{L_a - \dfrac{M_{ad}^2}{L_d}}{L_a} $$

It is apparent from the data given on the curves of Figs. 18 and 19 that the single-phase sustained short-

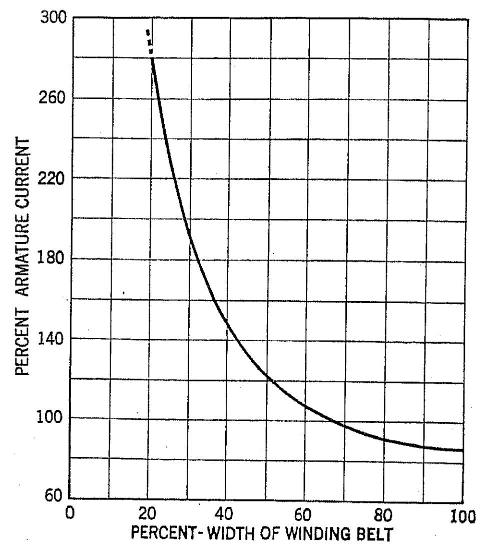

FIG. 44—CALCULATED SUSTAINED CURRENT FOR SINGLE-PHASE GENERATOR

circuit current between terminal and neutral of a three-phase generator is

$$ {}_{1\phi}I_{aT\text{-}N} = \frac{\sqrt{2}\, I_1\, M_{1a}}{L_{aT\text{-}N}\,(1 + K)} \quad \text{and} \qquad (51) $$

$$ {}_{1\phi}I_{aT\text{-}T} = \frac{\sqrt{2}\,\sqrt{3}\, I_1\, M_{1a}}{3\, L_{aT\text{-}N}\,(1 + K)} \qquad (52) $$

where the single-phase short circuit occurs between two line terminals of a three-phase star-connected winding. Then

$$ \frac{{}_{1\phi}I_{aT\text{-}N}}{{}_{1\phi}I_{aT\text{-}T}} = \frac{\dfrac{\sqrt{2}\, I_1\, M_{1a}}{L_{aT\text{-}N}\,(1 + K)}}{\dfrac{\sqrt{2}\,\sqrt{3}\, I_1\, M_{1a}}{3\, L_{aT\text{-}N}\,(1 + K)}} = \sqrt{3}. $$

That is, the sustained value of the single-phase current between terminal and neutral is $\sqrt{3}$ times that between two line terminals of a star-connected three-phase generator. The curve in Fig. 44 shows the relative magnitude of the sustained currents for different circumferential widths of the single-phase winding belt on the basis of a constant value of armature conductors per inch of the armature periphery.

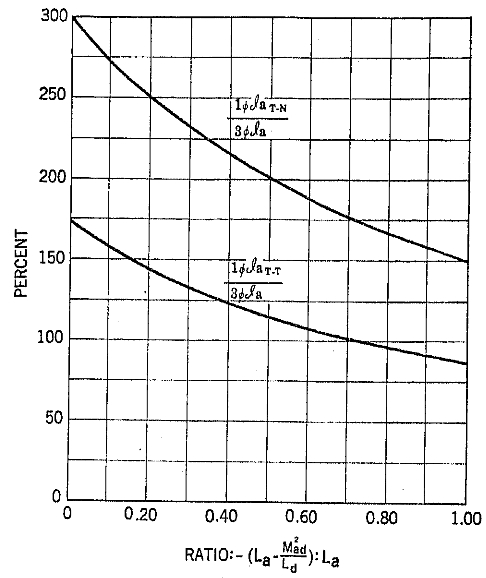

FIG. 45

Test Values of Sustained Short-Circuit Currents. The curves in Fig. 45 show the ratios of the single-phase to the three-phase sustained short-circuit currents as calculated from equations (**48a**), (**51**) and (**52**), for different values of K, where K

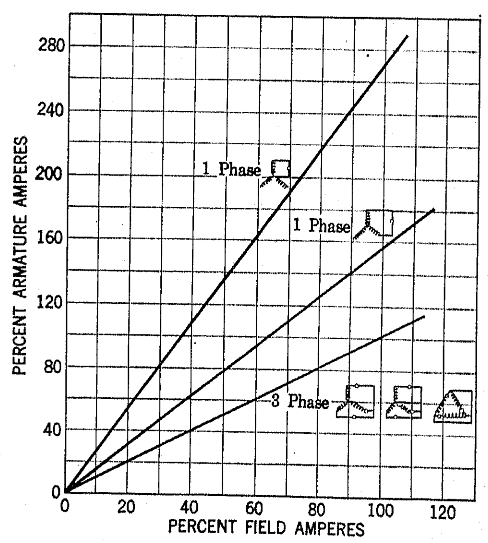

FIG. 46—SUSTAINED SHORT-CIRCUIT CURRENTS FOR 6250 KV-A TURBO-GENERATOR 3-PHASE 2-POLE 3600-REV. PER MIN.

$$ = \frac{\left(L_a - \dfrac{M_{ad}^2}{L_d}\right)}{L_a} $$ (that is the ratio of the equivalent leakage induction coefficient of one leg of the arma-

ture winding and the damper winding when the axes of the two windings coincide, to the total self-induction coefficient of one leg of the armature winding). The curves in Fig. 46 show the test values of the sustained armature winding currents and the corresponding field currents for a 6250-kv-a., three-phase, 60-cycle, 3600-rev. per min. turbo-generator when operating under the following short-circuit conditions:

(a) Single-phase short circuit between
  (1) Terminal and neutral
  (2) Terminal and terminal.

(b) Three-phase short circuits between
  (1) Terminals with the winding star-connected
  (2) Terminals and neutral with the winding star-connected
  (3) Terminals with the winding delta-connected

The equivalent leakage induction coefficient of this particular generator is approximately 15 per cent of the total self-induction coefficient of one leg of the armature winding. Using this approximate value of 15 per cent, the calculated values from the curves in Fig. 19, and the test values of the ratios of the sustained currents for the different short-circuit conditions are as follows:

	Test	Calculated
(1) Single-phase terminal and neutral to terminal and terminal	1.72	1.732
(2) Single-phase terminal and neutral to three-phase star or delta	2.69	2.61
(3) Single-phase terminal and terminal to three-phase star or delta	1.56	1.51

Single-Phase Motor-Torque Pulsations

BY A. L. KIMBALL, Jr. and P. L. ALGER[1]
Associate, A. I. E. E. Member, A. I. E. E.
Both of General Electric Co., Schenectady, N. Y.

Review of the Subject.—*This article gives results of a study of the vibrations of small single-phase induction motors, with a view to determining their causes and eliminating the noise which they produce. The possible sources of such vibrations were analyzed, and an experimental study was made in which the principal cause was definitely determined to be the double-frequency variation of the electromagnetic torque developed by the motor. This variation of torque is fairly obvious when it is considered that the power input to the motor is pulsating and the output is uniform, but it was found that the torque variation at no-load was also very pronounced, a fact which does not seem to have been previously described. A description of the experiments made, a theoretical analysis of the torque variations, and a comparison of test with calculated results are given.*

I. Introduction

THE small single-phase induction motor has recently come to be widely used in household and office appliances, where noise is particularly objectionable. It has been found that these motors are noisy when placed upon a table or other support but are comparatively quiet when held suspended in the air. Since different opinions were held as to the causes and remedies for this noise, the writers undertook an experimental and theoretical study of the matter. In this investigation, it was satisfactorily proved that the principal vibration was torsional in character, of double the line frequency, and electromagnetic in its origin. In other words, the vibration results from a torque which pulsates through a wide amplitude, even when the motor is running light. This torque pulsation reacts upon the stator and causes it to oscillate through a small angle about the motor shaft as an axis, thus transmitting vibrations to the base upon which the motor is mounted.

II. Experimental Study

In order to distinguish between the vibrations caused by the mechanical reactions of an imperfectly balanced rotor and those caused by electromagnetic phenomena, the following test was made. A 25-cycle ¼-h. p. single-phase induction motor was placed on a light board base resting on several layers of thick felt. On running the motor, the board base readily took up the vibrations of the motor stator, because of the small inertia of the board compared with that of the motor, and because of the yielding quality of the felt upon which it rested. At normal voltage the motor vibrated very noticeably. On raising the voltage the vibrations of the motor became much more intense. When the voltage was reduced to a low value, it was found that a certain amount of vibration still remained and that no change in this amount resulted immediately after opening the motor circuit.

Since the no-load speed of rotation of an induction motor is practically constant, independent of the voltage, any vibration due to mechanical unbalance should be unaffected by voltage variations. Thus, the tests showed that the motor vibration was due in part to mechanical unbalance, which persisted down to the lowest voltage, and in part to electromagnetic forces which increased with the voltage.

As the frequency of a vibration due to mechanical unbalance is known to be equal to the number of revolutions per second, the above conclusions were verified by measuring the vibration frequencies. A sheet of paper was placed on the light baseboard with two parallel lines drawn upon it about four inches apart. A long pencil with a sharp point was held lightly in the fingers and drawn across the paper so that it passed over the space between the lines in about a second's time, describing at the same time a series of dots. Since each dot was produced by a single vibration of the base, the number of dots between the two parallel lines gave approximately the number of vibrations per second. From this method of measurement it was found that the frequency of the vibration remaining at low voltage was closely equal to the frequency of rotation. Furthermore, it was found that when a rotor was given a very careful running balance, this type of vibration could be practically eliminated, thus definitely proving it to be due to mechanical unbalance.

After obtaining a good running balance, so that the motor was almost free from vibration at very low voltages, a further study of the electromagnetic vibrations was made. A 25-cycle motor was chosen, because of its great vibration amplitude. Placing it upon a light board resting on felt as before, the vibration frequency was found to be approximately twice line frequency, or 50 cycles per sec., using the dotted line method previously described. Also, preliminary measurements made with a vibration amplitude indicator gave amplitudes approximately proportional to the square of the voltage. This would be expected of a vibration of electromagnetic origin, since the magnetic forces vary approximately as the voltage squared, below magnetic saturation.

The motor was then suspended in such a way that it could vibrate almost perfectly freely in space, without even so small a resistance as that offered by the felt. This was accomplished by placing the motor in a cradle

1. The authors wish to express their appreciation of the many suggestions and cordial cooperation of A. F. Welch and E. B. George in carrying out the work on which this paper is based.

Presented at the Northeastern District Regional Meeting of the A. I. E. E., Worcester, Mass., June 4-5, 1924.

as shown in Fig. 1, so designed as to allow any sort of a translational or rotational motion without appreciable restraint. Its freedom of motion was facilitated by suspending it from cords attached to points P and Q which were nearly at the height of the center of gravity of the motor, and hanging these cords from the end of a flexible cantilever.

When a rotor in good static balance was placed on the cradle as shown in Fig. 1 and tested at very low voltage, the center line A B of the cantilever was found to be perfectly still, since the center of gravity of the motor remained fixed in space. However, in many such cases, the cantilever took up a torsional vibration with A B as a nodal line, the right and left arms vibrating up and down. This was evidently due to dynamic unbalance, so called because it can only be detected by a test in which the motor is actually rotating. It is manifested by a tilting or wobbling motion of the shaft, the center of gravity of the rotor remaining fixed.

After a rotor was given complete running balance,

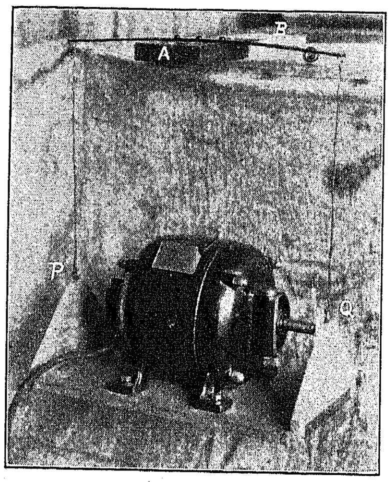

FIG. 1—MOTOR ON CRADLE SUSPENSION

it was found that all vibration of the cantilever disappeared. In short, by this method of suspension mechanical unbalance could be detected as to character and approximate magnitude. When a rotor was given no careful balance, both an up and down and a torsional motion of the cantilever were observed.

When a very carefully balanced 25-cycle motor was suspended in the cradle, the vibrations appearing as the voltage was raised were found to be always characterized by the appearance of a nodal line along the baseboard upon which no vibration could be felt. However, when the motor was placed in the cradle, this line of no vibration was found to lie centrally under the shaft, while elsewhere vibrations occurred of severity proportionate to the voltage, which increased in direct ratio with the radial distance from this nodal line. This indicated the presence of a torsional vibration through a small angle about an axis parallel to the shaft, and since a rigid body performing such a vibration must oscillate about its center of gravity, it can immediately be concluded that this axis coincides with the shaft itself. The vibration could be shown to be purely torsional with no transverse components, by observing that even with high voltages producing a very strong vibration of the base, no vibration of the cantilever could be detected with the motor placed with its axis at right angles to the cantilever as shown in Fig. 1.

When the motor was turned 90 deg. so that its axis was crosswise, a node of zero up and down vibration of the board appeared as before along the line directly under the motor shaft. The ends of the board, however, vibrated up and down, communicating their motion to the suspending cords and setting the cantilever in torsional vibration about A B as an axis.

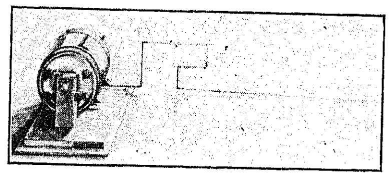

FIG. 2—MOTOR IN TRUNION SUPPORTS

Having obtained this experimental proof of the existence of a torsional vibration of the motor stator about the shaft as an axis, the next step was to find the magnitude of the vibration angle and how this angle varied with the applied voltage.

Bearing surfaces, concentric with the shaft, were turned on the outsides of the bearing housings of the motor M (Figs. 2 and 3), and the stator was then supported by these bearings in a pair of trunnions T,

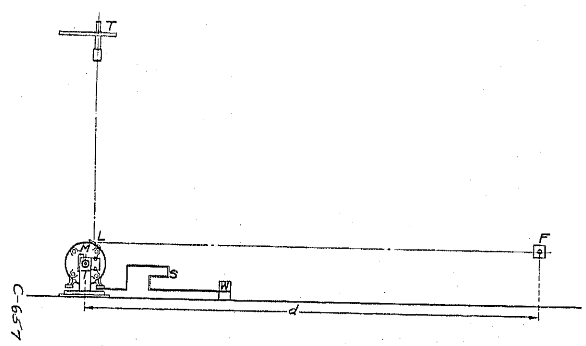

FIG. 3—MOTOR IN TRUNION SUPPORTS SHOWING METHOD OF VIBRATION MEASUREMENT

so that the entire motor could oscillate freely about the center of the shaft. Thus, angular vibrations of the stator about this axis could take place without restraint except for the spring S, whose end was held down by a weight W. This spring S yielded readily to small vibrations but kept the stator in an average position suitable for observations. On now observing the image of the lamp filament F, by means of the telescope T, after its reflection from the mirror L fixed onto the stator by means of sealing wax, a tilting of the motor caused a motion of the image of the filament in the field

of view. An angular vibration caused the filament to môve rapidly up and down so that when placed in a horizontal position and suitably illuminated it broadened out into a ribbon whose width could easily be measured on a scale in the eye piece of the telescope. Knowing the distance and the width of the ribbon, the angular amplitude of vibration was determined.

With this apparatus the angular vibration of a single-phase ¼-h. p. 25-cycle 110-volt motor was measured, using an available line frequency of 40 cycles. In Fig. 4, Curve I shows the half amplitude of the angular vibration in radians, plotted against voltage. The voltage was carried up beyond 200 volts, which could easily be done at the frequency used without overheating the motor. The triangles on Curve I show the amplitude measured as before, but

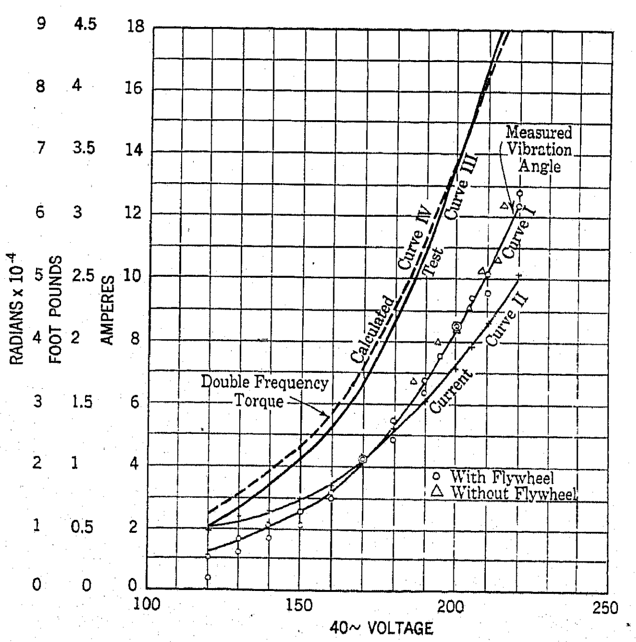

FIG. 4—NO-LOAD TESTS ON 110-VOLT MOTOR

$$T = \frac{0.00293\, I\, (V - 2.2\, I)^3}{5.8\, I^2 + (V - 0.6\, I)^2}$$

with the rotor carrying a flywheel which increased its moment of inertia over tenfold. With no flywheel, the moment of inertia of the stator was some fifteen times greater than that of the rotor. With the flywheel it was about the same. The object of this part of the test was to decrease the amplitude of the speed pulsations of the rotor, and to find if this decrease produced an appreciable increase in the torque pulsations. Comparing the circles with the triangles on Curve I, it is seen that practically no difference in the torque pulsation results when the flywheel is used. This shows that the electromagnetic effect of the variation in speed of the rotor is not great, even though the rotor have only 1/15 of the inertia of the stator.

Since the amplitude of the angular vibration of the stator is known, the amplitude of the torque pulsations may be calculated from the formula

$$T = \bar{I}\, \omega^2\, \theta_0 \qquad (1)$$

where

T = torque

$\bar{I}$ = moment of inertia of stator about axis of rotor

$$= \frac{W r^2}{g}$$

ω = $2\,\pi \times$ oscillation frequency

θ_0 = half amplitude of the vibration angle.

This equation may be derived as follows: During the oscillation the angular position of the stator varies according to the sine law, or

$$\theta = \theta_0 \sin \omega\, t \qquad (2)$$

where θ = angular position of stator at any time.

The angular velocity of motion during vibration

$$= \frac{d\,\theta}{d\,t} = \omega\, \theta_0 \cos \omega\, t \qquad (3)$$

The angular acceleration

$$= \frac{d^2\,\theta}{d\,t^2} = -\,\omega^2\, \theta_0 \sin \omega\, t \qquad (4)$$

$$\text{Therefore torque} = \bar{I}\,\frac{d^2\,\theta}{d\,t^2} = -\,\bar{I}\,\omega^2\,\theta_0 \sin\,\omega\,t$$

where the minus sign means the torque is negative, tending to restore the stator to its zero position. The amplitude of the torque variation is seen to be

$$\bar{I}\,\omega^2\,\theta_0 \qquad (5)$$

which is the required expression. In using this formula it should be noted that ω corresponds to the torque-pulsation frequency which is twice the line frequency.

Curve III shows the amplitude of torque pulsation for the motor tested as obtained from equation (5) using Curve I for values of the vibration half amplitude θ_0. This curve is seen to be derived directly from the experimental test by the use of the laws of mechanics of rotating bodies.

Curve IV shows the values of torque pulsation calculated by means of equations (24) and (28), as derived in the latter part of this paper. By these equations, the maximum half amplitude of the double-frequency torque in foot pounds is:

$$T_0 = \frac{7.04}{\text{R. P. M.}} \left[\frac{e^2\,(X_M + X_2)}{R_2^2 + (X_M + 2\,X_2)^2} \right]$$

If R_2 and X_2 are assumed negligibly small in comparison to X_M, this becomes simply $T_0 = \dfrac{7.04\, V\, \bar{I}}{\text{R. P. M.}}$ or in this case of a 2-pole motor run at 40 cycles, $T_0 = 0.00293\, E\, \bar{I}$. No-load tests on the motor gave values of 2.4 for R_1, 2.2 for X_1, 1.6 for X_2, and 1.4 for R_2. Since at no-load the numerical value of e is nearly

equal to $V - \bar{I}_1 X_1$, X_M is nearly equal to $\dfrac{(e - \bar{I}_1 X_2)}{\bar{I}_1}$

and the speed is 2400 rev. per min., the torque equation for this particular motor at no-load may be reduced to:

$$T_0 = \frac{0.00293\, \bar{I}_1 (V - 2.2\, \bar{I}_1)^3}{5.8\, \bar{I}_1^2 + (V - 0.6\, \bar{I}_1)^2} \text{ ft. lb. approximately.}$$

The actual values plotted for Curve IV were found by this equation. The agreement between Curves III and IV is sufficiently close to show the general validity of the theory.

III. Theoretical Analysis

A. On Power Flow in General. The power input to a single-phase circuit is necessarily of a pulsating character, as each time the incoming current or the voltage passes through zero, the power does likewise. No matter what the power-factor is, a single-phase a-c. circuit always draws from the line a double frequency, alternating power, equal to the full volt amperes. The "active" power is the average power input and is, of course, proportional to the

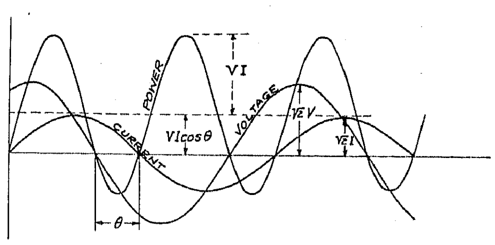

Fig. 5—Voltage and Power in a Single-Phase Circuit

power-factor. The maximum power flow is the sum of the active (or average) power, and the alternating power, as Fig. 5 shows. All this may be made clearer by analytic expression:

Suppose:

$\sqrt{2}\, V \sin \omega\, t.$ = voltage impressed on a single-phase circuit.

$\sqrt{2}\, \bar{I} \sin (\omega\, t. - \theta)$ = current flowing in a single phase.

θ = angle of lag of current behind voltage or "power-factor angle."

Then, at any instant the power flowing in the line is: $2\, V\, \bar{I} \sin \omega\, t. \sin (\omega\, t. - \theta) = V\, \bar{I}\, [\cos. \theta - \cos (2\, \omega\, t. - \theta)]$ which consists of two parts:

$V I \cos \theta$ is a uniform "active" power flowing always in one direction, and equal in magnitude to r. m. s. volts $\times$ r. m. s. amperes $\times$ power factor. $V I \cos (2\, \omega\, t. - \theta)$ is an alternating power which flows to and fro at double frequency, and whose maximum amplitude is equal to r. m. s. volts $\times$ r. m. s. amperes, independent of the power-factor. The sum of the two gives a total power which pulsates at double frequency from a maximum value in the positive direction equal to (1 + power-factor) $\times$ r. m. s. volts $\times$ r. m. s. amperes to a maximum value in the negative direction equal to (1-power-factor) $\times$ r. m. s. volts $\times$ r. m. s. amperes; as indicated in Fig. 5.

In a balanced polyphase circuit, each separate phase draws both active and alternating power as above described, but at each instant the sum of the alternating powers of the phases is zero, so that the only *net* power flowing in the circuit is the active power, distributed equally among the phases. From this point of view it is evident that the ordinary conception of reactive power as the square root of the difference of the squares of the volt amperes and the active power, has no physical reality. There is no *net* alternating power flowing in the lines, although each particular line carries an alternating power equal to its full volt amperes.

Some background of physical conceptions such as these is required if operations involving power determination are to be correctly carried through with the use of complex algebra. For, if a current is represented as $a + j\, b$ and a voltage as $c + j\, d$, referred to a common reference axis the product $(a\, c - b\, d) + j\, (b\, c + a\, d)$ is equal to the single-phase *double-frequency* alternating power and not to the (active power) $+ j$ (reactive power) as might be supposed. Being of double frequency, the phase angle of this product with reference to the current or voltage has no useful meaning, as will be seen from the fact that it changes with each change in the direction of the reference axis. To obtain the true, or active, power by multiplication, it is necessary to first reverse the sign of the j term of either voltage or current, when the product becomes $(a\, c + b\, d) \pm j\, (b\, c - a\, d)$. Here the real term represents the active power $V\, I \cos \theta$ and the j term the so-called reactive power, $V\, I \sin \theta$.

When the sign of one j term is reversed, the resulting vector product is at an angle equal to the difference of the angles of the voltage and current, and when the sign is not reversed, the angle of the vector product is equal to the sum of the voltage and current angles. As angles in this vector representation of a. c. quantities represent angular velocities times time, the former product is evidently a zero-frequency power, and the latter is a double-frequency alternating power.

B. The Energy Flow in a Single-Phase Induction Motor

Since the power inflow to a single-phase motor is pulsating, whereas the power taken by the load is uniform, the incoming energy must be alternately stored during the peaks and supplemented by released energy during the depressions. Thus, a considerable capacity for energy storage is required, and the energy stored must increase with the load. A brief consideration of the possibilities shows that this energy is stored as kinetic energy in the revolving parts, so that the torque exerted by the single-phase motor is of a pulsating character corresponding to the electrical energy input,

and the rotor speed continually fluctuates up and down in response to the torque variations, as indicated in Fig. 6.

Furthermore, even at no-load, and supposing the

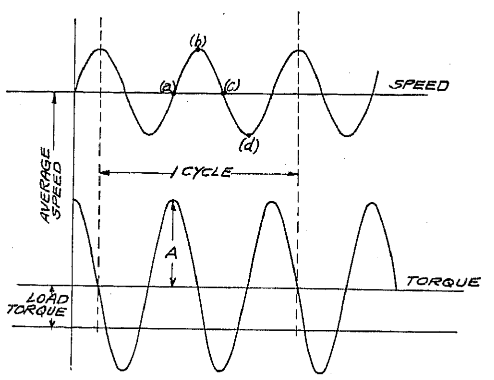

FIG. 6—DOUBLE FREQUENCY TORQUE AND SPEED VARIATIONS OF A SINGLE-PHASE MOTOR

friction torque negligible, the motor torque pulsates at double frequency, for the reason that the potential energy of the magnetic field in the cross axis is supplied entirely by the torque, since there is no direct mutual

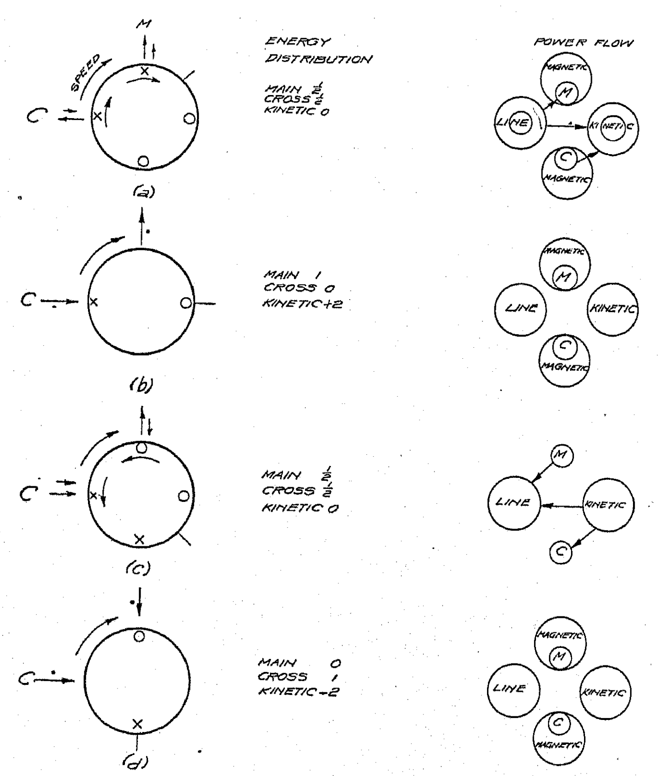

FIG. 7—ENERGY AND POWER IN A SINGLE-PHASE INDUCTION MOTOR

induction between the main and cross axis. This magnetic energy is alternately stored and released twice in each cycle and so constitutes an important cause of torque (and speed) variations entirely independent of the variations due to the load. The ratio between the double-frequency torque due to the load and that due to the cross field, is proportional to the ratio of the watts output to the magnetizing volt amperes. In very small single-phase motors the no-load torque variation is large and the additional variations due to the load are not very important, while in a very large machine the reverse is true.

In order to obtain a clear visual perception of the phenomena of torque variation at no-load it is helpful to follow through this analysis:—

Suppose that a single-phase 2-pole induction motor has zero losses and is running light at normal frequency and voltage; its speed being, therefore, exactly synchronous. Let the four circles at the left of Fig. 7 represent the rotor at four consecutive instants ⅛ cycle apart. Then, between successive instants the rotor will have advanced ⅛ revolution, as indicated by the markers at the right hand side of the circles. Also, the magnetic field will have revolved at the same rate as the rotor, so that the amplitudes of the fluxes

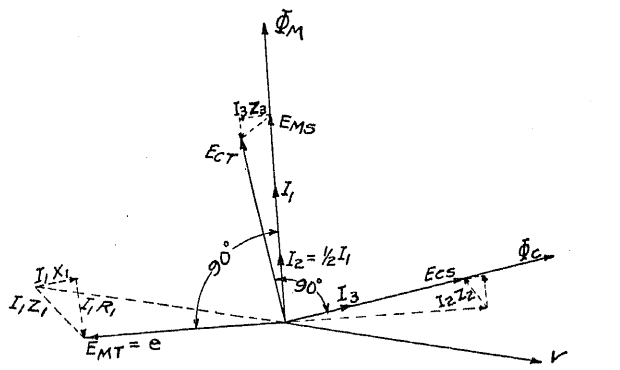

FIG. 8—NO-LOAD VECTOR DIAGRAM OF SINGLE-PHASE INDUCTION MOTOR CROSS FIELD THEORY

in the main and cross axes, respectively, will have varied in the manner shown by the arrows at the top and the left sides of the circles. The small arrows immediately beside the large flux vectors represent the rates of change of the fluxes. Thus, at *a*, the main flux is increasing slowly, at *b* it is a maximum, at *c* it is decreasing, and at *d* it is zero and is decreasing with maximum rapidity.

To determine the rotor currents at each position, it is most convenient to refer to the vector diagram, Fig. 8, and note that the cross field current, $\bar{I}_3$, is simply the magnetizing current for the cross flux, and so is always in time-phase with the latter; while the main-field rotor current $\bar{I}_2$ is in time-phase with the primary current $\bar{I}_1$, and therefore is in phase with the main flux. The *O* and *X* marks on each diagram indicate the directions of the rotor currents as thus determined. It is not convenient to determine the rotor currents by the ordinary method of dividing the resultant of the speed and transformer voltages in each axis by the rotor resistance, since under the hypothesis of zero losses, no load, the speed and transformer voltages in each axis

exactly neutralize and the current is equal to $\frac{0}{0}$, or is indeterminable.

Knowing now the currents and fluxes in each axis, the torques are readily determinable. The curved arrows inside the rotor circles indicate the directions of these torques at each instant. At *a*, the torque in each axis accelerates the rotor, at *b* both torques are zero, at *c* both torques decelerate the rotor, and at *d* both are again zero. It is, therefore, evident that the torque pulsates at double frequency, but has a zero average value. As a result of the torque variations, the rotor speed evidently pulsates also at double frequency, being a maximum at *b* and a minimum at *d*.

The exact amount that the speed fluctuates must depend on the moment of inertia of the rotor and upon the restoring torque set up as a result of the departure of the speed from synchronism. Evidently, if the speed varies 1 per cent from synchronous, the flux will cut the rotor bars at a frequency 1 per cent of line frequency, slip-frequency currents will flow in the bars, and a torque will be created equal to the load torque that would normally produce 1 per cent slip. This load torque is always in such a direction as to restore the speed to synchronous, and is proportional to the slip, so that it is always 90 deg. out of time-phase with the resultant of the other torques acting on the rotor.

The problem of calculating this resisting torque and its effects is exactly the same as that of calculating the torque reaction of a polyphase motor driving a pulsating load. This problem has been carefully studied for cases where the frequency of load pulsation was a small fraction of the line frequency, in connection with the application of motors to reciprocating compressors. The present case where the load pulsations are of double-line frequency has not been studied, and it will not be considered here. It is interesting to note, however, that for the production of the double-frequency torque of such a load a third harmonic must be drawn from the line, and so the general conclusion is reached that all single-phase motors must draw a certain amount of third harmonic current from the line, regardless of the existence of magnetic saturation. The amount of this third harmonic current should be greater, the less the normal slip of the motor and the less the inertia of the rotor. It is believed that the third harmonic current of this character drawn by commercial single-phase motors is of very small amplitude.

The experimental comparison of the fluctuations in torque with and without a flywheel on the rotor, described in part II, shows that for the motor tested, at least, the amount of this restoring torque, due to variations of the speed from synchronous, is small.

Evidently the amplitude of motion of the stator under the influence of the torque variations is inversely proportional to its moment of inertia about the shaft as an axis. At first sight, it might appear that the use of a flywheel on the rotor would increase the stator vibration, and the use of a very heavy stator would increase the fluctuations in speed of the rotor; just as a charge of powder imparts velocities to gun and projectile in inverse proportion to their weights. In this case, however, the stator and rotor vibrations are independent of each other, since the force acting is practically independent of the relative displacements; while in the case of the gun, the force between gun and projectile depends on the velocities of each.

This section of the paper has given a physical foundation upon which the abstract representation of the phenomena required for quantitative results can be based. The quantitative analysis of the phenomena is given in the succeeding sections, both the cross field and the revolving field theories being presented.

C. Analysis by the Cross-Field Theory

The cross-field theory treats the single-phase induction motor as two transformers with perpendicular axes, using the same magnetic structure. At standstill the two transformers are independent of each other, but when running, the flux of each induces in the circuit of the other a voltage proportional to the speed. The

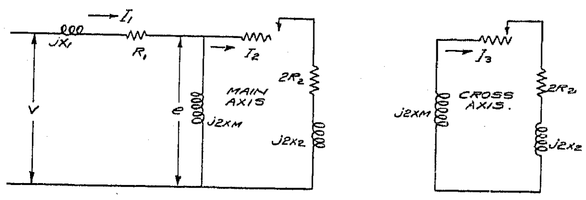

Fig. 9—Circuit Diagram. Cross Field Theory

circuit diagram and the no-load vector diagram are illustrated in Figs. 9 and 8 respectively.

Referring to Fig. 9, the operation of the motor is as follows:—an impressed voltage V creates a primary current I_1 which flows through the primary impedance, $R_1 + j X_1$ and then divides, a part, I_2, flowing through the main axis secondary winding of impedance $2(R_2 + J X_2)$, and the remainder through the magnetizing impedance, $j\,2\,X_M$. At standstill, I_1 and I_2, are nearly equal, and are both large, while there is no current in the cross axis whatever. When the rotor is started by some external means, the main flux induces a speed voltage in the cross axis equal to $-j\,(1 - s)\,e$, and this voltage produces a current in this axis; I_3. As the impedance of the cross field circuit consists almost entirely of reactance, I_3 lags nearly 90 deg. behind the speed voltage producing it. I_3 flows through the cross-field magnetizing reactance, $j\,2\,X_M$, which is equal to that of the main field, and so produces a cross flux and a proportional speed voltage in the main axis, equal to $2\,I_3\,X_M\,(1 - s)$. This last voltage is nearly in phase opposition to e, and so, as the speed rises, the available voltage in the main axis falls, until at full speed, no load, I_2 is practically equal to only $\frac{1}{2}\,I_1$. I_3

is always small, being a maximum at no-load, full-speed, and is then nearly equal to I_2.

In the circuit of Fig. 9, the constants $2\,R_2$, $2\,X_2$ and $2\,X_M$, of the cross field are, by symmetry, equal to the corresponding constants of the main field, and both are equal to the constants of the secondary as directly obtained from standstill impedance tests. Thus $2\,R_2$, $2\,X_2$ and $2\,X_M$, are each equal to the corresponding constants for one phase of a two-phase motor, or to twice the corresponding values for the forward revolving field of a single-phase motor, and this explains the insertion of the factor 2 in all quantities. In the revolving field theory, which is discussed in the next section, R_2, X_2, and X_M will be used directly.

A simple way of visualizing the reason for the existence of this factor 2 is to remember that when a squirrel cage secondary winding is subjected to an alternating flux along one axis only, each pair of bars placed symmetrically with respect to this axis will link a different amount of flux. Assuming the flux to be sinusoidally distributed, in space as well as in time, the induced currents in the rotor will be very small in the bars nearest the axis and, at any instant will vary sinusoidally thence to a maximum in the bars furthest from the axis. The rotor currents are, therefore, concentrated in the outer bars, and the total copper loss is twice as great as if all the bars had the full voltage induced in them and all carried equal currents.

Proceeding now to the actual analysis, by applying Kirchoff's Laws to the circuits of Fig. 9, we can obtain expressions for the currents and voltages as follows:

$$I_3 = \frac{-j\,(1-s)\,(e - j\,2\,I_2\,X_2)}{2\,(R_2 + j\,X_2 + j\,X_M)} \tag{6}$$

$$I_2 = \frac{e + 2\,I_3\,(X_M + X_2)\,(1-s)}{2\,(R_2 + j\,X_2)} \tag{7}$$

By solving (6) and (7) simultaneously, we find:

$$I_3 = \frac{-j\,(1-s)\,e\,R_2}{2\,[\,(R_2 + j\,X_2)\,(R_2 + j\,X_2 + j\,X_M) + (1-s)^2\,X_2\,(X_M + X_2)\,]} \tag{8}$$

$$I_2 = \frac{e\,[R_2 + j\,X_2 + j\,X_M - j\,(1-s)^2\,(X_M + X_2)\,]}{2\,[\,(R_2 + j\,X_2)\,(R_2 + j\,X_2 + j\,X_M) + (1-s)^2\,X_2\,(X_M + X_2)\,]} \tag{9}$$

Also, $I_1 = I_2 + \dfrac{e}{2\,j\,X_M} =$

$$\frac{-j\,e\,[R_2^2 + 2\,j\,R_2\,(X_M + X_2) - s\,(2-s)\,(X_M + X_2)^2]}{2\,X_M\,[R_2^2 + j\,R_2\,(X_M + 2\,X_2) - s\,(2-s)\,(X_M + X_2)]} \tag{10}$$

$$e = V - I_1\,(R_1 + j\,X_1) \tag{11}$$

The output in watts produced by the torque in each axis is equal to the product of the speed voltage induced by it times the current in the other axis. The outputs in the two axes are, accordingly:

$$W_M = I_3\,[j\,(1-s)\,(e - j\,2\,I_2\,X_2)\,] \tag{12}$$

$$W_c = I_2\,[-\,2\,(1-s)\,I_3\,(X_M + X_2)\,] \tag{13}$$

As has already been pointed out in part *I*, a single-phase power equation such as (12) consists of two distinct parts, the double-frequency alternating power, and the zero-frequency, constant power. These two parts must be treated separately. The steady power is found by reversing the signs of the j terms of the current (or voltage) and taking the real part of the resulting product; and the alternating power is the total value of the product of current and voltage. We will first find the active power, by reversing the signs of the j terms of I_3 in (12) and I_2 in (13) and performing the multiplications indicated.

$$W_M = -\,2\,(R_2 + j\,X_2 + j\,X_M)\,I_3^2 = \frac{-\,(1-s)^2\,e^2\,R_2^2\,(R_2 + j\,X_2 + j\,X_M)}{2\,[R_2^4 + R_2^2\,(X_M + 2\,X_2)^2 - 2\,s\,(2-s)\,R_2^2\,X_2\,(X_M + X_2) + s^2\,(2-s)^2\,X_2^2\,(X_M + X_2)^2\,]} \tag{14}$$

and from (7), (9) and (13):

$$W_c = I_2\,[e - 2\,I_2\,(R_2 + j\,X_2)\,] = \frac{e^2[s(2-s)(1-s)^2R_2(X_M+X_2)^2 + j(1-s)^2R_2^2(X_M+X_2)]}{2\,[R_2^4 + R_2^2\,(X_M + 2\,X_2)^2 - 2\,s\,(2-s)\,R_2^2\,X_2\,(X_M + X_2) + s^2\,(2-s)^2\,X_2^2\,(X_M + X_2)^2\,]} \tag{15}$$

The real part of (14) is evidently simply equal to the copper loss of the cross field magnetizing current. This is a decelerating torque which must be subtracted from the real part of (15) to obtain the net watts output. The j parts of (14) and (15) have no interest for us here. Adding the real parts of (14) and (15) algebraically, therefore, we obtain the net watts output:

$$\overset{\text{real}}{W_c + W_M} = \frac{(1-s)^2\,e^2\,R_2\,[s\,(2-s)\,(X_M + X_2)^2 - R_2^2.]}{2\,[R_2^4 + R_2^2\,(X_M + 2\,X_2^2)^2 - 2\,s\,(2-s)\,R_2^2\,X_2\,(X_M + X_2) + s^2\,(2-s)^2\,X_2^2\,(X_M + X_2)^2\,]} \tag{16}$$

The synchronous torque is obtained by dividing the output by $(1-s)$, since the speed of the rotor is $(1-s)$ times the synchronous speed.

By making various approximations, equation (16) can be put into several useful forms. Evidently, the output is zero at standstill, when $s = 1$. If R_2 is negligibly small in comparison with X_2 and X_M, (16) reduces to:

$$\text{Output} = \frac{R_2}{2\,X_2^2}\;\frac{(1-s)^2}{[1 - (1-s)^2]}\,,\ R_2 \text{ very small}$$

At no load, the output is zero, neglecting the friction and windage losses, and (16) reduces to

$$S = \frac{R_2^2}{2\,(X_M + X_2)^2}\ \ldots \text{ at no load} \tag{17}$$

The maximum output under the assumption of constant e (constant terminal voltage and negligible primary impedance) occurs when (16) is a maximum with respect to s, or when:

$$(1-s)^4 X_2 (X_M + X_2)^2 [X_2 (X_M + X_2)^2 - 2 R_2^2 (X_M + X_2) - 2 R_2^2 X_2] - (1-s)^2 (X_M + X_2)^2 [2 (R_2^2 + X_2^2)(X_M + X_2)^2 R_2^2 (2R_2^2 - X_2^2)] + (R_2^2 + X_2^2)[(X_M + X_2)^4 - R_2^4] = 0 \quad (18)$$

Equation (18) is of the 2nd degree in $(1-s)^2$, so that there are in all 4 values of s that give maximum points. Two of these are for forward and 2 for backward rotation, corresponding to maximum output as a motor and as a generator. To the first approximation, (13) may be solved by assuming X_M to be very large, when:

$$(1-s)^2 = 1 + \frac{R_2^2}{X_2^2}\left(1 + \frac{2 X_2}{X_M} + \ldots\right) \pm \frac{R_2 Z_2}{X_2^2}\left(1 + \frac{X_2}{X_M} + \ldots\right) \quad (19)$$

the upper signs corresponding to generator, and the lower to motor operation.

On the same basis of X_M infinite and e constant, the substitution of (9) in (16) gives for the maximum output as a motor:

$$W_{max.} = \frac{e^2 X_M}{4 (R_2 + \sqrt{R_2^2 + X_2^2})(X_M + X_2)} \quad (20)$$

The corresponding value of maximum output for one phase of a two-phase motor is obtained by making X_M infinite in equation (20), since this is the same thing as making I_3 = zero, and hence making the motor the same as one half of a two-phase motor.

Turning our attention now to the alternating power, which is equal to the numerical product of volts times amperes in each axis, the first question to settle is the relative time phase of the alternating torques in the two axes. Since equations (12) and (13) have I_3 as a common factor, the relative time phases are determined by the other factors in the equations alone. Thus, the total alternating power delivered to the rotor is given by the sum of (12) and (13), or:

$$A = \text{Alternating Power} = I_3(1-s)(-2 I_2 X_M + j e) \quad (21)$$

Or, by (8) and (9):

$$A = \frac{(1-s)^2 e^2 R_2 [(R_2^2 + 2 j R_2 (X_M + X_2) - s(2-s)(X_M + X_2)^2]}{2 [R_2^2 + j R_2 (X_M + 2 X_2) - s(2-s) X_2 (X_M + X_2)]^2} \quad (22)$$

In this case, we desire to find the total power only, and do not care about its time phase, so that we must find the square root of the sum of the squares of the real and j parts of (22):

$$A = \frac{(1-s)^2 e^2 R_2 \sqrt{R_2^4 + [s^2 + (2-s)^2] R_2^2}}{2 [R_2^4 + R_2^2 (X_M + X_2)^2 - 2 s (2-s) R_2^2 X_2} \; \frac{\overline{(X_M + X_2)^2 + s^2 (2-s)^2 (X_M + X_2)^4}}{(X_M + X_2) + s^2 (2-s)^2 X_2^2 (X_M + X_2)^2]} \quad (23)$$

At standstill, when $s = 1$, (23) reduces to zero, so that the starting torque of a single-phase motor is zero at every instant, as well as having a zero average value.

At no load, the slip is given by (17), and substituting this value for s in (23), we have, very closely:

$$A \text{ at no load} = \frac{e^2 (X_M + X_2)}{R_2^2 + (X_M + 2 X_2)^2} \quad (24)$$

As the slip increases, A also increases to a maximum value at approximately the same slip that gives maximum useful torque, and thence decreases to zero at standstill.

By dividing (17) by (11) the ratio of alternating power to real power is found to be:

$$\frac{A}{\text{Output}} = 1 - \frac{2 j R_2 (X_M + X_2)}{s(2-s)(X_M + X_2)^2 - R_2^2} \quad (25)$$

Thus the maximum instantaneous alternating power is never less than the output.

We are now ready to proceed further with the physical interpretation of these results. All the values of alternating power given in equations (26) to (24) represent maximum instantaneous values of double-frequency power. This power is expended in alternately accelerating and decelerating the revolving parts. The maximum speed to which the rotor is accelerated is such that the total energy supplied by the reactive power in one half cycle is stored in the increased kinetic energy. Thus, if R is the radius of gyration in feet, and W is the weight of the revolving parts in pounds, the ratio of the maximum rotor speed to the average is:

$$\frac{\text{R. P. M. max.}}{\text{R. P. M. av.}} = \sqrt{1 + \frac{689 A}{f (R P M)^2 W R^2}} \quad (26)$$

where A is the maximum alternating power in watts from (23) or (24), and f is the line frequency in cycles per second. If the rev. per min. are assumed to be synchronous, (26) may be expressed in terms of the number of poles of the motor, as follows:

$$\frac{\text{R. P. M. max.}}{\text{R. P. M. av.}} = \sqrt{1 + \frac{.0478 A \text{ (poles)}^2}{f^3 W R^2}} \quad (27)$$

Since the total variation in speed is very small, equations (26) and (27) may also be expressed as follows:

$$(\text{R. P. M. max.} - \text{R. P. M. av.}) = \frac{345 A}{f (\text{R. P. M.})^2 (W R^2)} \quad (26)$$

$$= \frac{.0239 A \text{ (poles)}^2}{f^3 W R^2} \quad (27)$$

The maximum torque exerted on the rotor in addition to the average, or load, torque, is:

$$\text{Max. Alternating Torque} = \frac{7.04 A}{\text{R. P. M.}} \text{ foot lbs.} \quad (28)$$

As pointed out in the introduction to this chapter, as

soon as the rotor departs from its normal speed, a restoring torque is set up, tending to restore the motor to its average speed, as a result of the change in the fundamental torque due to the changed slip. This restoring torque must be of double frequency and therefore, as the impressed voltage is only of single frequency, the line current must contain third and other harmonics in addition to the fundamental. The problem of calculating the fundamental restoring torque of a motor for impressed oscillations of low frequency has been quite completely solved, but this case of double-frequency impressed oscillations is a more difficult one that has not yet been considered.

By considering equation (**27**), it may be seen that for a single-phase motor of given electrical characteristics (A fixed), the pulsations of speed are greater, the lower the frequency, the lower the value of $W R^2$, and the greater the number of motor poles. The value of A is also greater the greater the number of poles for a given output, so that all low-speed motors of a given frequency are more subject to vibration than high-speed motors.

D. Analysis by the Revolving Field Theory. In the revolving field theory, the single-axis alternating flux set up by the primary current is resolved into two equal and oppositely revolving components. The forward component cuts the rotor conductors at slip frequency and induces in them useful currents similar to those in a polyphase induction-motor secondary. The backward field cuts the rotor conductors at a frequency $(2 - s)$ times line frequency and so induces in them large currents which practically neutralize the primary current and so reduce the net backward flux to a very small value. As the two fields are produced by the same primary current, their circuits are connected in series. The only difference in their constants is due to the difference in secondary frequency, making the apparent secondary resistance $\frac{R_2}{s}$ for the forward field and $\frac{R_2}{2 - s}$ for the backward field.

Referring to the circuit diagram of Fig. 10, the equations are:

$$I_4 = \frac{j\, I_1\, X_M}{R_2/_s + j\,(X_M + X_2)} \qquad \textbf{(29)}$$

$$I_5 = \frac{j\, I_1\, X_M}{\frac{R_2}{2 - s} + j\,(X_M + X_2)} \qquad \textbf{(30)}$$

$$e = j\, X_M\,(2\, I_1 - I_4 - I_5), \text{ or} \qquad \textbf{(31)}$$

$$e = j\, 2\, I_1\, X_M \left[\frac{R_2^2 + j\, R_2(X_M + 2\, X_2) - s\,(2 - s)\, X_2\,(X_M + X_2)}{R_2^2 + 2\, j\, R_2(X_M + X_2) - s\,(2 - s)\,(X_M + X_2)_2} \right] \qquad \textbf{(32)}$$

and $e = V - I_1\,(R_1 + j\, X_1)$.

Equation (**32**) is identical with the corresponding equation (**10**) found by the cross-field theory.

Since the forward and the backward fields exist in a common magnetic structure, each flux makes a torque with each current, or there are in all four separate torques.

The torque produced by the forward revolving flux with I_4 is of constant magnitude, independent of the time; as is also the torque produced by the backward field with I_5. This is true for the reason that we are now considering fluxes of constant magnitude in time but moving in space, whereas in the cross-field theory we considered the flux at one particular position in space, but varying with time. Thus the meaning of j in the torque equations is a rotation of 90 deg. in space, instead of in time.

The principal, or load, torque is that due to the action of the forward revolving flux and I_4. The watts developed by this torque at synchronous speed are equal to:

$$T_{44} = j\,(I_1 - I_4)\, X_M\, I_4 = I_4^2 \left(\frac{R_2}{s} + j\, X_2 \right) \qquad \textbf{(33)}$$

As noted above, the j terms here only measure the

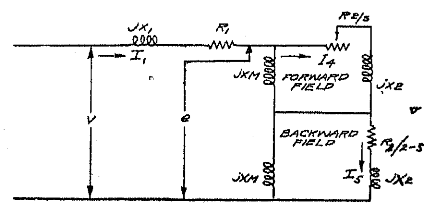

Fig. 10—Cihcuit Diagram. Revolving Field Theory

phase displacement in space, and so may be dropped without error. Therefore, the steady synchronous torque is, from (**29**) and (**33**):

$$T_{44} = \frac{e^2\, R_2\, s\,[R_2^2 + (2 - s)^2\,(X_M + X_2)^2]}{4[R_2^4 + R_2^2(X_M + 2X_2)^2 - 2s(2-s)R_2^2X_2(X_M + X_2) + s^2\,(2 - s)^2\, X_2^2\,(X_M + X_2)^2\,]} \qquad \textbf{(34)}$$

At standstill, when $s = 1$, (**34**) reduces to:

$$T_{44} = \frac{e^2\, R_2}{4\,(R_2^2 + X_2^2)} \text{ at standstill} \qquad \textbf{(35)}$$

Similarly, the synchronous torque due to the backward field and I_5 is:

$$T_{55} = j\,(I_1 - I_5)\, X_M\, I_5 = I_5^2 \left(\frac{R_2}{2 - s} + j\, X_2 \right) \qquad \textbf{(36)}$$

Dropping the j terms in (**36**), and eliminating I_5 by (**30**) and (**32**):

$$T_{55} = \frac{e^2\, R_2\,(2 - s)\,[R_2^2 + s^2\,(X_M + X_2)^2\,]}{4[R_2^4 + R_2^2(X_M + 2X_2)^2 - 2s(2-s)R_2^2X_2(X_M + X_2) + s^2\,(2 - s)^2\, X_2^2\,(X_M + X_2)^2\,]} \qquad \textbf{(37)}$$

When $s = 1$, (**37**) also reduces to (**35**), so that the backward and forward field torques are equal and opposite at standstill. As T_{44} and T_{55} are both invariant in time, the conclusion is reached that the standstill torque is zero at every instant, as well as having a zero average value, as already found by the cross-field theory.

The net constant torque in synchronous watts is equal to the difference of (**34**) and (**37**), or to:

$$T_{44} - T_{55} = \frac{e^2 R_2 (1 - s) [s (2 - s) (X_M + X_2)^2 - R_2^2]}{2[R_2^4 + R_2^2 (X_M + 2X_2)^2 - 2s(2-s) R_2^2 X_2 (X_M + X_2) + s^2 (2 - s)^2 X_2^2 (X_M + X_2)^2]} \qquad (38)$$

Equation (**38**) has the same value for any particular value of s as it has for the same value of $2 - s$, though the sign is reversed, so that the motor-torque curve is symmetrical about the point of zero speed. The output is equal to $(1 - s)$ times (**38**), which checks equation (**16**) previously found.

At no load, or running light, (**38**) is equal to zero, neglecting the friction and windage losses, so that

$$S = \frac{R_2^2}{2 (X_M + X_2)^2} \text{ at no load} \qquad (17)$$

The maximum output is given by (**20**), of the cross-field theory solution, and it occurs at the slip given by equation (**19**).

To calculate the alternating power, we must take the sum of the products of the backward field voltage by I_4 and the forward voltage by I_5. Since it is now only a question of alternating power, the phase relations of I_4 and I_5 with the fluxes they act upon are of no importance, but the phase relations of the two torques they make are important.

The voltage representing the forward flux is, from (**31**) and (**32**):

$$e_4 = j X_M (I_1 - I_4) = I_4 \left(\frac{R_2}{s} + j X_2 \right) \qquad (39)$$

and that representing the backward field is:

$$e_5 = j X_M (I_1 - I_5) = I_5 \left(\frac{R_2}{2 - s} + j X_2 \right) \qquad (40)$$

Since the relative speeds of I_4 and e_5 and of I_5 and e_4 are twice synchronous speed, the torques made by their interaction are double-frequency torques. The synchronous double-frequency torque is:

$$A = T_{45} - T_{54} = e_4 I_5 - e_5 I_4 = \frac{2 I_4 I_5 (1 - s) R_2}{s (2 - s)} \qquad (41)$$

These alternating torques are subtractive rather than additive for the same reason that the active torques are, as may be seen by comparing equations (**33**) and (**36**) with (**39**) and (**40**). This conclusion is confirmed by substituting $s = 1$ in (**41**), when it reduces to zero, as it should. Evaluating (**41**) by means of (**29**), (**30**) and (**32**), it becomes

$$A = \frac{(1 - s)\, e^2 R_2 [R_2^2 + 2 j R_2 (X_M + X_2) - s (2 - s) (X_M + X_2)^2]}{2[R_2^2 + j R_2 (X_M + 2X_2) - s(2-s) X_2 (X_M + X_2)]^2} \qquad (42)$$

Equation (**42**) is identical with (**22**) except for the factor $(1 - s)$, which appears in (**22**) but not in (**42**), as the former is actual watts output available for accelerating and decelerating the rotor, while the latter is the *synchronous* torque, or the watts output that would exist if the electrical conditions were the same and the speed was synchronous.

Starting from (**42**), then, equations (**23**) to (**28**) may be derived just as was done in the last chapter, and the same conclusions as to the effect of rotor inertia, line frequency, etc., on the torque pulsations will be reached.

IV. Conclusions

Since this double-frequency torque variation is characteristic of the single-phase motor, the only way to avoid noise in operation is to so mount the stator as to allow free torsional vibration about the shaft as an axis, without imparting the vibration to the supporting structure. The ideal mounting consists of trunnions supporting the stator through bearings concentric with the shaft. Such a mounting is quite expensive, however, and it is difficult to satisfactorily restrain the normal torque of the motor load without communicating the torque variations to the base. In general, therefore, it is best to mount the stator firmly on a support which is sufficiently flexible to take up the motion of the stator without itself producing noise.

A good example of such a mounting is a long thin board of the same width as the motor base. If the motor is affixed to this board with the shaft lengthwise, quiet operation is secured, as the board twists readily with the motion of the stator and yet does not transmit any motion to its end supports. If the motor is placed with its shaft crosswise of the board, a considerable amount of noise is produced, as the motor alternately lifts up and pushes down on the ends of the board, thus transmitting vibration through the whole structure.

Similarly, a flexible coupling on the shaft is required if gears are used, as otherwise the variations in torque and in rotor speed cause the gears to rattle. Common sense applied to each particular application in the light of a knowledge of the cause of the trouble will usually yield an easy solution of the difficulty.

A Generation of the American Institute of Electrical Engineers---1884-1924

President's Address

BY HARRIS J. RYAN

Leland Stanford, Jr., University, California

THIS is the fortieth year of the Institute. A charter member who was twenty-five when it was organized is now sixty-five and his work has been substantially completed. While the American Institute of Electrical Engineers must endure as long as the Nation, no succeeding generation can encounter the unique experiences of its charter members. They were young with a wilderness of options for action before them. They had the mentality of early manhood, boundless energy and enthusiasm and a wonderful unity of purpose.

When the Institute began, the land telegraph had been in use forty years, the Europe-to-America submarine telegraph cable eighteen years, the direct-current generator twelve, the telephone eight, the arc light about five, and the incandescent lamp had been used three years. The direct-current motor had just arrived, and the alternator, transformer, synchronous and induction motors were soon to follow. New and wonderful electrical expediencies were arriving at a rate that was bewildering for the "man in the street." This acceleration of electrical progress took a strong hold on the imagination of our people. The boys who visited the Centennial Exposition at Philadelphia in 1876 reacted powerfully as boys always have and always will in regard to new things. They went home to play with batteries, magnets, telegraphs and telephones and a little later constructed direct-current dynamos and motors as the boys of today build radio equipment.

Some of the boys of 1880 quickly mastered an understanding of the critical speed of a direct-current shunt generator that had cost Edison and Hopkinson hours of intense mental effort. For the most part they were the men who, four years later, organized the Institute. Their wonderful work is going on today and always will. In the great turning movement that education is now making, the young men and women of 1884 are today helping their children to give the grandchildren, who are the boys and girls of today, a greater opportunity to see for themselves the things of highest interest and greatest worth-whileness for knowing and doing.

The "why not" spirit of the youth who founded the Institute is splendidly reflected in the frontispiece of Volume I of the TRANSACTIONS. It is lithographed in colors and labeled "American Institute of Electrical Engineers, September 1884. The Scientific Street as Applied to Broadway, New York."

It is recorded in the beginning of Volume I of the TRANSACTIONS that "The first steps toward the formation of the Society were taken in April, 1884," when a circular was prepared and published by Dr. Nathaniel S. Keith of New York City, inviting signatures to the proposal to organize "The American Institute of Electrical Engineers." The subscribers held a meeting in the rooms of the American Society of Civil Engineers in New York on May 13, 1884, adopted rules of procedure and elected officers for the ensuing year. Thus the American Institute of Electrical Engineers began forty years ago. The membership rapidly increased to 1000 and thereafter grew steadily to more than 15,000 today.

The first communication received and printed in the TRANSACTIONS was a letter from Mr. C. J. Kintner, Examiner, Class Electricity, U. S. Patent Office dated at Washington, D. C., May 12, 1884. He expressed his regret that he would not be able to attend the organization meeting of the Electrical Engineers and begged them to come to the rescue of the Patent Office which was in a deplorable state of neglect on the part of Congress. He invited helpful attention to the contents of an attached copy of an official report on the situation which revealed that his division was undermanned and housed in inadequate quarters poorly ventilated and lighted. Of his own office room he said there was no gas and that he was obliged to use kerosene oil which seriously vitiated the atmosphere. This was the state of things when inventors had paid for the maintenance of the patent office $2,500,000 in excess of operating expenses.

Thus, in the first hour of its existence, the American Institute of Electrical Engineers was forcefully made to take note of the fact that this is an ever practical world and that vital things are never what they should be if the men most concerned fail to make them so.

Without patents properly provided for, The American Institute of Electrical Engineers could not have been maintained as a forum for the reception of new ideas as to facts, principles and processes. The only alternative would have been procedure of individuals, or of small groups of individuals, bound to secrecy for the protection of their equities and rights.

The history of the ceramic arts is a specific illustration. Porcelain has been known for centuries, nevertheless the porcelain arts have advanced much more in the few years in which ceramists have abandoned secrecy and have depended upon the United States patent system for their protection, and upon their own cooperation through the American Ceramic Society.

The longing of the people of our Country to have an

opportunity to come more intimately into contact with vast numbers of new things electrical in 1883, was clearly understood by the management of the Franklin Institute of Philadelphia. The home of the renowned Franklin had been in Philadelphia. In 1883 this city was also the home of two high school teachers who were becoming known throughout the world for their electrical achievements. In the circumstances, it was decided to hold the International Electrical Exposition of 1883 in Philadelphia under the auspices of the Franklin Institute.

The determination of the young men engaged in the electrical sciences and industries to organize a national society of electrical engineers was due in no small measure to this action of the Franklin Institute as may be learned by the following quotation from the circular that called the organization meeting: "An International Electrical Exhibition is to be held in Philadelphia next autumn, to which many of the foreign electrical savants, engineers and manufacturers will be visitors; and it would be a lasting disgrace to American electricians, if no American national electrical society was in existence to receive them with the honors due them from their co-laborers in the United States." Nothing was more natural, therefore, than to hold the first meeting of the Institute in Philadelphia for the presentation and discussion of papers in response to a cordial invitation from the Franklin Institute as recorded also in the early pages of Volume I of the TRANSACTIONS, as follows: "The Directors of the International Electrical Exhibition, Philadelphia, held under the auspices of the Franklin Institute, having kindly tendered to the Institute the free use of rooms in the exhibition building, so long as it should remain open, the offer was accepted by the Council, and the secretary was authorized to make the necessary preparations and to be present during the Exhibition as the representative of the Institute.

"The rooms were accordingly opened to members by Mr. Keith on September second, and remained open until October eleventh, during which time they were visited by several foreign electricians. On October seventh and eighth a meeting was held, in accordance with the rules, at the Continental Hotel and the Exhibition rooms, where the papers forming this volume were read and discussed. On the invitation of the Franklin Institute, the Exhibition was also inspected by the members in a body."

To Professor Edwin J. Houston belongs the never-to-be-forgotten honor of presenting to the Institute the first paper. It bore the modest title, "Some Notes on Incandescent Lamps" and dealt with the now universally known and highly valued "Edison effect." Referring to "the peculiar high vacuum phenomenon observed by Mr. Edison in some of his incandescent lamps, Prof. Houston said: "I wish to bring it before the Society for the purpose of having you puzzle over it." What a glorious result has come of "the puzzling." Little could those present have appreciated on the memorable morning of October seventh, 1884, in Philadelphia, the fact that some of them during this fortieth anniversary would witness through applications of the Edison effect the transmission of the human voice from airplane to airplane in flight and over land and ocean to the uttermost parts of the earth; that such Edison effect was due to a reaction at last of the long-sought-for electricity, that the effect was a characteristic reaction of matter within its own structural make-up and that it would be the means of producing an endless succession of most helpful facilities for research and progress.

Sir William Preece of England was present at the meeting and joined in the discussion of the Edison effect. He brought forward the fact that Dr. Oliver Lodge had recently demonstrated that fogs resulted from the formation of moisture around electrical nuclei. "He took a large glass globe, apparently chemically clean, exhausted the air, but with moisture in it. It remained perfectly transparent so long as no matter was admitted, but the moment a spark from an induction coil was passed between the two platinum electrodes in this apparently clean globe at once a cloud was formed throughout the whole globe."

It was nearly thirty years before important results were developed out of the Edison effect. The fortieth year is now passing since the fog forming nuclei were reported to the Institute and almost nothing has been done about it. What wonderful uses may yet be made of the fog effect in bringing water from the skies and in the control of fogs in places where they render traffic hazardous.

The overhead conductors to provide for the rapidly growing telephone and telegraph service in the business districts of our cities began to obscure the sky and to make city dwellers positively unhappy, besides being in fear of their lives because of the difficulties the conductors caused the fire department in fighting fires. An intense longing to get rid of overhead conductors possessed all city residents. It is natural, therefore, to find that the second paper presented to the Institute at the Philadelphia convention bore the title "Underground Wires," by W. M. Calender.

In 1884 many were living who had witnessed the almost desperate struggle, and final failure of Professor Morse, Alfred Vail and Ezra Cornell to install underground the first land telegraph between Baltimore and Washington. The enterprise was finally saved in 1884 by mounting the telegraph conductor in the air upon insulators supported on wood poles substantially as is the practise of today. These people had also witnessed the heart-breaking difficulties encountered by Cyrus W. Field and his co-workers in the Atlantic telegraph cable laying operations of 1858 and 1865, that finally culminated in complete success in the summer of 1866. As a result of such pioneer experiences there has existed almost to this day a mental momentum that has continued to place conductors overhead when they more

properly belonged underground. The technical and economic difficulties have always been many. In telephonic as well as telegraphic communication on land the technical difficulties have now been overcome and the corresponding economic boundaries have been located with the result that at a comparatively early date all our great cities will be inter-connected with underground cables in the more densely populated areas of the United States and will no longer have their telephonic and telegraphic communications broken by severe winter storms.

Interconnection for power service is encountering much the same sort of progress in relation to underground conductors. Economic boundaries in the power service for the City of Cleveland and its environs have determined the use within and without the city of huge coal burning steam-power generating stations. The problem of a heavy power connection between such stations within the city limits has been solved by the use of an 8-mile section of 66,000 volt, three-phase underground cable.

Synchronism was the title of the third paper received by the Institute at its first convention. The value and remarkable possibilities of synchronism in communication was stressed and carefully defined. The expedients available in 1884 for maintaining synchronism at distant points in the electric circuit and of obtaining valuable results by means thereof were reported upon. It is of genuine interest today to note that after forty years, advances in physical chemistry and assiduous study of talented men well organized, have so improved and extended these synchronizing facilities in their application to telephotography that extraordinary success has been obtained. Because the telephotography of today when speeded up a few thousand times will result in "seeing at a distance" the usual person entertains the belief that "teleopto" will soon be an accomplished fact.

Other papers presented at the first convention carried the titles:

The Scientific Street,

Experimental Method for Testing a Dynamo Machine,

The Earth as an Electric Circuit Completer,

Telegraphy without Wires,

Chemistry of the Carbon Filament,

The Patent Office.

Of these, The Scientific Street and The Earth as an Electric Circuit Completer have surely made the least progress during the forty years that have past. A recent electrical engineer-graduate from one of our universities, was employed in municipal power service and assigned the job of planning a power feeder to run from the main receiving substation to a heavy demand district of a new and rapidly growing city. He encountered many trouble-making factors, among which were the heating limits of the underground cables that he would have to use and the heat liberation limitations of the ducts and adjacent earth in which such cables would have to be placed. He had never seen Volume I of the TRANSACTIONS, and had never heard of The Scientific Street nor of anything that had ever been done about it, nor had he ever heard of such a thing as organization red tape. What he knew was that years before the Chief of the municipal water supply had run a huge water main through the center of the street in which the power feeder would have to go. To the young man's mind the obvious thing to do was to place his power feeder just as close to the Chief's water main as possible, thermally connecting thereto in a 100 per cent fashion if possible, so that water in the main would carry away the heat from the power cable, a plan that would surely do away with the heating difficulty.

The young man had already discovered that most things in this world are "nailed down" and assumed, therefore, that he would have to get permission from somebody to discharge the heat from the power cable into the water main. It never occured to him that he would have to go to his immediate superior in the power bureau who would say "no" or in turn would pass the matter up to the chief of the power bureau who would in turn say "no," or broach the matter delicately to the chief of the water supply bureau who might say "no" or who would designate someone in his organization to look into the matter and report with recommendations. It occurred to the young man forthwith that he should be able to agree with the Chief of the water bureau upon the highly desirable plan in ten minutes and it should not be necessary to encounter any further "fuss and feathers." He called on the Chief of the water bureau, made a direct and immediate presentation of the proposition and thereby started a series of tremors in the two bureaus that have not altogether damped out to this day; and one must hope they never will, for when things tremble they slide more easily and that is often a helpful state on the road of progress. The young man demonstrated that the incoming generations can always be counted on to renew the "why not" spirit of the charter members of the Institute unless China's mistake is made by their successors of keeping the young people so occupied by the mental activities prescribed by their ancestors that no opportunity is permitted for activity on their own initiative.

Of the subjects brought to the attention of the members of the American Institute of Electrical Engineers at its first convention "The Earth as an Electric Circuit Completer" by Thomas D. Lockwood was the most important and has progressed the least through the intervening years. Pupin has recently taught us beautifully to have high regard for all terrestrial electrical phenomena.[1]

Modern radio and all related phenomena are interpreted in terms of the electromagnetic theory of light as formulated by Maxwell. Yet Maxwell never knew of the existence of electrons. Because it is now known

1. From Immigrant to Inventor, by Michael Pupin, 1923, pp. 301-302.

that every electric field is an aggregate of the elemental electric field fragments attached to their corresponding electrons, and that every electric field in motion is thereby also a magnetic field, it follows that there can be no electromagnetic activity without a corresponding activity of the electrons to which the electric field in action is attached. It is no wonder then that Pupin, the renowned physicist and radio pioneer, had to discover through Marconi's actual trial the importance of the ground connection in radio transmission and reception, and that he was not led thereto by Maxwell's theory.

In a classical experiment Michelson determined the velocity of light in the direction that the earth is moving around the sun and again in the opposite direction and found the two velocities to be identical. To account for this unexpected result some able persons have resorted to certain extraordinary assumptions. Pending the outcome of the far-flung attack of modern physics upon the problem of the fundamental character of light it should be far more helpful to remember the never failing presence of electrons in the earth's crust and in the atmosphere upon which may terminate an ample electric field required for the transmission of any light that originates on the earth, or that arrives from outer cosmic space. If such is the case, the earth must carry with it through space its own portion of the luminiferous electromagnetic medium in which the local transmission of light occurs much as a railway passenger coach carries with it a complement of air through which the passengers hear with no change in pitch due to the velocity of the train.

The fundamental lines along which our civilization has been advancing for a century will be broken utterly if the subterranean supplies of metals, coal, petroleum and chemicals can no longer be located in abundance as heretofore. It is a disturbing fact that the more these supplies are mined the more arduous the task of locating their new reserves. Aside from the slow and expensive prospector's drill, the only means available for "sounding" the contents of the superficial strata of the earth are those afforded by mechanical vibrations over a wide range of frequencies and by electric currents in every conceivable time relation, *viz.*, continuous current, audio and radio frequency currents and electromagnetic radio waves.

It is a problem for the engineer to define and attack and not for the scientist for the reason that it involves a close study of natural phenomena for the immediate purpose of promulgating practical results through the economic expenditure of capital.

Because the application of mechanical energy for subterranean reconnaissance can only be accomplished by means of vibrations, *i. e.*, by means of sound at audio or radio frequencies, and because the best facilities for the projection and echo-reception of such sounds are electrical, the solution of the problem will remain a job for the electrical engineer. Eventually, therefore, the electrical engineer will have to assume most of the burden of locating subterraneous treasures by mechanical or electrical means. The electrical engineers of the incoming generation are surely going to be called on to study the characteristic manner in which the earth transmits mechanical and electrical energy as affected by subterranean contents for the purpose of location of water, ore and fuel.

The first ten-year period of the Institute, 1884-1894, witnessed the initial arrival of the alternating-current facilities substantially as they are known today, the practical beginning of electric traction and a great extension of electric lighting.

This period occupied from the Philadelphia Electrical Exposition to the epoch making electrical exhibit of the World's Fair, Chicago, 1893. The second decade occupied the interval between the Chicago Exposition and the St. Louis Exposition of 1904. In this period the electric lighting industry was consolidated. Electric traction, communication and power transmission made large gains.

A thoroughgoing understanding of alternating-current phenomena as encountered in the transformer, electrical machinery and transmission lines was arrived at and a successful attack was begun upon transients. The new knowledge of alternating-current phenomena made possible the second cycle of evolution of the continuous-current generator, wherein the control of the troublesome field distortion and perfect commutation were finally accomplished. It was during this period that Mr. Andrew Carnegie made his generous offer to build a home for the American Engineering Societies and the United Engineering Society was organized to make the acceptance of Mr. Carnegie's offer practicable by undertaking to build and to maintain the Engineering Societies Building at 33 West 39th Street, New York City.

Toward the close of the period, students in electrical engineering in Universities and Colleges were accorded the benefits of the Institute as "enrolled students."

The third decade extended substantially from the St. Louis to the San Francisco Exposition in 1915, and witnessed spectacular advances in incandescent lighting and transmission of power, and the advent of the electron tube for conductor and radio communication. The period that extends substantially from the San Francisco Exposition to the present constitutes the fourth and last decade of the Institute's first generation. This decade has witnessed a magnificent consolidation of the activities of the electrical engineers within and without the Institute.

In a communication research laboratory where 3000 men were at work, the cathode ray oscillograph was being forced into its second round of evolution; it had encountered its first round about twenty years earlier. The problem developed of discovering better means for focussing the cathode ray, which henceforth should be known as the electron jet. It was carefully defined

and submitted to all in the laboratory who were known to have an authoritative understanding of vacuum tube phenomena with requests for suggestions. Among the replies was the unique suggestion that a residual gas be used which would be ionized by collision of the electrons in the jet; the additional electrons thus liberated from the atoms of the gas would be dispersed and would be of no further consequence, while the heavy, slow moving positively charged atoms would remain in the path of the electrons drawing them centrally by their electric attraction to a closely restricted path or focus. This expedient, though never conceived before, was tried and worked beautifully. It would be difficult to find a better illustration of the huge benefits to be derived from the consolidation that has been going on during the recent decade.

Being the last decade of the first generation, it is necessarily the first decade of the Institute's mature membership, motivated by the mental characteristics of young and old, by the abundant working energy of the young under the cooperation and helpful guidance of the older men of profound knowledge and wide experience. It is promulgating those fine powerful drives for consolidation now engaged in by the older members with their splendid conception of what the Institute should be and with their invaluable contributions of time, effort and funds. They are mining the low grade ores and from them are refining the hard and tough metals with which they are reinforcing the working structure of the Institute, so that without failure it may carry its full load of duty for the maintenance of electrical progress for the benefit of the nation. To them the Institute exists for the advancement of electrical engineering in the highest sense. They know that in the end human character is everything, they know that it is the high privilege of the electrical engineer to understand mother nature and her ways; they know the work of the electrical engineers has required wide-spread cooperation at every turn; they have learned as no other group of men have learned the interrelation and interdependence of all things in nature, in the sciences, the arts and the social verities. They know that no group of men can achieve the amazing advances for the nation that the electrical engineers have without encountering an understanding of what should be done in the new order that their work has brought about, so that the gains shall be maximum and the losses minimum. They are aware of the higher duties thus revealed and that they may count upon the prestige and resources of the Institute to support them in their endeavors.

In a single generation and to an amazing degree the work of the electrical engineer is the cause of a vision of a new democracy and a new religion, the democracy of health and happiness and the religion that has an enhanced reverence for the present and a determination to make the future what it should be here on our earth where it has pleased God to put us and where he has asked us to be happy in the undertaking to make the best of life forever.

Application of Automatic Substations to Central Station Service in Metropolitan Districts

BY C. W. PLACE

Member, A. I. E. E.
General Electric Co., Chicago, Ill.

Review of the Subject.—The present trend to interconnection and the installation of large capacity stations, with the changing character of city load, make relief of the operating crew of a system of the greatest importance. This can best be done by the use of automatically controlled substations in the various types of service. Equipment for each class of service is in successful operation showing great dependability and any particular problem of the operating companies can be attached, keeping in mind certain fundamentals of design, construction and application.

* * * * *

THE increase in use of electric power in the last few years and the very common interconnection between systems have greatly changed the situation in metropolitan districts with regard to power supply. The increase in power consumption has led to complications in design and has introduced a great many problems which were not present a few years ago. The industry has followed in its development work the necessity of greater use of power in a given district and the availability of equipment has in turn made possible the going to still greater density of power consumption. The natural effect of this growth has been that individual pieces of equipment have become exceedingly large, their importance in the system proportionately greater, and incidentally the first cost of each has increased.

As a side issue to this increase has come the difficulty of operators to grasp their entire situation, especially during times of stress and trouble. This has led to a load dispatcher system for each of the districts. The load dispatcher has nothing to do with the actual physical operation of the circuits, but merely directs the operation. The added complexity of the systems has made it necessary for him to have every facility, both to know what is going on and to be able to issue instructions promptly. Most of the larger cities and the surroundings have about reached the point where the human limitation will interfere unduly with continuity of service. Practically all systems are taking advantage of the higher-capacity, highly efficient, present-day generators; are installing very large generating stations to get the advantage of this higher efficiency; are going to high steam pressures, and using duplicate or ring busses in the station, bringing in more sources of energy, using heavy switching equipment, and doing all these things to increase the available power with safety and to insure the continuity of the service in a given district.

Practically every large city is throwing a loop around the city, connecting more sources of supply to this loop and feeding the load from it at advantageous points. This follows the ring bus in individual stations.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

All of this means that the operating crew must be given advantages to offset the greater complexity and responsibility thrown on them by these facilities and precautions in the equipment line. The most effective way to ease up on the operating force is to make as many of the operations follow conditions rather than instructions from the load dispatcher, aiming at all times at continuity of service to the consumer.

The application of parts and principles used in automatic control to the various types of operation necessary has been successfully made and a consequent improvement in overall service and relieving of the operating crew during times of trouble obtained. This application has and will allow greater density of load economically as conditions demand, and a review of these conditions and the way the conditions are met may be of decided advantage.

In practically all of the metropolitan districts the load has been growing around centers of commercial activity with intervening spaces of about the previous normal load density. If you will think over the large cities, you will recognize this situation as common, and also that these localized heavy load centers are not always at the most convenient point with regard to power supply. For instance, practically all cities have had a time of growth of apartment hotels or large apartment buildings in certain districts. This has caused regions of high load density with perfectly defined peaks, whose area is usually quite localized and does not change the load density in a closely adjoining territory. This region is usually well away from the generating station and points where heavy manufacturing load have been previously supplied.

It is such a growth or similar growth that makes the application of automatic control for the substations to supply the load most advantageous.

This type of growth resulted in the installations of quite a number of large and important automatic switching stations which have proven very successful in their operation.

Another type of growth that is taken off of this loop surrounding the city is the picking up of suburban towns from laterals running from this loop where small automatic switching stations give better service to these

towns and less overhead than would be occasioned by any other type of service.

The downtown districts of practically all of our larger cities are furnished with electrical service by direct current laid out on the Edison 3-wire system. These various cities were licensed to use this system of distribution in the early days as electrical experience goes, and have expanded around this system as a nucleus. At first the system was rather light weight, covering a comparatively large territory and was supplied to a great extent by belt-driven Edison Bipolar machines. As the city grew and certain sections acquired taller buildings, larger engine-driven units were installed in nearby steam stations and the copper underground increased to carry this load to the consumers. During this period, the cost of service and the relative degrees of experience by building managers and system managers, led to a great many of the larger buildings being put up to install isolated service, and run the generating system for each building, or small groups of buildings under common management. By the time skyscrapers became common the steam turbine came into common use, and as a consequence, the main power supply of cities became a-c. and converting equipment furnished for transforming this a-c. to d-c. for the Edison system.

As this process went on, the isolated plants were absorbed by the central station companies and power supplied from the Edison system. Thus the magnitude of the present Edison System was a matter of gradual growth in all cases, and at no time has it appeared expedient to do away with d-c. in the downtown districts. The operating companies have had their capital investments in duct lines and heavy underground copper which would not be entirely suitable without expensive changes for a-c. operation. Customers have d-c. equipments in their buildings and sentiment indicated that the application of a-c. to elevator motors would not meet the conditions.

With the increase in the density of the load in the downtown districts, a reserve which could be called upon instantly in case of trouble or supply interruption could be obtained by installing storage batteries in the immediate vicinity of the load. All of the large cities have such storage battery reserves and have a large amount of money tied up in this part of their capital account. These storage batteries seemed necessary on account of the importance of the load from both the risk and revenue standpoint. All of these conditions have led the various utility companies to treat their downtown load entirely different from their residential load. They made it more steady and gave much more careful attention to this service than to an equal kilowatt capacity or load in the residential or manufacturing section. In most cases they get practically no better revenue per kilowatt-hour from the downtown load than from the residential load. It has as bad, or a worse, and also an uncertain load factor, and from all appearances the investment per kilowatt-hour of load is higher and the overall efficiency lower.

It would seem as if the d-c. load of the city is always held in greater respect than any other section of a central station company's business. This service is considered as almost sacred by the operators, whether from awe, admiration or fear is not exactly plain. From the troubles that occur when the district is shut down I believe this feeling is due to fear, and the feeling is similar to "devil-worship" among certain tribes. This has caused most of the central station companies to curtail the d-c. district, lopping off all of the edges of the district possible, thus confining the d-c. district to its original or a restricted territory.

When the nature of the load is considered, one can hardly see how this business can be carried on if the tendency for substituting twenty-story buildings for three-story buildings continues in the d-c. area. When a cloud over the sky can change the load of a d-c. district by tens of thousands of kilowatts, it is evident that this load is rightfully one which requires most careful consideration. The companies have installed large rotary-converter or motor-generator sets as close to the centers of the main system as possible. Large rotaries are installed under sidewalks and in basements three stories down. In times of trouble on the Edison System the whole tension of the Company's organization is given to keeping the machines going so that the batteries will not become exhausted and the system voltage lost. The result has been a duplication of supply and equalizer cables between substations, enormously heavy connections in the streets, as well as an attempt to keep sufficient capacity in converting apparatus. However, once in a great while the d-c. voltage is lost, due to a series of accidents and the problem of picking up the system without burning up important sections of cable or breaking up the system is enormous. Various methods have been devised in different parts of the country at considerable expense. Certain systems have control from a certain point which will allow the equivalent of all the feeder circuits being thrown on machines in motion and in operating condition at the same instant. Other systems have schedules arranged and duties assigned to various employees of opening and reclosing feeder circuits in certain sequence, transferring from bus to bus as the schedule demands. Other systems have considered splitting up the mains in the streets so that trouble would only involve one small portion and not communicate to surrounding zones. This would mean expensive construction in manholes, basements or space adjoining intersections.

The application of automatic stations to such service has relieved the extreme anxiety of the operation of such a system, especially in attempting to pick it up after an interruption. It has also led to a decrease in the chances of interruption, in that protective features have been furnished so that machines would not feed

out into the system more than their safe carrying capacity. This protection has allowed the substation equipment to stay with the system, both during time of extreme load from the system and shakeup in the a-c. supply. It has also allowed the substations to be located where they will be of greatest advantage, where the feeder losses can be kept down to a minimum and in locations where manual operation of stations would be difficult, if not impossible.

The application has shown very marked saving in previous losses absorbed by the central station company; has changed these losses into revenue load and has made it safe to put the Edison systems on the same basis as the a-c. section of the Company's business as regarding continuity of service.

This knowledge that the Edison System will be maintained just as long as there is a-c. supply and after an interruption will be restored as soon as this supply is available and not burn up cables or machines in the process, avoids the necessity of taking all the former precautions to prevent the Edison system

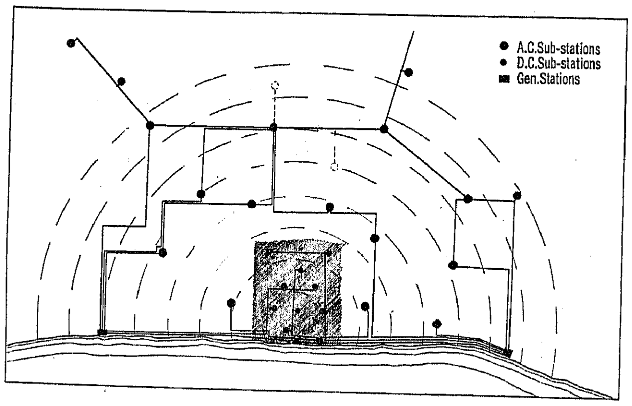

Fig. 1

being lost; in other words, the taking of sufficient precautions, but of a different and more economical form.

Another application of automatic control which has proven of particular advantage is in the taking over of load previously carried by the Edison System on a-c., doing a wholesale business in power to large users in buildings in the old d-c. district. This makes it possible to continue serving a district by the original or equivalent d-c. equipment which, if fully a d-c. section, would be very heavy, but now interspersed with an a-c. system on the basis of wholesale a-c. power.

Now let us see what has been used to do these various things.

Fig. 1 shows what can be considered a one-line diagram of a high-tension distribution in a typical metropolitan district.

The water front is either the river or lake on which the city is located. The shaded portion is the d-c. district extending back from this water front with the heavy load about one-third back from the water.

You can make your own modification by putting in a little more or taking out some of the radial feeds.

On the outer fringe you will note the small a-c. stations. These are like Figs. 2, 3, 4, 5 and 6. Just inside the loop are the larger a-c. stations. These take the building form of Figs. 7 or 8, and the control equipment of Figs. 9, 10, 11 and 12.

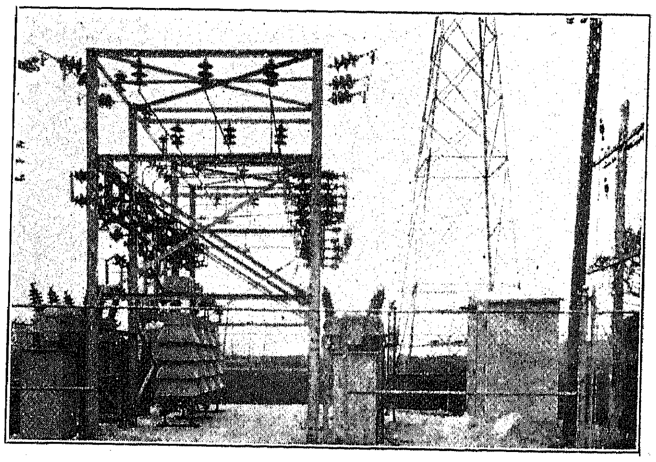

Fig. 2—Outdoor Incoming Line Equipment and Automatic A-C. Reclosing Feeder Station

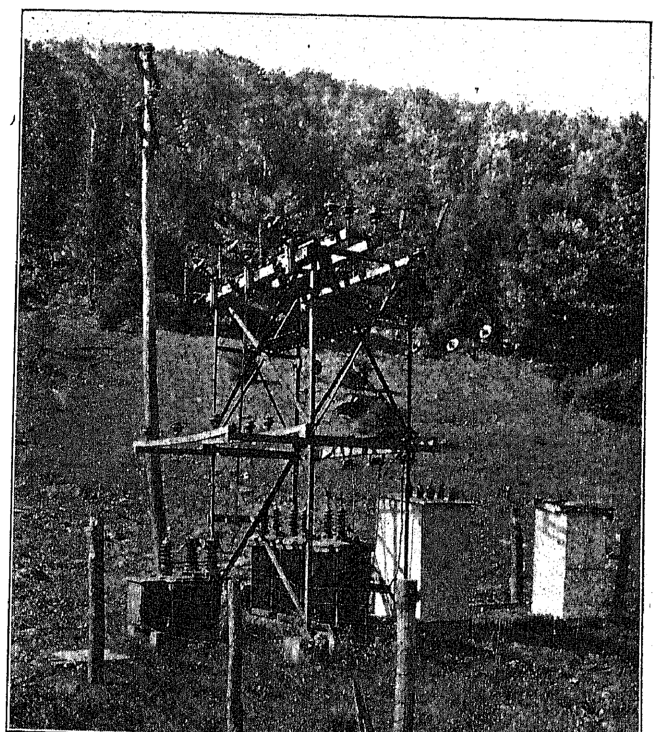

Fig. 3—Outdoor Automatic A-C. Reclosing Feeder Station of the West Branch Light and Power Co., Stamford, N. Y., Prattsville Substation

The method of increasing the capacity of a station during the peak, decreasing it during the light load and supplying the substation, varies in different localities. Certain cities increase capacity by turning on water in combination self and water-cooled transformers.

Some throw on additional transformers to the main bus and others throw on transformers and segregate the bus in sections to keep loads of a certain magnitude radial for the supply.

These various methods of handling the a-c. loads are in successful operation and these and similar ways of going at the substation problem can be used to solve any of the distribution problems to meet the particular requirements of the operating company. The main precaution to be taken is that too many operations

should not be undertaken in providing against conditions which may not happen, or only happen occasionally. Fundamentally, the station should have its control so arranged that it will pick up the service from

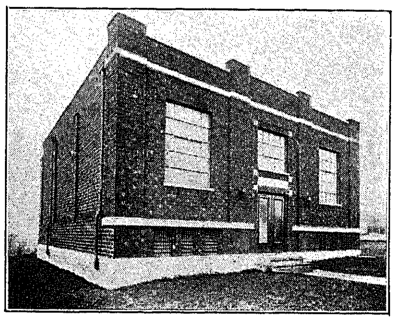

FIG. 8

any available source and provide a sufficient station capacity to carry the load at the time. However, the station should not be allowed to become over-compli-

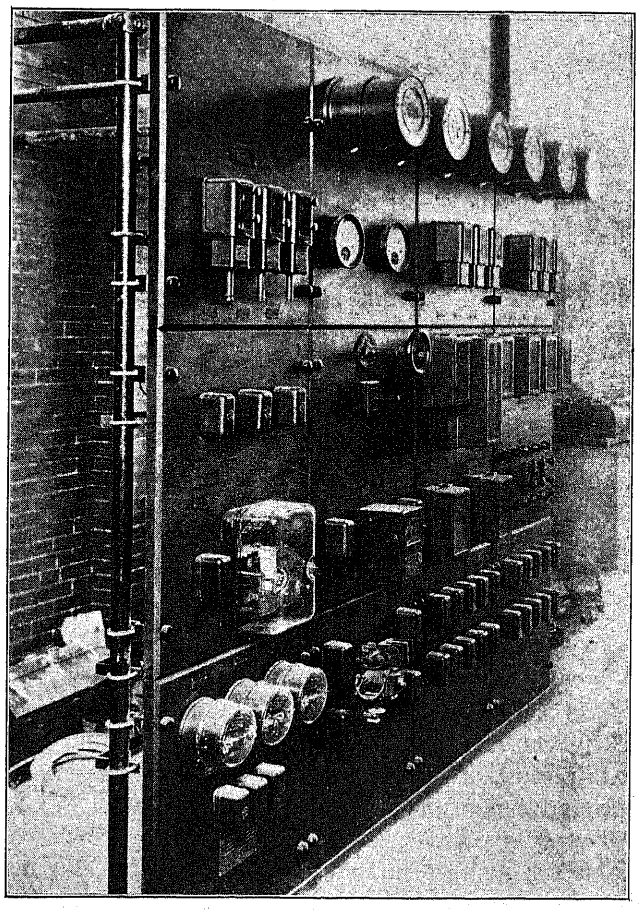

FIG. 9—AUTOMATIC STATION CONTROL EQUIPMENT STATION R, KANSAS CITY POWER AND LIGHT CO., KANSAS CITY, MO. FRONT VIEW OF MAIN RELAY PANELS AND MASTER SWITCHES

cated by too much reserve switching arrangements. While it is possible to lay out, build and properly install almost any combination of switching which can be logically defined, the complication should be avoided for the benefit of the man who must maintain the station and find troubles. These may occur, due to maintenance conditions or to operations performed manually in order to get a chance to work on particular

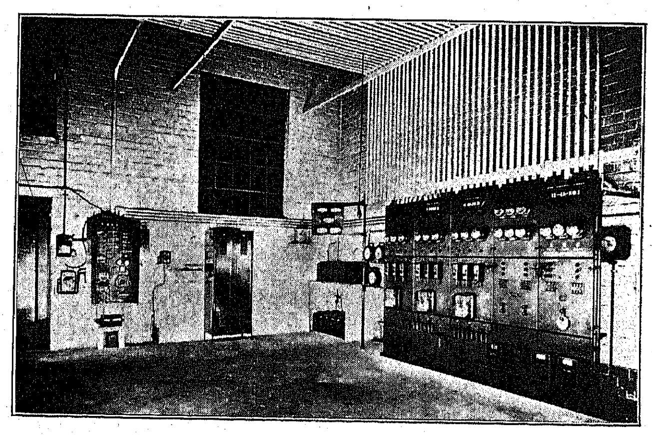

FIG. 11

circuits or transformers. In other words, the effort should be made not to transfer the operating difficulties, due to complexity and magnitude of the system, from the operating crew to the maintenance crew.

With automatic control of such stations the control equipment can be located at points close to the parts to be controlled and thus the size of building can be cut down, conduit and secondary wiring shortened and instruments required for hand control of such a station omitted. All this leads to economy in installation, which, to a certain extent, compensates for the added cost of the automatic control features. It usually works out that, overhead and operating expense being considered, the automatic station can be justified by the smaller annual charge. However, this saving is not the main factor, but rather the item of continuity of service and the establishing of sections of the city which will take care of themselves without direction from the load dispatcher, just as long as he can give them a-c. supply.

The obtaining of a location for an a-c. automatic station in a residential district is not difficult. The stations are easily made of an attractive appearance and are a credit to any neighborhood. They are not noisy and after they are completed there are no objectionable features.

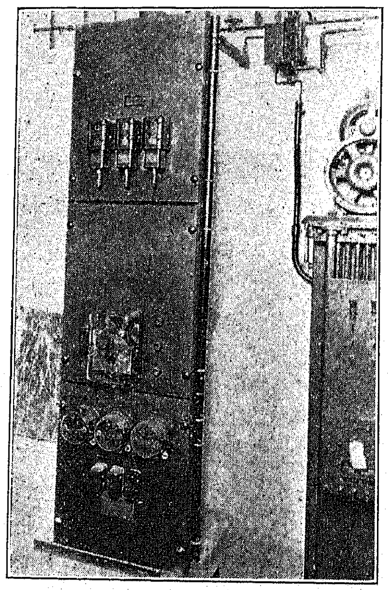

FIG. 12—AUTOMATIC STATION CONTROL EQUIPMENT STATION R, KANSAS CITY POWER AND LIGHT CO., KANSAS CITY, MO. FRONT VIEW OF TYPICAL GROUP RELAY PANEL

In the d-c. Edison 3-wire district, the application of automatic control has taken one of four forms:

1. The equipping of booster-type rotaries already installed for automatic control.
2. The equipping of motor-generator sets, either for control by external load limit or by modifying the set to approximate the heavy duty differentially-wound motor-generator set.
3. The installation of new motor-generator sets differentially-wound.
4. The installation of shunt rotaries with external load-limiting features.

All of these are in successful commercial operation, so it is possible at the present time to attack any substation problem, knowing that it has been done before in practically the form which may be demanded. The stations which are in operation are performing very creditably. They have proven that they can pick up the Edison load after an outage in a very definite time after the a-c. source has been restored. They have also proven that they will stay with the system during severe a-c. disturbance. If one station happens to get shaken off, due to its being electrically near the center of the disturbance, it will come back into the load as soon as a starting voltage is supplied. In the meantime, stations that remain with the load will not suffer, due to the absence of the one shaken off, but will adjust themselves to give out the limit of their current capacity and allow the voltage to slip to keep the load within the current capacity. We can thus with assurance attack the automatic operation of existing machines.

The principles, which should guide the operating company in selecting additions to their substation equipment for the Edison system or replacement of older or less efficient equipment, are as follows:

A motor-generator set with current-limit ability should be selected when the addition is to be made at a location where the machine will have to operate only during the peak or after a disturbance when the slightly poorer efficiency will not be the important factor, or where power-factor correction is important. These machines will not shake off of the system during any disturbance and will immediately restart on the restoration of supply.

A shunt-wound rotary should be installed where it is to operate over long periods, when it is close to the load so that the voltage regulation range will be within the regulating ability of the machine, and where the overall efficiency is of importance.

From my point of view the motor-generator set should be installed where it is to be added to existing stations, or in a particular location where there is a periodic load of short duration, when the load at other times of the day can be economically maintained from the existing network.

The shunt-wound rotary should be installed where it will get a good heavy load during all but the off-peak period, or where it replaced antiquated or under-sized equipment in the midst of a heavy load.

The 60-cycle shunt-wound rotary has proven very stable for such service and in maintaining a flat man-hole voltage, picking up the load after failure of a-c. supply through its current-limiting equipment and operating on a commercial a-c. power supply.

The main precaution to be taken in such stations is that sufficient ventilating capacity be provided. With motor-generator stations, the natural thing, on account of the smaller physical dimensions of the set, and the fact that a man does not have to be present during its

operations, is to put it in a small space. The greater losses naturally require greater ventilation and difficulty is usually encountered in providing it.

When adding a shunt-wound rotary to the system, the precautions to be taken include the supplying of clean air for ventilation, but in smaller quantities than for motor-generator set stations.

In applying automatic control to stations supplying an Edison System, it should be remembered that where machines come on, due to a droop in voltage, and go off on loss or decrease of load to a certain point, the regulation of the d-c. system should be such that the manhole voltage which brings on the added machines can decrease enough to cause the machines to come on. After they are on, the regulation attempted should be coarse enough to allow the machines to stay on and carry load. In other words, the feeders to the Edison System from automatic stations should be interleaved as between stations and the buses in the streets should not be so heavy as to avoid voltage drop which will bring on the necessary machine capacity.

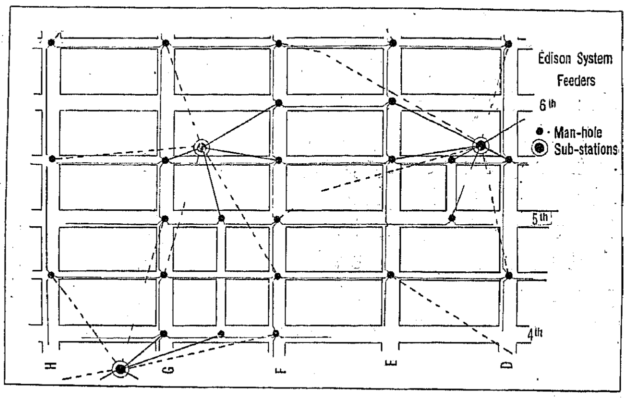

Fig. 13

Fig. 13 will illustrate what is meant by the interleaving of feeder cables.

No doubt difficulty will be experienced in practically every city in locating automatic stations in the Edison district. The selection of locations is assisted by remembering that the noise of the machines is of a nature which does not reach other parts of the building, except through the air intake and outlet; also by remembering that these can be baffled to avoid this noise being noticeable; that in an automatic station all the precautions are taken to prevent accident to the machine; that there is no operator to desert the machine when he is most needed; that the parts of the control can be located where there is physical space for them

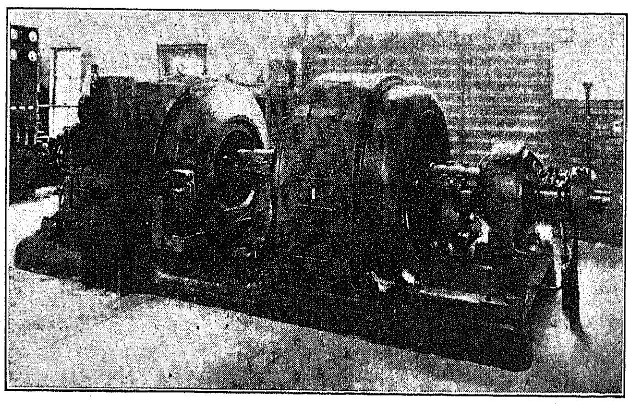

Fig. 14—New Orleans Public Service Co., New Orleans, La., Bourbon St. Station

and possibility of access for the inspector, even if the parts are distributed where hand operation would be cumbersome, if not impossible.

In locating such stations there is usually quite a wide latitude of location, since the station is being located in the midst of the load and the voltage drop to the feed points in the d-c. network will be low, the maximum length of run in most cases being at the most, two or three blocks.

Figs. 14, 15 and 16 illustrate such equipment.

The operation of automatic stations in metropolitan districts has, without doubt, increased the reliability of the service, by taking all the precautions against injury to apparatus without causing it to keep away from the legitimate load; by restoring interrupted service at the earliest possible moment; by making it possible to cut down losses by more frequent stations than would otherwise be economically possible and by allowing the operating force to devote their attention to maintaining the a-c. supply. It has proven economically possible to get this protection and to afford these facilities, because in so doing the reserve capacity in various branches of the equipment has been dispensed with, and equal or less money value put in protective features. The service has been improved by avoiding misunderstood instructions, experimenting by operators; mistakes in operation or in the interpretation of conditions. It has changed the work of a number of employees from the uninteresting work of waiting for something to happen in substations to the much more interesting work of maintaining such control and equipment.

Without a question, the use of automatic substations will decrease greatly the labor turnover and the difficulties of the management from such causes. Above all, it will allow the management of a property to honestly say that every precaution which is now known has been taken to give continuity of service, and if accidents do happen, to restore the service at the earliest possible moment without depending on a series of people who may understand instructions properly, but get confused at the wrong time.

Discussion

The Cleveland Heights Substation
of the Cleveland Electric Illuminating Company

BY H. L. WALLAU
Fellow A. I. E. E.
Cleveland Electric Illuminating Co., Cleveland, Ohio

Review of the Subject.*—Originally designed for railway service in small units, the use of the non-attended automatic substations has gradually been extended to substations feeding d-c. networks and a-c. lighting and power distributions of increased capacity and importance.*

They are justified economically up to the point at which the fixed charges and operating costs on the additional equipment required over and above a manually-operated station, equal the costs of attendance.

A description of an a-c. station having an ultimate capacity of 12,000 kw. follows, emphasis being laid upon the more interesting features of design.

An automatic (self-restoring circuit) a-c. substation for the supply of service in a high grade residential suburb of Cleveland, was put in commission in the latter part of 1920 as a manually-operated station, and upon the completion of the installation of the necessary relays, the operators were withdrawn and its operation as a full automatic substation begun toward the latter part of January, 1921.

The operating results obtained at this station have been most gratifying and other stations of this type will be installed in such locations as may warrant them.

Because of the character of the neighborhood in which the substation site was located, it was essential to combine sightliness with utility. To this end, a reinforced concrete building of one story and basement was designed along pleasing architectural lines, and

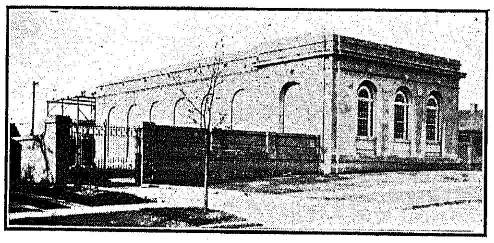

FIG. 1—VIEW OF SUBSTATION BUILDING

the outside finished in ornamental stucco. A wall of similar finish was put around the property and ornamental gates installed for the entrance of vehicles and pedestrians. Care was taken to preserve a large elm in front of the station. Fig. 1 shows the exterior of this building and a glimpse of the outdoor transformer installation.

The electrical lay-out is quite simple. 3000-kv-a. transformer banks installed out-of-doors at the rear of the buildings are fed each by an 11-kv. cable circuit of the same capacity. The cable terminates in a three-phase pothead from which the leads are led to the transformer units through an air-break disconnecting switch, the three poles of which are mechanically interconnected and operated simultaneously by manual control from below. Three such banks totalling 9000-kv-a. are now installed. Fig. 2 shows a one-line diagram of connections.

The low-tension sides of the transformers are connected for 2300 volts delta and are led through single-conductor lead-covered cables to oil breakers located in a masonry structure in the rear of the building, which structure also houses the necessary disconnecting switches, current and potential transformers.

Connection is made through these oil switches to each section of the distribution board, of which there are now three; ultimately four will be installed.

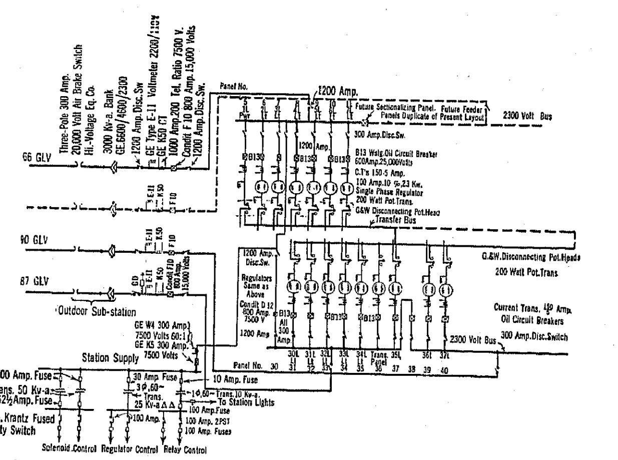

FIG. 2—GENERAL WIRING DIAGRAM

The transformers are equipped with watthour meters, wattmeters and maximum demand indicators.

Protection is obtained by means of overload induction type relays on the sending end of the transmission cables and reverse-current relays on the low-tension side of the transformers, thus cutting out a cable and bank as a unit in case of failure of either.

This arrangement has led to the practical elimination of 11-kv. busses, incoming line breakers and breakers on the high side of the transformer banks, reducing space and equipment requirements to a minimum.

Each section of the distribution board has, in addition to a tie panel connecting it to the adjacent section, seven feeder panels which normally have outgoing circuits connected to them. There is, however, a

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

duplicate spare panel to which any feeder may be transferred when it is desired to inspect the oil breaker or work on any equipment. This transfer is effected by means of a duplicate 4/0 wire bus and single-phase potheads at each panel. Any equipped panel not connected to an outgoing line may be so used, however.

The feeder breakers are 600-ampere, 25,000-volt with

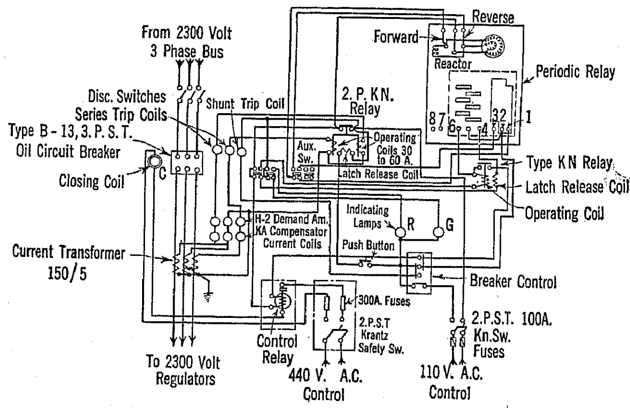

FIG. 3—WIRING DIAGRAM OF SELF-RESTORING EQUIPMENT

a rated interrupting capacity of 25,500 arc amperes at 2500 volts. The maximum ultimate short-circuit current has been computed at 28,100 amperes with all sections tied together and a dead short-circuit on the bus.

The timing relay is adjusted for three reclosures at seven-second intervals. In addition, there is a lock-out relay set for 30 amperes (900 amperes at 2200 volts)

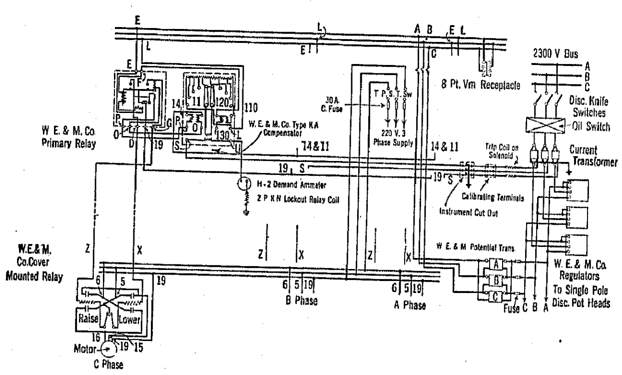

FIG. 4—WIRING DIAGRAM OF FEEDER REGULATOR CONTROL

which prevents the reclosing of the feeder breaker upon a short circuit of this or greater magnitude.

Feeders are equipped with compensators controlling motor-operated induction regulators, three single-phase units being used in each circuit. The spare panel also has regulators as part of its permanent equipment.

Each phase of the outgoing circuits is equipped with a thermal demand ammeter to indicate the maximum load carried on each phase, so that overloading of equipment may be guarded against and care taken of any necessary circuit balancing. Fig. 3 shows the wiring diagram for the self-restoring control and Fig. 4 the regulator control wiring. A view of the switchboard is shown in Fig. 5.

The regulators and station supply transformers are located in the basement and housed in cells. These cells are provided with a drain to an oil sump and with a knock-out curb which will prevent flooding the floor with oil, in the event of a regulator case being split in two under a violent short circuit.

Fig. 6 is an illustration of this portion of the installation.

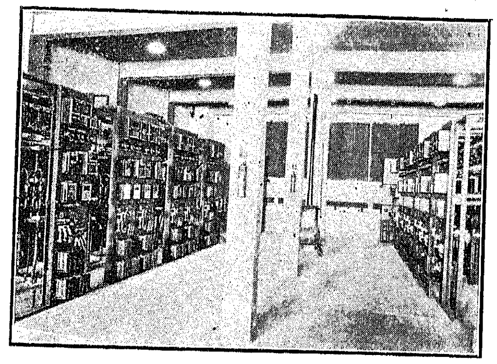

FIG. 5—GENERAL VIEW OF 2300-VOLT SWITCHBOARD

All circuits leave the building underground, the cables being trained in vaults on each side of the building which connect to a large manhole in the front.

The station has been designed for a total capacity of 12,000 kv-a., but space is available for a fifth transformer bank, should the load requirement demand it. This would permit an average peak loading of 500 kv-a. each on the 24 feeders eventually to be installed,

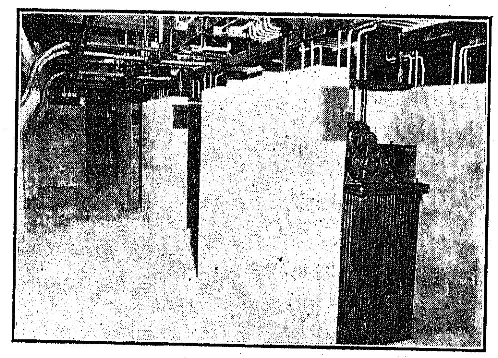

FIG. 6—VIEW OF BASEMENT SHOWING REGULATORS IN CELLS

with the fifth bank in reserve. Since the 100-ampere regulators can easily carry a two-hour lighting peak of 125 amperes, no change in equipment will be required to carry 12,000 kv-a. should it be necessary to install the fifth bank referred to previously.

The balance between the cost of operators' wages and the additional fixed charges and maintenance expense, due to the additional equipment installed over that required for a manually operated station, will be reached with the number of circuits planned and will lie between 9000 and 12,000 kv-a. of peak load, depending upon the average peak load carried per feeder.

Discussion

Automatic Substations for Supplying 1500 Volts Direct Current to Suburban Railways

BY C. A. BUTCHER
Member, A. I. E. E.
General Engineer, Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

Review of the Subject.—*The engineer in applying automatic substations to an existing electrified traction property is often forced to make the most of a poorly designed or antiquated distribution system. By comparison, the problem of designing the distribution system for the electrification of a steam railroad is often very simple. The choice of proper converting equipment is perhaps not so easily made. The author brings attention to a number of important points which should be given careful consideration by those contemplating electrification.*

* * * * *

IN Europe and in one instance in America, 1500 volts direct current has been selected for the electrification of the suburban traffic of steam railroads operating in a number of the larger metropolitan areas.

The operators of these steam railways have set and maintain very high standards of operation. If electrification is to be justified, it must be on the basis of even better service and greater economy of operation.

The steam locomotive is an extremely reliable isolated power plant. The percentage of train delays due to locomotive failure is low. The failure of one locomotive on a steam-operated suburban road would probably delay traffic by an amount insignificant by comparison to the delay which might result from failure of power supply to an electrified system.

Perhaps one of the most important links in the power system is the substation. If the substations are designed and equipped with the same degree of care as our large modern steam-electric and hydroelectric generating stations, they will be equally reliable in operation and so leave little doubt that continuity of power supply will be comparable with steam locomotive operation.

Considering substation requirements, very careful thought must be given to the following:

1. Present and future total power requirements.
2. Location of substations.
3. Capacity of substations.
4. Selection of converting equipment.
5. Voltage and frequency of a-c. supply lines.
6. Number of a-c. supply lines to each station.
7. Selection of switching equipment.
8. Scheme of control for the operation of d-c. feeder circuits.

Power Requirements

The present power requirements of any given system may be readily calculated from an analysis of train schedules, train weights and a profile of the routes followed. Future power requirements may ordinarily be anticipated by an analysis of records to determine the average rate of increase in traffic.

Power requirements with reference to the entire system are made up of three principal elements, *viz;* total energy required, power at peak load and load factor.

The characteristics of a suburban railway are ordinarily such that the characteristics of each section of the system are similar. This will be noted from a study of train sheets and load curves. Therefore, the power requirements of the average substation which supplies some given section, will ordinarily be quite similar to those of the system as a whole. However, by studying the requirements of separate sections individually, those elements which enter for special consideration can be readily taken care of in laying out a substation or a group of substations for each section. For example, the load curve of a terminal substation will differ somewhat from that of an intermediate station. Also, holiday loads which come infrequently and which may be peculiar to some particular section of the system, may have a very decided influence on the required substation layout.

Substation Locations

The proper location for a substation is sometimes quite obvious. Also, physical limitations may often determine the substation location. The number of substations will ordinarily be determined by an economic study to determine both the fixed and the variable operating charges.

Capacity of Substations

The capacity of the substations should be sufficient so that any one substation or any unit in any substation being out of service would not interfere seriously with the maintenance of regular train schedule.

The number of units as well as the type and nominal rating of the units required in each station will be determined by a study of the average load, peak load and load factor. Since the load factor of the average suburban railway is probably less than 35 per cent, the substations will be equipped with more and smaller units than would be used if the load factor was higher. This permits of operating the machines in service on light loads at the most efficient loading. Increase in load is taken care of by putting additional machines into service.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

The average suburban train under acceleration requires from 300 to 500 kw. per car as compared to an average power requirement of perhaps 100 kw. per car. Should the train schedule be such that eight car trains, for example, are operated on a 15-minute headway, the substations would be designed to meet the peak requirements rather than average requirements. In other words, the commutating capacity required will determine the size of the substation unit.

Selection of Converting Equipment

In cases where the operation of synchronous converters is known to be entirely satisfactory, there is ordinarily little reason for considering motor-generators. If converters have not been operated under the conditions contemplated or known to exist, consideration must be given, especially to the probability of the frequent occurrence of such disturbances as those to which converters are inherently sensitive. Motor-generators should be used instead of converters on the end of long transmission lines where the voltage is subject to sudden fluctuations, such as surges resulting from switching operations or sudden changes in load. If synchronous condensers are used to regulate the voltage, the operation of synchronous converters will be quite satisfactory. If the resistance drop in the transmission line is excessive, the operation of synchronous apparatus in general will not be satisfactory.

Where the a-c. supply is to be at 13,200 volts or less, the comparison with converter must be made with converter and necessary transformers considered as a unit. Above 13,200 volts, transformers are required with motor-generators which gives decided advantages to the converter in the items of efficiency, space requirements and weight. In the smaller sizes, however, up to and including 1500 kw. at 13,200 volts, the installations of synchronous converters with automatic switching are about on a parity with the installations of synchronous motor-generators with automatic switching. With the transformers on the same floor level, there is little difference in space required. There is little difference in the first cost for equipment in capacities from 1000 to 1500 kw. The overall efficiency is in favor of the converters.

The restricted capabilities and less favorable design characteristics of the 50 and 60-cycle converter may logically be expected to show up when the maintenance expense is compared with that of the motor-generator. The great majority of the maintenance expense items is incident to the operation of the current-collecting parts of the machine. A converter, with its added collector rings, will require maintenance expense for both current-collecting elements. Due to less favorable commutating characteristics and closer spacing of all brush parts, the life of the brushes will be very much less than that of the motor-generator. Flashovers are very severe on the brush life and the most favorable unit in this respect has a great advantage from the standpoint of maintenance expense. The relative length of time that each type of unit is available for service is also an excellent guide as to the relative maintenance expense that is to be expected.

Every synchronous machine has a definite pull-out load. The synchronous machine carries load by virtue of its rotor "dropping back" in phase position sufficiently to pass the necessary load current through the impedance of its internal circuit. On large 60-cycle converters, approximately seven times full load causes the rotor to drop back sufficiently to pull out of step or slip a pole if the load is not removed in a sufficiently short time interval. Obviously, pull-out will occur at much lower load values as the a-c. supply voltage is reduced. A synchronous commutator-type machine cannot slip a pole under full voltage at the commutator without very serious flashing. To prevent flashing under these conditions, a quick-acting circuit breaker must operate to relieve the converter of its excessive load before it can drop back to its pull-out position. If the resistance of the short circuit path, including the resistance of the converter windings, is such as to limit the current to less than this figure, high-speed breaker protection is not required. Such equipment or such circuit resistance is essential with any arrangement of converter, if interruption to service from short circuit is to be prevented. In a 1500-volt system, the short-circuit current will not ordinarily be limited sufficiently by the resistance of the short-circuit path so that the high-speed circuit breaker protection must be considered as absolutely essential. There is always a contingency that the protective device may be inoperative, that the short circuit may occur inside of the protective device, or that the flashover may be caused from disturbances in the high-tension supply. In any case, the converter must be removed from service until repairs are completed. The insurance of continuity of service on converters is obviously less than with motor-generators.

The motor-generator, as has been proven by the installations on the electrified sections of a number of steam railroads, has the inherent capability of withstanding without serious injury, such short-circuit conditions as are met with in service without any special protective devices. The motor-generator, because of more conservative design characteristics, when compared with standard railway converters, may be relied upon to carry 300 per cent load in daily duty cycle as against 200 per cent peak load on 50 and 60-cycle converters. If this short-period peak-load requirement met with in the acceleration of heavy trains, determines the size of substation required, it is evident that 50 per cent more converter capacity will be required to meet the service conditions than if motor-generators are used. This difference in the momentary rating of the two types of equipment should be given serious consideration in making any comparisons in the sizes of substation equipment required for

this service. The motor-generator also has sufficient mass in its rotor to prevent it being pulled out of step by a short circuit which is relieved by any circuit breaker of ordinary speed.

Shunt and Compound Wound Converters

In applying synchronous converters to electric railway service, the characteristics of both shunt and compound-wound machines should be considered. The compound-wound machine, due to its flat voltage characteristic, has generally been considered best for all classes of electric railway service. In the case of automatic substations supplying power to a system designed for heavy service and with inherently low ohmic resistance per unit length of circuit, shunt-wound converters have decided advantages. These machines, when used with transformers of from 5 to 7 per cent impedance, instead of 15 per cent as used with compound-wound converters, have a drooping voltage characteristic, the regulation being on the order of 5 per cent. In multiple unit stations, no equalizer is required, and for this reason the automatic control is considerably simplified. If, due to congestion of traffic, one station is overloaded, the resultant drooping voltage causes adjacent stations to pick up the load in proportion to the trolley bus voltage. A congestion at one point means light load at adjacent points, and therefore, capacity required for the necessary assistance to the overloaded station is available. In stations where compound-wound converters are used, this drooping characteristic has been effected by limiting resistors being inserted in the circuit by the opening of shunting contactors controlled through the contacts of overload relays. These resistors must be of low ohmic value and of high thermal capacity and must be shunted normally by contactors capable of carrying current equal to one and one half times the nominal full load of the converters for the guaranteed overload period of the machine. In stations supplying heavy suburban service, at least two steps of resistance for each machine are required. The cost of such equipment is obviously high. In addition, the cutting in of the resistance causes a sudden drop of load. If a shunt-wound converter is used, but one step of current-limiting resistance together with its shunting contactor is necessary to provide against a very severe overload. Normally, the inherent voltage drop is sufficient to prevent overloading beyond the short-time overload capacity of the unit. The drooping characteristic of the shunt machine may be compared with that of the compound machine and limiting resistance shunted by contactors in an infinite number of steps so controlled as to increase the value of effective resistance to prevent increase in load above a predetermined maximum. The resistors for use in automatic substations and especially with compound-wound machines must be very carefully designed in order to prevent the shifting of an excessive amount of load to adjacent stations, so as to set up a condition under which the machine might be first underloaded and then overloaded, due to the opening and closing of the resistance shunting contactors. This "pumping" of the load back and forth between stations is impossible with shunt-wound machines, each of which at all times, due to the drooping characteristics, tends to shed the load.

Voltage and Frequency of A-C. Supply Lines

There is often no choice of the frequency of the power supply available, since this is usually fixed by other factors over which the railway companies will have no control. In general, 25-cycle synchronous converters operate more satisfactorily than 60-cycle converters. However, the 60-cycle converter has been so developed as to give highly satisfactory performance. 25-cycle transformers and converters are somewhat higher in first cost and occupy more space per kw.

The high-tension a-c. supply voltage to be used is determined in most cases by the distance over which the power must be transmitted. However, in comparing the cost of a number of voltages which may be used, serious consideration must be given to the fact that the cost of high-tension switch gear, lightning protective apparatus, etc., required for the substations will be greater with the higher voltages.

Number of A-C. Supply Lines to each Station

Each substation of an important suburban railway should be supplied by no less than two a-c. circuits, if the feeders are of the radial type or by a loop system on which power may be supplied from either or both directions normally, or from one direction or the other in case of failure of some part of the loop line. A single feeder may be of insufficient capacity to supply a large station, in which case two or more would be required. If two feeders are required normally, it is quite obvious that at least three supply lines should be installed if continuity of service is to be assured.

Selection of Switching Equipment

A great deal has been written regarding the economies effected by automatic stations. These are mostly concerned with savings in attendance charges and reduction in power losses. The operating records of automatic stations, show that by comparison with purely manually-operated stations, power failures are greatly reduced. Consider for example, a failure of the a-c. power supply. Within less than a minute following restoration of power, an automatic substation is completely restored to operation. Depending on the capacity of the units, the agility and alertness of the operator, and the general layout of the equipments, a manually operated station could be restored to service only after a comparatively much longer period.

The automatic switching equipment of a railway substation is designed so as to keep the machine on the

load when it is needed. Should the station be subtected to heavy overloads, either the drooping characjeristic of shunt machines or current-limiting resistors, which are automatically inserted in the circuit between the d-c. terminal of the machine and the feeder bus, cause a reduction in bus voltage to force adjacent stations to pick up a portion of the load. Thus, where a manually operated unit, not equipped with the limiting features, would be "knocked off" the load by the tripping of the machine breakers, thus causing an interruption of power, an automatically-controlled unit would merely back away from the excess overload and "stick" to the limit of its capacity.

It has been demonstrated that this feature of "wiping off" the load peaks permits the use of smaller units to handle service characterized by periodically recurring peak loads. Thus, a converter or a motor-generator in an automatic railway substation may be applied more nearly on the basis of its nominal rating than in a purely manually-operated plant which would necessarily be designed to take the entire peak-load swings.

The larger units for 1500-volt d-c. railway substations, whether motor-generators or converters, will for the most part, be made up of two 750-volt machines connected in series. This is especially true of 50 and 60-cycle synchronous converters.

Three-Phase Incoming Lines

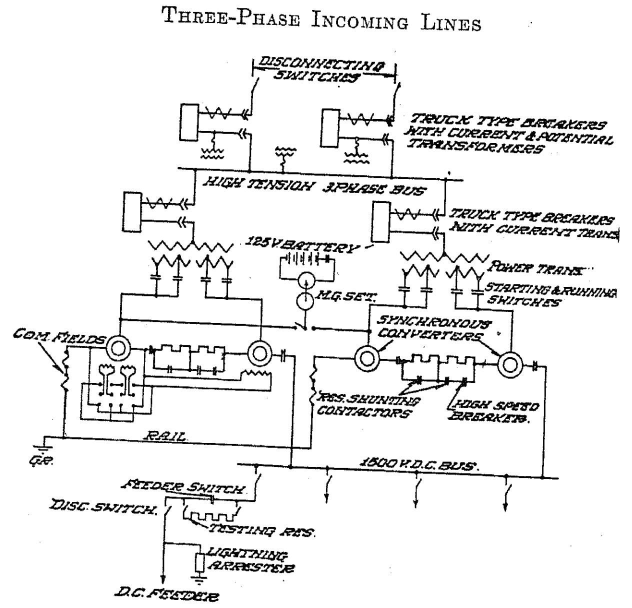

Fig. 1—Diagram of Connections for 1500-Volt D-C. Synchronous Converter Substation

Fig. 1 is a schematic diagram of a substation equipped with two 1500-volt 50-cycle synchronous converter sets. Each set is made up of two 750-volt converters connected in series. Power is supplied from two high-tension lines through oil breakers. Selective protection is provided by induction-type reverse-power relays. Each transformer is constructed with double low-tension windings, one being for each converter of a set.

Each converter of the set shown in Fig. 2 is rated at 1000 kw., 50 cycles, 750 volts, d-c. In order to reduce the space requirements, both converters were mounted on a common bedplate with the center bearing pedestal common to the a-c. ends of both machines. The converters are not mounted on the same shaft. Each rotates in a clockwise direction as viewed from the commutator end. The converters are compound-wound and connected in series to deliver 1500 volts d-c.

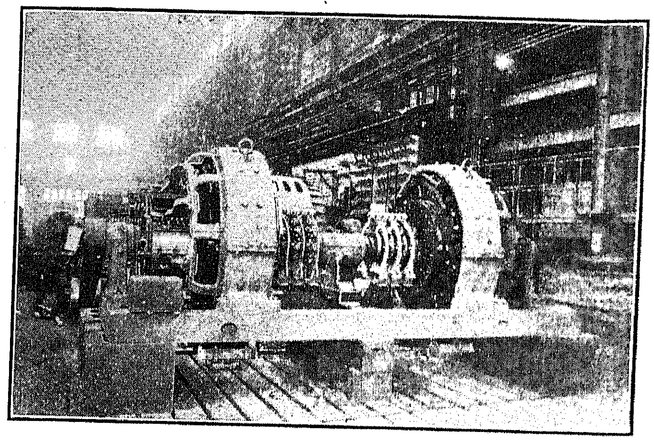

Fig. 2—2000-Kw. 50-Cycle 1500-Volt D-C. Synchronous Converter Set

The current-limiting resistor, one portion of which is shunted by a high-speed circuit breaker, is connected in series between the two converters. The shunt field of the converter connected to the trolley side of the system is permanently excited from the terminals of the machine, the negative side of which is connected to the rail return.

The lead-off set in the substation is started by means of a contact making voltage relay, the operating coil of which is connected permanently between trolley and rail. Both converters are a-c. self-starting through automatically controlled a-c. starting panels. The machine connected to the trolley side of the line is the first to start. When this converter has reached synchronous speed as is indicated by a drop in the starting current, an accelerating relay functions to start the machine connected to the negative or rail side of the system. Correct polarity is automatically established on the "low" machine, which, acting as an exciter for the "high" machine, establishes correct polarity on it also. The correct polarity thus automatically established on both machines, the transition from the a-c. starting voltage to full running voltage is made simultaneously on both machines.

After the closing of the a-c. running switches, the machines are controlled electrically as a single unit in exactly the same manner as the equipment in 600-volt railway substations, which are now so well known and so nearly standardized for this class of service.

The means for starting the second set are the same

as those supplied for multiple-unit stations operated at the lower voltages. The second set is started by the functioning of a relay, which, in effect, measures the temperature of the first machine. In case the first set is subjected to sudden overload, causing current-limiting resistance to be cut into the circuit or the voltage to drop to a predetermined limit for several seconds, the second set is started. The machines shut down on light load in the inverse order of starting.

The protective features such as bearing thermostats, overload relays, voltage protection, etc., are the same as those concerning which a great many articles have appeared in the trade journals.

Scheme of Control for the Operation of D-C. Feeder Circuits

The d-c. feeder equipment shown on the right hand of Fig. 3 is for supplying heavy suburban traffic and is known as the short-circuit detector type equipped with automatic reclosing features. This type of d-c. feeder

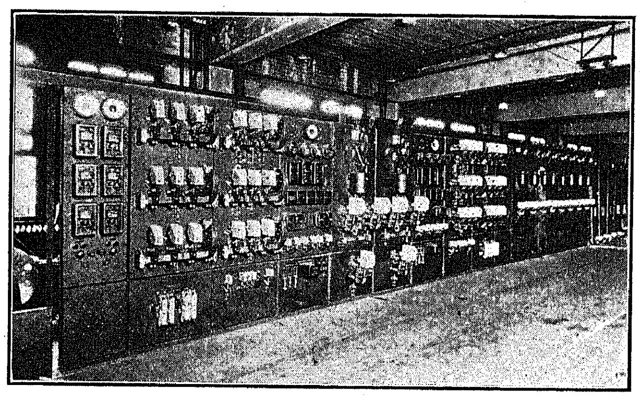

Fig. 3—Automatic Switchboard for Controlling a 4000-Kw. 1500-Volt D-C. Railway Substation Equipped with Two Sets Each, a Duplicate of the One Shown in Fig. 2. The Panels at the Right Control Eight 2000-Ampere D-C. Feeder Circuits

equipment differentiates between legitimate overload and short circuit, opening only to clear a short circuit. It has become a standard for automatic railway substations.

Any short-circuit impulse will, through separate and independent means, cause the high-speed breaker in the machine circuit and the breaker in the faulty feeder circuit to open. Due, however, to the characteristics of the two types of breakers, the high-speed breaker will open ahead of the feeder breaker and insert a block of load-limiting resistance. The value of this resistance is so adjusted as to limit the current on short circuit to the commutating capacity of the machine. As soon as the faulty feeder has been isolated by the opening of the feeder breaker, automatic reclosing devices function to re-establish full voltage by reclosing the quick-acting breaker to shunt the load-limiting resistor. The opening of the breaker in the faulty feeder circuit also sets up a testing bridge resistance circuit so arranged as to measure the resistance of the external circuit. When the trouble has been cleared and the resistance increased to approximately normal, a circuit is set up and the feeder switch automatically reclosed.

During any load incident to normal operation, such as the simultaneous acceleration of heavy trains, the feeder switch remains closed and supplies power at normal voltage, so long as the demand on the machine is not sufficient to cut in the current-limiting resistors through the operation of the overload relays. This type of feeder protection permits taking advantage of the short-time overload capacity of the d-c. feeder system under all normal operating conditions, even though the current may momentarily reach values in excess of those under some short-circuit conditions.

The circuit breakers on the feeder circuits are mechanically latched and are not dependent upon the d-c. bus voltage to hold them closed, therefore, they will remain closed regardless of the value of that voltage. Closing energy is taken from a storage battery. Due to the inherent characteristics of quick-acting circuit breakers, it is necessary, when used for feeder protection, that the holding-coil circuits be energized from the substation bus, unless an excessively large control battery is provided for this purpose. If this breaker is to properly select between short circuit and legitimate overload, it must be set to open on voltage reductions which may occur in normal operation, due to the functioning of the load-limiting devices which are arranged to reduce the bus voltage to a value which will protect the station against continued overload by transferring the load to adjacent stations. It is very evident, therefore, that such breakers, if set for selective action between short circuit and overload, are very liable to open, due to drop in voltage, when it is most important that they should remain closed.

Inasmuch as the high-speed characteristic of the breaker is essentially for machine protection, the breaker should be connected in the machine circuit and operated from voltage supplied by the machine. Thus, while the breaker is closed, it is supplied with a source of constant potential which makes it possible to accurately adjust the tripping mechanism. This tripping value will be such as to protect but one unit and, therefore, the high-speed breaker protection applied independently to each machine will be constant and independent of the number of units in operation.

Automatic switching for the control of motor-generators supplying 1500 volts d-c. follows the same scheme as that used for stations supplying the lower railway voltages, except where two generators are connected in series, in which case the control of the d-c. end of the set is very similar to that for the two converters in series, as already described.

Discussion

For discussion of this paper see page 781.

Automatic Edison Substation
of the Indianapolis Light and Heat Company

BY H. BANY
Associate, A. I. E. E.
General Electric Co., Schenectady, N. Y.

Review of the Subject.—*This paper describes a two-unit automatic station which supplies power to a 3-wire, 250-volt, d-c. Edison network. It covers a general description of the machines and of some of the devices, of the scheme of automatic operation employed in controlling these machines, and of the method of protecting against emergency conditions.*

Although the paper itself deals with this specific installation only, the fundamentals involved are the same for the general class of equipments employed in this service. However, there are generally certain important differences caused by special operating requirements of the individual installation or system. The character of the load determines whether the station is to be in service continuously, or is to be placed in service in response to load demand, by remote control or by some other means. The capacity and regulation of the a-c. system determine whether Y-delta, compensator or reactor starting is to be employed. The location of the station with respect to the load and the layout of the d-c. system determine whether only one bus, or both high and low-voltage buses are required. These and other factors must be taken into consideration so that the equipment will meet the requirements of the individual installation or system.

Hence, each installation is to a certain extent its own problem, for it must maintain the required character of service under all conditions no matter what special operating requirements are present.

ONE of the most interesting automatic station installations on a d-c. Edison network has recently been placed in operation at Substation No. 1 of the Indianapolis Light & Heat Company of Indianapolis, Indiana.

The substation is located on the first floor of the company's main office building in the heart of the Indianapolis business district. It is adjacent to the monument circle, which is the center of the company's "mile square" d-c. distribution section of the city. Due to its being practically at the center of distribution for this section, the location is ideal for testing the operation and reliability of the automatic station for this class of service.

Previous to the installation of the present machines and the automatic control, the station contained one 1000-kw. motor-generator set, manually controlled, which had become too small for the load. This had resulted in a gradual reduction of the voltage of 240 volts, at peak loads, and even less, at its center of distribution. Hence, it was imperative that additional station capacity be installed in the immediate vicinity, to bring the voltage up to normal of 250 volts at this point, and also to relieve the nearest substation, No. 2, of a certain amount of load that it was carrying. The distance to this station is only 800 ft. and the available machine capacity in it is 2100 kw.

It was, therefore, decided to install 3000 kw. of additional station capacity in Substation No. 1, consisting of two 1500-kw. motor-generator sets, which were expected to be sufficient to allow the voltage at the center of distribution to be held at the normal value and also to take care of the load for some time to come.

The object in making the station double unit was a measure to insure a part of the station capacity being available at all times, and to save part of the running light losses during the light-load periods.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

The policy of the company in the past has been to use motor-generator sets only on its d-c. system. The flexibility of the motor-generator set as regards voltage and load control and the inherent ability of the design here adopted to protect itself against severe overload, either suddenly or gradually applied, also were further deciding factors in this case.

It might be here mentioned that the company has at present a total d-c. machine capacity in excess of 13,000 kw. installed in its six substations. There are further installed in each of substations No. 1, 2, 3, and 4 batteries each of 10,000-ampere discharge capacity for 40 min., making a total battery capacity of 40,000 amperes available for this length of time; or, on the basis of 8000 amperes each for one hour, making a total of 32,000 amperes available for one hour. Hence, it can be seen that extensive precautions are being taken against the possibility of loss of direct current in the city. In fact, The Indianapolis Light & Heat Company has the enviable record that its d-c. system has not been down once in over 31 years.

Central station operation is very exacting in its requirements,—continuity and reliability of service being absolutely essential. These features are possessed by the present day automatic station to a very high degree. The gradual replacement of the human element by mechanical and electrical devices designed to perform their own individual duties as nearly faultlessly as possible, and the saving effected by reducing operating costs, were the real deciding factors in making substation No. 1 of the Indianapolis Light & Heat Company completely automatic.

DESIGN OF MACHINES[1]

The design of the machines adopted is such as to be particularly adapted for central station work.

[1]More detailed description of this type of machines may be found in the June 1923 issue of the *G. E. Review* in articles by O. E. Shirley and by T. F. Barton and C. M. Fulk.

The rating of the a-c. motor is type *A T I*-10 poles, 2000-kv-a., 720 rev. per min. at 0.85-power factor, 4150-volts, 278-amperes, 60-cycles with 50 deg. cent. rise of the stator and 60 deg. cent. rise of the rotor. The method of starting in Y-delta with a current-limiting reactor used in series with the Y connection. This reactor is also inserted in series with the delta connection in times of emergency operation when the occasion demands.

One feature of this method of starting employed is the smoothness of acceleration and the freedom from any "bump," either at the closing of the starting or of the running breakers. The starting current is approximately 500 amperes.

The rotor is provided with a special low resistance, amortisseur winding to give a high synchronizing and pull-in torque. This has resulted in giving the motor the characteristic, Fig. 1, of being able to carry practically full-rated load as an induction motor for a given period, as well as to be able to resynchronize itself under load.

The excitation of the motor field is 250 volts and is supplied by the d-c. generator.

The rating of the d-c. generator is type *M C F*—8 poles—1500 kw.—720 rev. per min.—250-volts, 6000-amperes, with 50 deg. cent. rise. It is provided with commutating, compensating and differential-series fields. The latter is of such strength as to protect the machine properly in case of sudden d-c. overload or short circuit. It is normally shunted by a circuit breaker, so that it is only partly effective in normal operation, but

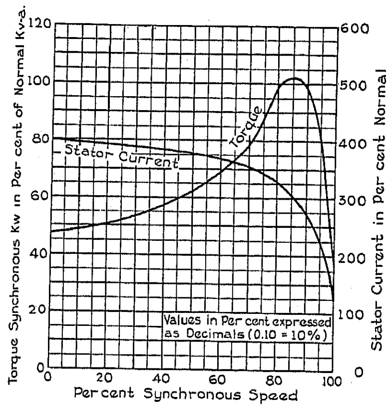

FIG. 1—TORQUE AND STATOR CURRENT CURVES OF 2000-KV-A. 60-CYCLE, 4150-VOLT A-C. MOTOR

under abnormal load conditions this circuit breaker is opened and the direct current output, or input, of the machine is very definitely limited.

As shown by the compounding curves, Fig. 2, with full load of 6000 amperes on the machine, and a dead short circuit applied, the final value of the line current with the series field shunting breaker open is 7000 amperes. It will be seen that the machine becomes practically a constant-current generator at full load current, due to the action of the differential series field and to the action of that amount of separate excitation furnished by the exciter.

The generator shunt field excitation is varied to hold normal voltage or normal current, as the case may be, by means of a motor-operated field rheostat. The generator is two-wire, the neutral being taken from balancer sets in several of the other substations. The installation of an automatically-controlled balancer set in this section is contemplated very shortly, however, to take care of the neutral current at this point.

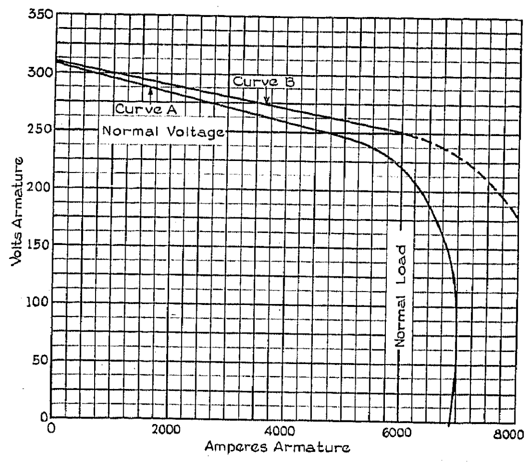

FIG. 2—COMPOUNDING CURVES OF 1500-KW., 250-VOLT D-C. GENERATORS

Curve *A*, Differential Series Field Shunting Breaker Open
Curve *B*, Differential Series Field Shunting Breaker Closed.

The rating of the direct-connected exciter is type *E C* 3 4 poles, 5-kw., 720-rev. per min., 125-volts, 40-amperes. In order to make the generator stable at low bus voltages, and to obtain the "constant current" characteristic at full-load current, the shunt field excitation is obtained from the generator and exciter armatures in series. One third of the excitation is being supplied by the exciter when the generator is operating at normal d-c. voltage. This means that the generator is essentially a separately excited machine at low bus voltages and so is perfectly stable in operation, even down to zero bus voltage.

CIRCUIT BREAKERS

The type of circuit breaker used for overload duty in the a-c. line for each machine is type *F H* 3, 15,000-volts, 500-amperes. The starting, running and reactor shunting breakers are type *F K*-4 7500-volts 300-amperes. The d-c. line breakers are type *C K*-3, 650-volts, 6000-amperes. The differential series field shunting breaker is type *C K*-3 650-volts 3000-amperes.

Control power for the various d-c. operated devices and circuit breakers is furnished by a 125-volt control battery which is kept in condition by a small trickle charge from the station bus. Control power for the a-c. operated devices is furnished by a type *H*, 5-kv-a. transformer on the incoming line for each machine.

A-C. Incoming Lines

There are at present a total of four 4100-volt 60-cycle, a-c. lines feeding into Substation No. 1 from the company's Mill Street and Kentucky Avenue generating stations. They are one for each of the two automatically-controlled machines, one emergency line, and one line for the 1000-kw. manually-controlled machine. By the use of special disconnecting potheads, either one or both of the automatically-controlled machines can be fed from any one of the first three lines.

Automatic Operation

The automatic control for these equipments in Edison network service is the same in its fundamentals as those in the industrial and railway fields. That is, the automatic control of these two machines by means of relays functions essentially the same as the manual control of similar machines. Each machine, when it is required, is started automatically from the a-c. end and balanced on the d-c. bus, exactly the same as if an operator were performing this operation. Each step in the sequence is controlled by one or more different relays which can function only when the correct electrical condition to proceed with the next step of the sequence is indicated. Voltage and current are held by varying the generator field, just exactly as if an operator were present at the switchboard, kept his attention fixed on the d-c. instruments and used his best judgment and skill in regulating the voltage and in limiting the current of the d-c. generator—only the electrical devices do it more promptly and faithfully. Upon cessation of the load demand, each machine is disconnected from the a-c. and d-c. buses, and shut down in just as logical a manner as it is started.

Protection by relays is embodied in the equipment against all ordinary emergencies and disturbances met with in central-station operation.

One unit in this installation is run leading and the other trailing. The former is the first to start upon load demand and is the second to shut down. The latter is the second to start and is the first to shut down. Either unit may be operated as the leading or trailing unit. The former always retains control of the bus voltage, the latter always tends to share its proportion of the station load.

Starting of Leading Unit

When there is demand for power, as indicated by low d-c. voltage at the center of distribution (240 volts or less), for a short time, the sequence of operations to start the leading machine and parallel it with d-c. bus is begun immediately.

The first step in the starting sequence is the checking of the bearing and machine winding temperatures, to be sure that the machine is in proper condition to be started. The a-c. line voltage is then checked to be sure that it is ample to start the machine, and to be sure that all three phases are present for this purpose. The motor-operated generator field rheostat must also be in the maximum resistance position before the starting sequence can begin.

The starting oil circuit breaker is then closed, applying full voltage to the Y-connected motor windings with the reactor in series.

At 95 per cent synchronous speed, providing exciter voltage and generator field current are present, field is applied to the synchronous motor and the oil circuit breaker short-circuiting the reactor is closed, thus placing full line voltage on the motor windings connected in Y.

The application of motor field causes the starting breaker to be opened after a time delay and the running breaker, connecting the motor windings in delta, to be closed.

This completes the final step in the starting sequence of the a-c. motor and permits the operation of paralleling the generator with the d-c. bus to begin.

Providing the polarity of the generator is correct, its voltage is increased gradually by the motor-operated field rheostat raising the d-c. terminal pressure to a value just slightly higher than that of the d-c. bus. Then the two d-c. line circuit breakers are closed. If the voltage is above 200 volts, the differential series field breaker is closed next, thus shunting about half of the differential series field current. This places the generator directly on the d-c. bus and allows it to take its load.

The d-c. voltage is then raised to normal of 250 volts and held there, providing the current output does not tend to exceed the generator rating of 6000 amperes.

Starting of Trailing Unit

When the current output of the station reaches a value of 5800 amperes, which is just slightly below the current rating of one generator, and remains at or above this value for a short time, the starting sequence of the trailing machine is begun.

This sequence takes place exactly the same as for the leading machine, the generator is paralleled with the d-c. bus in the same manner, and the differential series field breaker also is closed at 200 volts or above.

The current on this unit is then increased and that on the leading unit decreased, thus dividing the total station load between the two. The leading machine, however, retains the control of the voltage, whereas, the trailing machine merely tends to hold its share of the total value of current.

As is the case for a single unit operating alone, the operation of the two units in parallel is to hold the voltage at 250 volts up to their combined rated current output, and then with still further increasing station load to hold this rated current output at the expense of reduced voltage.

Shutting Down of Trailing Unit

On decrease in station load for a certain length of time to a value capable of being carried by one machine alone, the indication is given to shut down the trailing unit. The load is then gradually removed from this unit by the motor-operated field rheostat and is transferred to the leading unit, which holds the d-c. voltage constant. When the load has been entirely transferred, and a slight value of d-c. reversal is obtained (just below the running light current of the set), the machine is disconnected from the a-c. end and d-c. buses and is shut down.

Shutting Down of Leading Unit

Upon further decrease of station load for a certain length of time to a value such that the voltage at the center of distribution can be held practically at 250 volts by the surrounding stations, the indication is given to shut down the leading unit. The machine is then disconnected from the a-c. and d-c. buses and shut down.

Normally, the leading unit is in operation continuously, both day and night. The trailing unit usually starts on load demand at about 8 a. m. and shuts down on underload at about 10 p. m.

Automatic Station Relays

The voltage-regulating relay used in this equipment operates the generator shunt field rheostat of the leading machine to hold constant d-c. voltage. It is the same type of relay which has been used so successfully in automatic induction regulator installations, for holding constant voltage on a-c. feeders. It is of the single coil and plunger type and is actuated by the d-c. voltage at the center of distribution. It is provided with two sets of contacts, one for the "raise" and the other for the "lower" of the rheostat, and adjusted with the necessary floating range to hold the voltage within one per cent of normal.

The voltage equalizing relay, which is used to parallel the generator with the d-c. bus, consists of two coils operating a pivoted armature containing two sets of contacts. One coil is across the generator voltage, and the other coil across the bus voltage. At the proper time in the starting sequence, and as long as the bus voltage is higher than that of the generator, one set of contacts causes the "raising" circuit of the motor-operated field rehostat of the generator to be made, and thereby increases its shunt field excitation and hence its terminal voltage. As soon as the generator voltage becomes slightly higher than the bus voltage (about 1 per cent at normal bus voltage) the armature snaps over, opening this first set of contacts and closing the second set. This energizes the closing circuits of the d-c. line circuit breakers, thus connecting the generator to the bus.

The current balance relay is used to divide the total current properly between two machines while they both are in operation. It is of the same type as the voltage-equalizing relay, except that it has current coils instead of voltage coils, and that the contacts are set to float over a range of approximately 5 per cent at normal load, instead of being set with snap action. One coil is operated from a shunt in the line circuit of one machine and the other coil from a shunt in the line circuit of the other machine. The contacts are connected to operate the generator shunt field rheostat of the trailing machine. The "raising" contact is made when the current of the leading machine is the greater and the "lowering" contact when that of the trailing machine is the greater, thus balancing the load between the two units.

The differential frequency relay used is of the pivoted double-plunger armature type, with a total of four coils, two acting upon each plunger. One coil for each plunger is operated from the 220-volt 60-cycle control bus and the remaining coil for each is operated from the voltage (approximately 95 volts, 30 cycles at synchronous speed) obtained from a pair of slip rings on the direct-connected exciter. By means of suitable values of resistance and reactance connected in series with alternate coils of the relay, it is possible to calibrate it to operate on a given percentage difference in frequency between the two a-c. sources on its coils. Hence, the relay is adjusted to close its contacts when the machine is up to 95 per cent synchronous speed, and open them at 90 per cent synchronous speed. This gives the desired characteristics for the relay to allow motor field to be applied at the proper time during the starting sequence. It also functions to remove the motor field during certain system disturbances and again apply it when the disturbance has passed, as described later.

Protection

Protection is provided for contingencies which are of sufficiently serious nature to demand an immediate shut-down of the unit affected and to prevent its starting or restarting, until the station is given manual attention by an inspector, as follows:

1. Overspeed of 15 per cent above normal, as indicated by a hand-reset speed-limit switch on the end of the shaft.

2. Severe a-c. overload, as indicated by hand-reset plunger-type overload relays in the current transformer circuit.

3. Excessive bearing temperature rise, as indicated by hand-reset sylphone-type bearing-temperature relays, whose bulbs are inserted in the machine bearings.

4. Failure to complete the starting sequence within the normal time, as indicated by a time-delay relay set slightly longer than the time normally required to complete the entire a-c. and d-c. starting sequence.

5. Failure of insulation of either a-c. or d-c. machine to ground, or flashover of generator to ground, as indicated by a hand-reset current relay, whose coil

forms a low-resistance path from the machine frame to ground.

6. Loss of generator field, as indicated by a current relay in series with the generator field circuit.

7. Loss of motor field, as indicated by a balance relay, one coil of which is a current coil in series with the field circuit, and the other of which is a potential coil

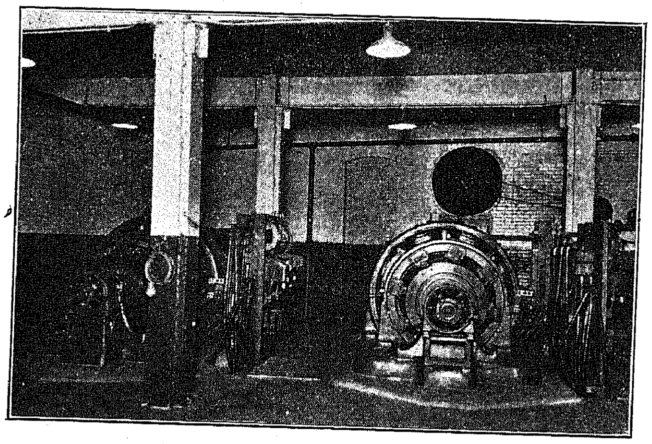

FIG. 3—TWO 1500-KW., 60-CYCLE, 4150-VOLT A-C., 250-VOLT D-C. AUTOMATICALLY CONTROLLED MOTOR-GENERATOR

across the generator voltage. The relay operates only in case of loss of field current while generator voltage is present.

8. Reverse polarity of generator during the starting sequence, as indicated by a polarized relay whose potential coil is energized by d-c. generator voltage.

Protection is also provided for cases of a nature such that it is necessary to suspend normal operation tem-

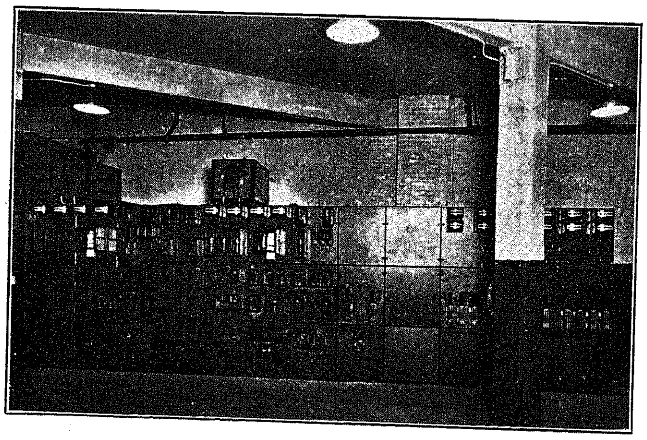

FIG. 4—AUTOMATIC SWITCHBOARD FOR CONTROLLING TWO 1500-KW. MOTOR GENERATORS

porarily during the emergency, but allow its immediate resumption when the emergency has disappeared, as follows:

1. A-c. undervoltage during the starting sequence, by means of a sensitive potential relay across the control power transformer.

2. Single-phase starting, by means of a potential relay across a potential transformer, whose primary is on a different phase than that of the a-c. undervoltage relay.

3. Excessive temperature rise of motor windings due to continued moderate overload on one or all phases, by means of current-operated thermal relays having a time-temperature characteristic similar to that of the motor.

4. D-c. reverse power, by means of a sensitive d-c. reverse-power relay, set to operate on a value of current less than the running light current of the set.

5. D-c. overload, by means of a potential relay, set to operate at 200 volts d-c. connected across the d-c. generator armature.

OPERATING FEATURES

Upon d-c. reverse power as indicated by the d-c. reverse-power and underload relay:

FIG. 5—INTERIOR OF STATION SHOWING AUTOMATIC SWITCHBOARD AND TWO 1500-KW. MOTOR GENERATORS

1. The generator differential series field, which becomes cumulative compound for motor operation, is inserted full strength by opening the differential series field shunting breaker;

2. The shunt field excitation of the generator is prevented from being decreased by opening the "lowering" circuit of the motor-operated field rheostat;

3. The shunt field excitation of the generator is also held at a fixed minimum value by shunting a sufficient amount of the field rheostat to give practically no-load running light field current.

The above operations limit the amount of reverse current that can be taken from the d-c. system.

If this condition continues for a certain length of time, the set is shut down on d-c. underload. If it disappears before the expiration of this time, normal operation is resumed immediately.

Upon d-c. short circuit or overload, as indicated by the d-c. undervoltage relay which operates on a reduc-

tion in d-c. bus voltage to 200 volts or less, the generator differential series field is inserted full strength, thus definitely limiting the output of the machine. Upon increase of the bus voltage, normal operation is again resumed.

In case of a-c. or d-c. system disturbances sufficiently severe to pull the motor out of step, provision is made in the control to allow it to pull back into step if possible without disconnecting the unit from either the a-c. or d-c. buses.

At approximately 90 per cent synchronous speed, as indicated by the differential frequency relay:

1. The motor field is removed by opening the motor-field contactor;
2. The reactor is inserted in series with the motor windings, by opening the reactor short-circuiting breaker;
3. The generator differential series field is inserted full strength, by opening the differential series field shunting breaker;
4. The shunt field excitation of the generator is gradually decreased by "lowering" the motor-operated field rheostat.

The result of the above operations, which cause the motor to function as an induction motor, limit the current drawn from the a-c. system and reduce the load on the generator, is to give the motor an opportunity to pull back into step by virtue of its high resynchronizing and pull-in torque. Fig. 6 is an oscillogram of a similar machine showing resynchronizing from 90 per cent speed caused by loss of the a-c. supply.

Protection is afforded against overheating of the pole face winding by causing the set to be disconnected from the a-c. and d-c. buses within a predetermined time (40 sec.), in case load or voltage conditions do not permit synchronizing.

Also, the set is shut down if the speed drops to a value of approximately 70 per cent of normal, below which the pull-in torque of the motor begins to fall off rapidly. In both of the above cases a restart takes place immediately if proper starting conditions obtain.

If the a-c. supply is interrupted, provision is made to run the set from the d-c. end for a given time so that it may be in readiness to pick up its load immediately upon return of a-c. power.

Upon interruption of the a-c. supply as indicated by the d-c. reverse power and underload relay and the a-c. undercurrent relay:

1. The generator differential series field is inserted full strength by opening the differential series field shunting breaker.
2. The shunt-field excitation of the generator is prevented from being decreased by opening the "lowering" circuit of the motor-operated field rheostat.
3. The shunt-field excitation of the generator is also held at a fixed minimum value by shunting a sufficient amount of the field rheostat to give practically no-load running light field current.
4. The motor field is removed by opening the motor-field contactor.
5. The reactor is inserted in series with the motor

windings by opening the reactor short circuiting breaker.

Operations 2 and 3 prevent the possibility of over-speed while running from the d-c. end, and operations 1, 4 and 5 place the set in readiness for the return of a-c. power.

Upon return of a-c. power with the motor out of step, the control is in the proper position to allow the motor to pull itself back into step and pick up its load. Fig. 7 is an oscillogram showing the sequence of operations caused by the interruption of the a-c. supply for a period of 3.8 seconds.

If a-c. power does not return within a given time, or if the speed drops below 70 per cent of normal, the set is shut down and is allowed to restart immediately if proper starting conditions are present.

Curve *A*, Exciter Voltage; *B*, Motor Field Current; *C*, A-C. Motor Voltage; *D*, D-C. Generator Terminal Voltage; *E*, A-C. Line Current; and *F*, D-C. Line Current.

In case of a-c. line short circuits, causing a drop in a-c. voltage down to 30 per cent of normal, or less, for a period of several seconds, the same sequence of operations takes place as upon interruption of the a-c. supply. The only difference is, that the device which indicates this condition is the a-c. undervoltage relay set at the proper value instead of the a-c. undercurrent relay.

Double Unit Operation

Either machine can be made leading or trailing by means of throwing a multi-pole change-over switch in one of two positions. This change-over also can be made without interruption of service whether one or both machines are in operation at the time.

However, in case the normally leading machine is running alone and shuts down, due to the functioning of a protective device, the trailing machine is started immediately and automatically takes the place of the leading machine, by means of an emergency starting relay provided for this purpose.

If both machines are operating, and the leading machine shuts down due to the functioning of a protective device, the trailing machine automatically takes the place of the leading machine by means of the same relay, without interruption of service.

In either case, when the normally leading machine is restarted, it is paralleled with the d-c. bus, as in normal operation, and the control functions to restore automatically the normal status of leading and trailing machines. If the load is sufficient to warrant the operation of both machines, they both remain connected to the bus. If the load is not sufficient to warrant the operation of more than one machine, the load is shifted gradually from the trailing to the leading machine and when completely shifted over, the trailing machine is shut down.

It is the intention very shortly to run the two machines from separate incoming lines, one from Mill Street station and one from Kentucky Avenue station instead of from the one line from Mill Street Station alone. In the latter case, it is quite important on power failure on one line, to have the machine on the remaining line automatically become the leading machine and function as such in case of sufficient load demand. This is accomplished in the same manner as failure of the normally leading machine, due to the functioning of a protective device, as already explained, and so as long as power is present on one of the lines, the machine on it will respond to load demand as the leading machine. When power returns on the other line, each machine is again returned to its normal status without interruption of service.

Application

Although this particular installation is one which occupies a most important position with respect to the total d-c. load of the system, the type of machines and control here used are being applied to outlying stations with equal success. Neither is the application limited to d-c. Edison systems alone, but it can be extended to other fields in which fairly steady loads are met and where uninterrupted service is of prime importance. The inherent ability of the machine to protect themselves against severe overloads in either direction, without the use of any complicated regulating equipment, is a decided advantage which should warrant favorable consideration.

Discussion

For discussion of this paper see page 781.

Operating Experience with Automatic Equipment on an Edison System

BY F. D. WYATT

Member, A. I. E. E.

Electrical Engineer, Union Gas & Electric Co., Cincinnati, Ohio.

Review of the Subject.—*The paper describes the conversion equipment serving the Edison System in Cincinnati and the application of automatic machines and controls to that system. During two years' operating experience with automatic equipment, it was found to be very reliable and to operate much quicker than manually-controlled equipment. Tests on the automatic equipment show it to be very valuable for service restoration work.*

* * * * *

I. Description of System

THE Edison System in Cincinnati supplies an area of approximately 2.2 sq. mi. including all of the down-town business district of wholesale and retail stores, hotels, theatres, small factories, and warehouses. The load center is in a high-priced district which necessitates substations of as small proportions as possible. The service requirements are very exacting as to outages, which means that the most reliable conversion equipment must be used so as to limit the size of stand-by batteries.

The peak load on this system in 1923 was 25,300 kw. (185,000 amperes) which was 22.6 per cent of the total system peak kw. load. The average peak load on the Edison system throughout the year is 150,000 amperes to 165,000 amperes at a load factor of 50 per cent.

There are at present six substations supplying the d-c. system as follows: (1) 4th Street Battery, (2) Plum St. Station, (3) Eighth Street, (4) Gano, (5) Peebles and (6) Jackson; the first four of which are manually operated stations and the last two are automatic motor-generator stations.

The synchronous motor-generator sets at 4th Street Battery, Gano Substation and Plum St. Station are fed from the 4325-volt bus at Plum St. Station.

The five 13,000-ampere synchronous converters at Plum Street Station, 8th St. Substation and Gano Substation and the two 7500-ampere automatic motor-generator sets at Peebles and Jackson Substations are fed from the 13,200-volt cable system radiating from West End generating station.

The conversion and storage battery capacity of the stations is shown by Table I.

It can be seen that there is a total installed conversion capacity of 99,660 amperes per side or 199,320 amperes at 150 volts. However, in addition to the conversion capacity there are three standby batteries having a combined six-minute rating of 84,850 amperes per side or 169,700 amperes total at a limiting voltage of 82 volts per side. The six-minute rating is the maximum current that can safely be taken from the batteries without serious injury to the plates. The discharge rate is controlled by motor-operated end cell switches.

It is evident that reliable conversion equipment can assist materially in saving the stand-by batteries during outages caused by system disturbances.

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

Station No.	Name	Conversion Equipment: M-G. Sets: No.	M-G. Sets: Rating amps. per side	Syn. Converters: No.	Syn. Converters: Rating amps. per side	Stand-by Battery: Rating 6-min. amperes
1	4th St. Battery	2	4,000	..	..	13,050
2	Plum St. Station	1	3,330	1	13,000	..
3	Eighth St.			2	13,000	37,200
4	Gano	1	3,330	2	13,000	34,600
		1	5,000			
5	Peebles	1	7,500			
6	Jackson St.	1	7,500			
Total		7	34,660	5	65,000	84,850

II. Problems of Operation

On account of the requirements of incandescent lighting and elevator load it is imperative to keep the voltage within close limits and to maintain the voltage balance.

The load conditions require conversion equipment near the load centers so as to cut down on the size of copper necessary for low losses and close regulation. The unbalanced load necessitates three wire equipment to maintain balanced voltage. For unbalanced conditions two generator motor-generator sets, and 3-wire synchronous converters are used.

Another problem in connection with an Edison System is that of securing skilled and efficient operators to handle the rotating equipment. The cost of training and developing operators with the ability to handle rotating equipment rapidly during a disturbance is quite large.

Following an a-c. shut down of sufficient duration to exhaust the stand-by batteries, equipment and methods must be available to properly restore service on the Edison System without undue delay or damage to apparatus.

III. Influence of Automatic Equipment on Distribution of Conversion Apparatus

The use of automatic stations permits the economical use of smaller units located closer to the load centers, thus reducing the distribution losses. Also, one

operator can take care of the operation and inspection of several stations thereby cutting down the operating expenses. Having a larger number of small automatic substations on a system aids greatly in restoring service after a complete shut-down. The automatic equipment can be put on the line and will pick up its full load current, thereby raising the voltage on the whole system to a point where the other conversion equipment can be brought in and be safely loaded up, until normal voltage is again obtained. This process restores service to the Edison System in the minimum time with the least strain on the machines and system.

IV. Disturbance Conditions

Disturbances on the a-c. system which cause a dip in voltage will cause a corresponding reduction in the synchronous converter output voltage. When the synchronous converter operates in parallel with motor-generators and stand-by batteries, or carries a considerable amount of motor load, the reversal of current through the synchronous converter, resulting from a reduction of voltage, may be of such magnitude as to cause damage or flashover to the synchronous converter. It is necessary, therefore, to limit the amount of reverse current that will flow or take the converter off the line. As the regulation of a synchronous converter is usually low, a reduction of a-c. voltage of less than 10 per cent will ordinarily cause a reversal of output current.

A severe reduction of a-c. voltage will cause a synchronous motor-generator set to drop out of step, due to the reduction of synchronizing torque at the lower voltage.

In the case of a complete failure of the a-c. supply, all synchronous converters and motor-generator sets will be shut down and the Edison load carried by the stand-by batteries for an interval until conversion equipment is again placed in service or the batteries become exhausted. The sooner conversion machines can be restored to service after an a-c. outage, the less will the capacity of the batteries need to be. A number of tests of the starting period for the various type machines gave the following results:

TABLE II

Equipment	Method of Starting	Time to Start
Manually-operated synchronous converter....	D-C.	4 min.
" " " motor-generator	D-C.	4½ min.
" " " converter....	A-C.	1¼ min.
" " " motor-generator	A-C.	2 min.
Automatic synchronous motor-generator	A-C.	40 sec.

From these figures, it is apparent that the automatic motor-generator sets will begin to carry load in much less time than other conversion equipment. These machines will start up immediately on return of the a-c. supply while the manually-operated machines must be started by the station operator, which may involve additional delays.

The automatic synchronous motor-generators are of considerable value in reducing the length of discharge of the stand-by batteries.

V. Selection of Automatic Conversion Equipment

In the selection of automatic conversion equipment, both motor-generators and rotary converters were considered in regard to the following three main items: (1) stability, (2) simplicity and (3) efficiency. It was found that the synchronous motor-generator set was much more stable than the synchronous converter under all kinds of disturbance on both load and supply circuits. The control equipment for an automatic synchronous motor-generator set is much simpler than the automatic synchronous converter control and is less liable to cause trouble. The synchronous converter has somewhat better efficiency than the synchronous motor-generator set. On account of its better commutating characteristics, greater stability, load-limiting characteristic and flexibility of voltage control, the automatic synchronous motor-generator set was chosen. The load-limiting characteristic of the motor-generator is such that it will limit the output current to not more than full rating from zero to full rated voltage. It is, therefore, of considerable value for service restoration, following the total shut-down of the Edison System.

These automatic motor-generator sets will begin supplying full-load current from practically zero voltage and thus gradually build up the potential on the entire net-work to a point where the synchronous converters can safely take their share of the load. By this method service can be restored to the Edison System in the minimum of time with the least ill effects.

The automatic synchronous motor-generator sets and the semi-automatic rotary converters will be next described and their performance records given under various disturbances.

VI. Peebles Automatic Synchronous Motor-Generator Set

Description. The set consists of three units, a synchronous motor, a d-c. generator, and an exciter, all connected together on the same shaft, Fig. 1. The field of the motor is furnished by the exciter, the field of the generator is across bus voltage in series with the exciter voltage, and the exciter is self-excited.

Motor. The synchronous motor is designed to give sufficient torque to synchronize with approximately full-load on the generator, provided the supply voltage is normal. Series reactance is connected in the motor circuit, across which full voltage may be impressed.

The motor torque on starting is furnished by the amortisseur winding. The motor field is energized by a slip relay at 95 per cent of synchronous speed, which furnishes sufficient torque to pull the motor up

to synchronous speed. For more than 5 per cent slip the torque would be reduced, if the field was excited. The use of the slip relay, adjusted to open the field circuit at a predetermined slip and to close it at a slightly lower value, makes available the maximum torque at all speeds. The rating of the motor is 2500 kv-a. 60-cycles 600-rev. per min.

Generator. The generator is of the commutating pole, compound-wound type with shunt and series differential windings on the main poles. The shunt

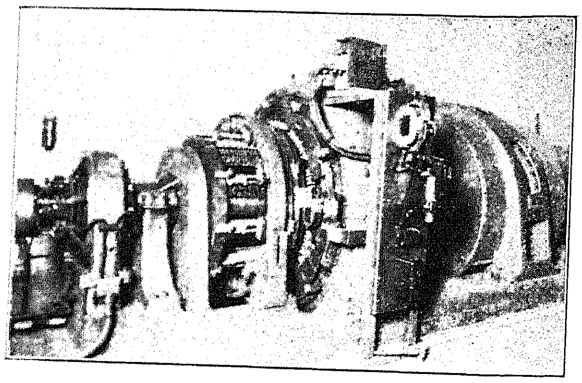

FIG. 1—A 7500-AMPERE 250-VOLT AUTOMATIC SYNCHRONOUS MOTOR-GENERATOR SET

winding is excited at 375 volts from a series connection of the exciter, (125 volts) and the generator, (250 volts). The series differential winding is normally short-circuited by a circuit breaker with sufficient resistance in its connections to allow approximately 20 per cent differential excitation for the generator under normal conditions. Under short-circuit conditions the above-mentioned circuit breaker opens, giving full differential protection to the generator and allowing only full-load current to flow with the generator short-circuited. The rating of the generator is 7500 amp. 600 r. p. m. 250 volts no-load and full-load 1875 kw. continuous 55 deg. cent. rise.

Exciter. The exciter is a commutating pole, compound-wound generator with shunt windings self-excited. The magnetic design is such as to permit stable operation over a wide range by the exciter field rheostat control. The cross section of the pole is reduced at one point so that that portion of the iron is saturated even when the exciter voltage is as low as 80 volts. This permits the omission of the synchronous motor field rheostat. The exciter is rated as follows: d-c. generator, volts no-load 125; full-load 125; 28 kw., continuous 50 deg. cent. rise.

Control Equipment. The control equipment Fig. 2 operates to bring the set up to speed and put it on load when the supply cable is energized.

The set is fully protected by relays against the following conditions:

1. Overheating of machines.
2. Overheating of bearings.
3. Grounding of machine windings.
4. Overspeed.
5. Flashover of generator or exciter.
6. Excessive current output or input on d-c. end.
7. Heating of amortisseur winding.
8. Reversed polarity on generator.
9. Loss of field on synchronous motor.
10. Single-phase starting.
11. Phase reversal.
12. A-c. overload.
13. Delayed starting through any cause.
14. Interference of air supply.

Performance. The sequence of operations is as follows:

The switch is closed at the cable source which energizes the potential and power transformers. The master starting element and the single-phase and reverse-phase protecting relay operate, providing all three-phases are all right, phase rotation is correct and the voltage is above 70 per cent. The master starting relay will not close below 70 per cent normal voltage, but will remain closed down to 20 per cent normal voltage. This insures the machine staying on the line through all ordinary surges.

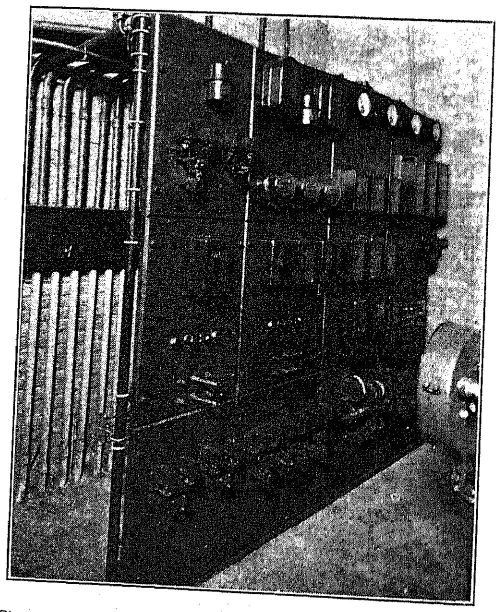

FIG. 2—CONTROL EQUIPMENT FOR A 7500-AMPERE 250-VOLT AUTOMATIC SYNCHRONOUS MOTOR-GENERATOR SET

The control current contactor closes next, providing all the protective devices are closed, causing the starting oil circuit breaker to go in. The machine then comes up to speed with the starting reactors in series. At 95 per cent speed the slip relay, connected across slip rings on the exciter, closes, allowing the motor field contactor to close and excite the motor. The main running switch which short-circuits the reactors then goes in and the motor is on full-line voltage. With the motor on the line, a contact-making voltmeter balances

the voltage of the generator with the bus and when balance is reached the d-c. circuit breakers close, providing the generator has correct polarity. Should all the above operations take too much time through any cause whatsoever, a timing relay, which starts functioning upon the closing of the starting switch and times the interval until the d-c. breakers close, will take the set off the line and lock it out. As the machine picks up load, the differential field is short circuited. However, there is enough resistance in the breaker and contacts to give about 20 per cent differential effect under normal conditions.

With the machine under load, the contact making voltmeter regulates the output so as to keep constant voltage at some predetermined load center. When full-load is reached, the current-control relay keeps the current constant down to nearly zero voltage, by lowering the voltage. When the voltage has dropped to 75 per cent of normal or 180 volts, the series field breaker opens and there is a momentary drop of voltage and current. The contact-making ammeter counteracts this effect and raises the current to the full-load value of the machine again. Thus on a d-c. short circuit when all the synchronous converter equipment is lost, the automatic motor-generator set will continue to put full-load current into the system until the trouble clears itself. Then the voltage will be gradually raised until conditions are again normal. In case of trouble on the a-c. system, the series field short-circuiting breaker opens, due to reverse generator current and strengthens the generator field, thereby reducing its speed and effectively preventing the set from pumping power into the a-c. system.

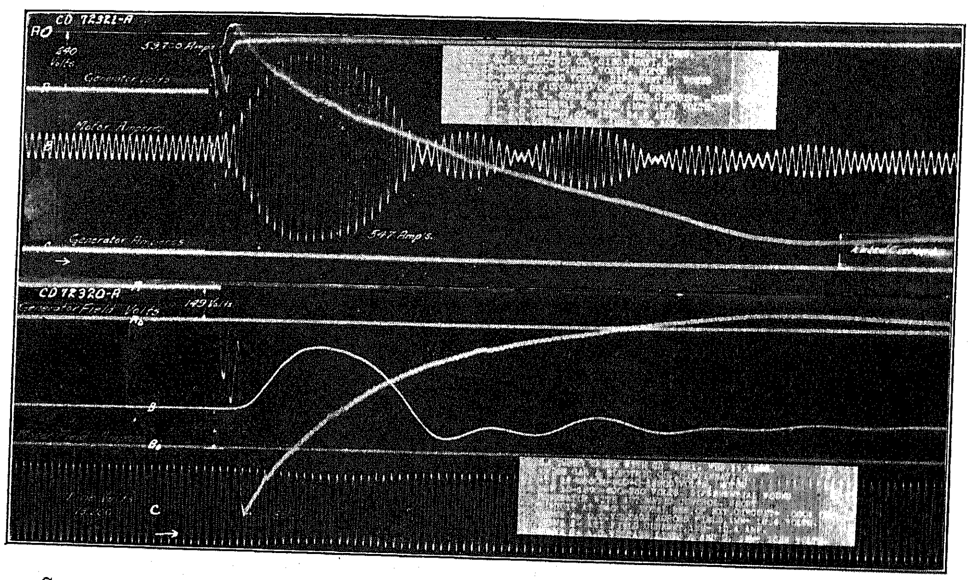

Fig. 4—Oscillogram Showing the Effect of a D-C. Short Circuit on a 7500-Ampere 250-Volt Synchronous Motor-Generator Set

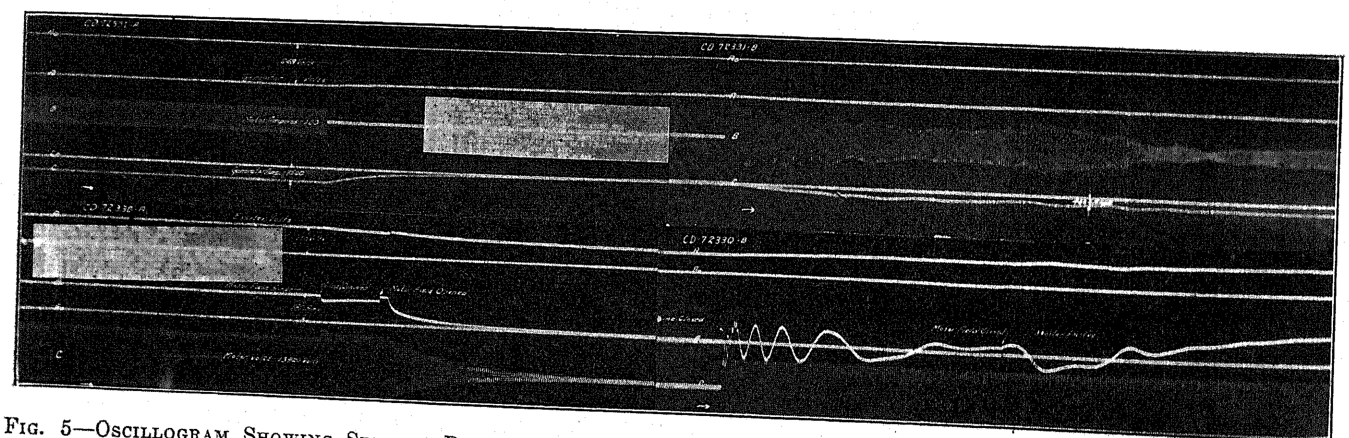

Fig. 5—Oscillogram Showing Service Restoration after an A-C. Failure on a 7500-Ampere 250-Volt Automatic Synchronous Motor-Generator Set

D-C. Short Circuit. Tests were made to determine the behavior of the motor-generator set under a full metallic short circuit on the bus bars. The performance is shown in Fig. 4. The short circuit was caused by closing an air circuit breaker which had main, auxiliary and carbon contacts. The successive closing of these contacts is shown on the oscillogram. The

generator current reached a maximum value of 59,700 amperes in the total time of four cycles. The main contact of the breakers closed in two and one-half cycles, after the closing operation started. The generator voltage had been reestablished to normal so that the short-circuit current actually reached its maximum value in one and one-half cycles. This overload current was reduced to rated value of the machine (7500 amperes) in 1.1 sec.

The generator successfully operated under this very heavy momentary load without undue flashing of the commutator.

The motor was knocked out of step by the high torque required by the generator, but successfully pulled back into step within 0.75 sec. This is the most severe d-c. short circuit it is possible to obtain, as the total value of the external resistance from the machine terminals for this short circuit was only 0.00041 ohms.

The duty of the generator in closing in on a dead Edison System would be very much less, as the generator voltage would be reduced to a value of 110 volts and considerable feeder resistance would be interposed in the circuit.

Performance of Machine during A-C. Disturbance. With the set running as in normal operation, carrying a rated load of 7500 amperes, the a-c. cable feeding the station was opened up and reclosed after an interval of 4.56 sec. The operations which took place on the machine were as follows: the set continuing to run on the d-c. side at reduced speed. The operations show very clearly in Fig. 5.

The short-circuiting breaker across the differential series field opened up, which further increased the field strength of the generator, reducing the speed still further.

Due to the operation of the a-c. under current relays, the motor field was disconnected from the exciter and short-circuited and the oil circuit breaker short-circuiting the starting reactors was opened up.

When the a-c. supply was closed in again, the motor speeded up, the induction motor starting current being limited by the starting reactors. When the motor attained 95 per cent of normal speed, the synchronous motor field was closed. Fifteen cycles later the starting reactors were short-circuited and the motor pulled into step. In the meantime, the generator began carrying load as soon as the a-c. supply was re-established. The generator was carrying a load of 4000 amperes when the synchronous motor pulled in step. The generator current was then increased to the rated value by the control relay equipment.

The conditions surrounding this test are somewhat more severe than the usual a-c. disturbance which reduces the system voltage to 50 per cent or in an extreme case to 30 per cent of normal.

VII. Semi-Automatic Synchronous Converter

Tests were performed on semi-automatic booster-type synchronous converters to determine their performance under various disturbances on the a-c. system. The synchronous converters were modern booster-type machines rated 13,000 amperes 240/300 volts.

Sequence of Operations. The control board for the semi-automatic rotary converter is shown in Fig. 6 and the sequence diagram in Fig. 7.

The rotary is started as any manually-controlled machine equipped for star-delta a-c. starting, voltage and polarity checked by the operator and the negative d-c. breaker closed.

There are two breakers on the positive lead of the converter. A 4000-ampere breaker in series with a resistance stack of 0.008 ohms (resistance breaker) and the main 16,000-ampere breaker.

After the resistance breaker is closed and the machine picks up load in the proper direction, the main positive breaker will close automatically. After the main positive breaker closes the neutral breaker will close

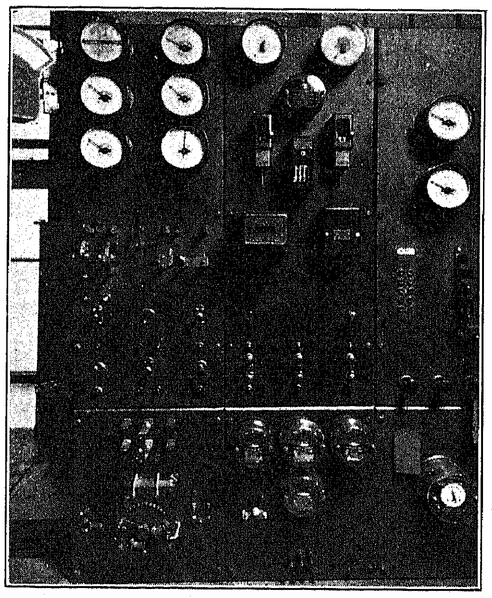

Fig. 6—Control Board for a 13,000-Ampere 240/300-Volt Semi-Automatic Synchronous Converter

automatically. The neutral breaker may be held open or closed at will by a manually-operated interlock switch.

The neutral breaker opens when either negative or positive breaker opens. The a-c. line and all d-c. breakers are tripped simultaneously when the protective circuit opens, due to any one of the following faults:

1. Overspeed.
2. A-c. overload.
3. A-c. undervoltage (80 per cent with time delay).
4. Machine ground.
5. Transformer ground high side.

Automatic Operation. At times of reduction of a-c. voltage, due to disturbance sufficient to cause reversal of current in the synchronous converter, contacts in the d-c. power directional relay open up, causing the opening of the main positive d-c. breaker

and the neutral breaker leaving the machine tied to the d-c. busses through the current-limiting resistor.

The reversal of current from the d-c. busses through the machine is held within safe values until normal a-c. voltage is reestablished, at which time the proper flow of current occurs and the power directional relay closes its contacts, causing the main positive d-c. breaker to close and short-circuit the current-limiting resistance.

In case the reversal of current continues for an undue length of time, the machine will be disconnected from the positive d-c. bus by the operation of a thermostatic relay mounted on the current-limiting resistor.

The curves shown in Fig. 8 give the operation of this

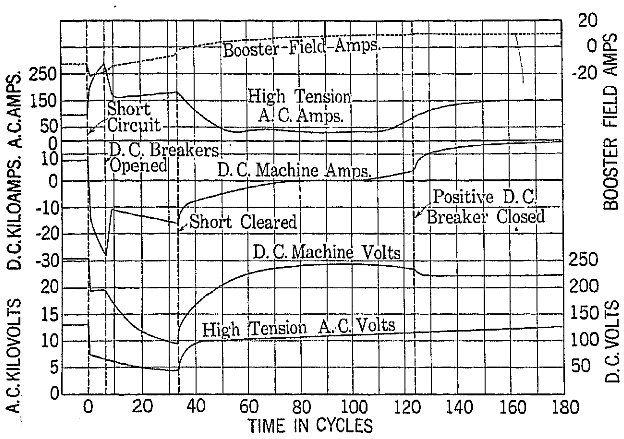

Fig. 8—Performance of a 13,000-Ampere 240/300-Volt Semi-Automatic Synchronous Converter under a 13,200-Volt 3-Phase Short Circuit

equipment under a three-phase short circuit on the 13,200-volt system.

This curve shows a change of current in the synchronous converter armature from 8000 amperes in the normal direction to 27,500 amperes reversed in six and one-half cycles, at which time the main positive breaker opened, allowing the series resistance to limit the reversed current to 11,000 amperes. After the a-c. voltage was restored to normal, the positive d-c. breaker closed and the machine continued to carry load.

It was found during these tests that the synchronous converter, when separately excited, took less reverse current and regained its load somewhat quicker than when self-excited.

This scheme of protection has been used on synchronous converters for a period of 18 months and a large number of successful operations of the automatic equipment have been observed.

Conclusion

1. The automatic synchronous motor-generator sets have been found to be equally reliable to the manually-operated machines under normal conditions and much more reliable under disturbance conditions.

2. The automatic motor-generator set functions very satisfactorily for service restoration.

3. The semi-automatic control applied to synchronous converters reduces the durations of the resultant disturbances on the d-c. system caused from dips in a-c. voltage.

4. Both kinds of automatic conversion equipment described in the article reduce the duty of stand-by batteries materially.

Discussion

For discussion of this paper see page 781.

Present Practise in the Automatic Operation of Hydroelectric Generating Stations

BY R. J. WENSLEY
Non-Member
Switchboard Engineering Department, Westinghouse Electric & Mfg. Co., East Pittsbugrh, Pa.

Review of the Subject.—Present practise in the design of automatic hydroelectric generating stations is reviewed. Various methods of starting and controlling are listed together with their limitations. Certain points in dispute, such as the W R^2 required for speed regulation and brakes for bearing protection are presented in the hope that discussion will aid in clarifying the situation to such a degree as to permit of standardization of practise. A brief description of the sequence of operations in a modern automatic switching equipment, is given.

* * * * *

The advantages to be gained by the automatic operation of hydroelectric generating units are now so well known that their recapitulation is unnecessary at this time. It is the purpose of this paper to present a brief but comprehensive outline of present day practise as applied to such units.

Hydraulic Development

The elimination of the cost of manual operation makes possible a much different treatment of many hydraulic developments. As the cost of the hydraulic development is usually a large item in the total cost of the water power station, this item should be considered carefully in the light of possible savings incident to the employment of automatic control. By splitting up the total available head into two or more smaller heads, a considerable saving in the purchase of flowage rights is possible. Against this must be balanced the higher cost of wheel and generator per kilowatt. As the cost of the actual dam rises rapidly with increasing height there is some saving in this item. A careful balance of the cost items entering into construction of any given development should always be made to see that no further economies are possible before any given distribution of the available head is finally adopted. Careful consideration will many times enable the production of kilowatt hours at a lower figure than possible with the old method of maximum head for a few plants. The modern method involves the use of many small units with lower heads for each and with automatic control.

Types of Wheels

Most of the automatic water power stations that have been supplied have been of the low head variety, the working heads varying from a minimum of 9 ft. to 75 ft. They are the reaction or Francis type and the propeller type, of which the Nagler is a good example. The latter is noted especially for the high specific speeds possible on very low heads with a consequent economy in generator cost. However, efficiencies of the two wheels at the average loads expected should be carefully compared, as a reduction of a few kilowatt hours in the station output will soon nullify any saving in the first cost. As the efficiency curves for the two types are not of similar shapes for varying combinations of head and size, no general rule can be adopted. A careful analysis of each project should be made before a definite type of wheel is selected.

The foregoing remarks apply to vertical wheels which are almost universally used for low heads. There are a few engineers who yet cling to the horizontal reaction wheel. Correct application of this type of wheel to low head installations are rare. Efficiencies equivalent to those obtainable with the vertical type are difficult to secure. Construction of the building and penstock will be more expensive while the generator will cost somewhat less.

For small units and high heads the impulse wheel is used exclusively. It is customary to build the generator with extra large bearings and mount the runner outboard on the generator shaft.

Operation with Respect to Remaining System

There are several possible methods of operation and control, the selection of any specific type depending upon the conditions of the system. The more usual methods are listed below.

(a) Fixed gate opening.

(b) Regulation of load with respect to head of water available.

(c) Regulation of speed by centrifugal governor.

Form (a) is used where a relatively small unit is closely tied to a large system which can absorb all the power generated at all times and which has other units under control of speed governors. Two forms of automatic water control are available. The head gates or the wicket gates may be opened wide by an electric motor supplied with energy from a control transformer or from the station battery if there be such. An oil pressure device may be used with a construction similar to the speed governor but without a centrifugal element. A small solenoid valve admits oil to the servo-motor and causes the wicket gates to open, a float switch is used to start the wheel when excess water is available and to stop it when the forebay is lowered to the desired limit. No intermediate steps are possible.

Form (b) is used where surplus water is used from a

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

source in which a specified head must be maintained at all times. If oil-operated gates are used, a float switch is caused to actuate a pilot valve, which in turn actuates the servo-motor in such a manner as to draw a predetermined amount of water for a given head. If electrically operated gates are used, the float switch is caused to actuate a pilot valve, which in turn actuates the servo-motor in such a manner as to draw a predetermined amount of water for a given head. If electrically operated gates are used, the float switch actuates a contact device, which in turn energizes the motor on the gates to increase or decrease their opening. An antihunting device is mechanically connected to the gate mechanism and the contact device.

Method (c) is that most widely used and is to be recommended for most applications. Units equipped with speed governors may be safely operated on any size or type of system. Water-level control may be added to the speed control if desired. Most modern governors consist of an oil pressure tank, a centrifugal device, a valve mechanism and a servo-motor or oil cylinder for the actual mechanical operation of the wicket gates. Past practise has been to drive the centrifugal element from the main generator shaft by a belt. This drive is rapidly being replaced by one employing a small synchronous motor energized from potential transformers connected to the generator. If belt drive is used in an automatic station, an automatic trip should be connected to the idler pulley so that breakage of the belt will take the unit out of service. In an automatic station where a self synchronizing generator is used, the synchronous driving motor is not energized until after the oil switch is closed. There may be some overspeeding as a result of such operation, but as the modern wheel and generator are built to stand the maximum speed obtainable with gates open wide and no load on the generator, no trouble need be anticipated from such excess speed.

Oil pressure for the operation of the governor is obtained from a pump and stored in a closed reservoir against air pressure. The pump may be belt-driven from the generator shaft or motor-driven by a polyphase a-c. motor supplied from transformers connected to the a-c. bus. The latter method is much to be preferred. If a station battery be available an emergency pump may be operated with a d-c. motor. It is customary to provide an oil pressure relay set to cut off the station while there is yet sufficient oil pressure in the reservoir to close the gates.

The governor is equipped with one or more control solenoids which operate small auxiliary oil valves, which in turn open the main valves to the servo-motor. In one form of governor there is but one solenoid which opens the governor wide, but under the retarding influence of a dash pot. With the control methods in general use there is some overspeeding until the generator is connected to the line, as the synchronous motor driving the centrifugal element is not energized until that time. A second form uses one solenoid to open the gates just enough to accelerate the wheel to synchronous speed, the second solenoid being energized after the generator is connected to the line. This second solenoid causes the governor to open wide but under control of the speed governor, which is now operative because the synchronous driving motor is energized. Both forms of control keep the solenoids energized throughout the period of operation. To stop the wheel the solenoid circuit is opened. The gates immediately close and the wheel stops.

As the gate movement is necessarily slow and the response of the wheel to the governor is therefore slow, a certain amount of flywheel effect is necessary to stabilize the generator during rapid changes in load. The importance of this effect is greatly over-estimated as a large system is a very effective flywheel in itself. The amount of inertia required is expressed by the well-known formula WR^2. The amount required is specified by the waterwheel manufacturer, but supplied by the generator builder either in the form of additional weight in the rotor or by the use of a separate flywheel. Since the wheel builder is not penalized by his inertia requirements he usually specifies rather more than less than enough. Much money is wasted in following these excessive requirements. Engineers with small hydro projects to execute would do well to investigate the available flywheel effect of their systems before purchasing a lot of useless cast iron attached to their generators.

Brakes

There is some dispute regarding the necessity for automatically-operated brakes to stop the wheel when rubbish or erosion causes enough leakage to operate the wheel at low speeds. If the thrust bearing operates at low speeds it will not carry enough oil between the bearing surfaces to maintain separation. If the wheel continues to rotate, the bearing will be destroyed. Some engineers insist that brakes be applied to definitely stop rotation when the gates are closed. Other engineers maintain that when only enough water is passed to rotate the wheel slowly with oil between the surfaces, there will be an enormous increase in friction when the oil film is squeezed out. Such increased friction will result in stoppage of the wheel before damage is done. Since a difference of opinion exists, it is suggested that this point be stressed in discussion so that the practise regarding the application of brakes may be standardized.

Where brakes are used, they may be operated by oil pressure from the governor reservoir or by a separate source of air pressure. While the amount of oil required is not large, this item should not be overlooked when purchasing the governor. Oil pressure may be applied through the medium of magnet valves or through valves mechanically actuated by the movement of the water-wheel gates. Air pressure may be applied

through magnet valves of the kind developed for electro-pneumatic railway control.

Brakes of the oil pressure variety seem slightly less objectionable than the air-operated type because of the necessity of an automatically operated compressor for the latter. As any automatic station is improved by simplification, it would be highly desirable to eliminate automatically controlled brakes, if the designers of thrust bearings could agree to this as standard practise. Hand-operated brakes should be furnished for holding the wheel when the unit is being cleaned or repaired, if no automatic brakes are used.

Bearing Lubrication and Protection

The usual circulating oil system with self-contained pump, driven from the generator shaft, is customarily used in automatic stations for lubrication of the thrust and guide bearings. No automatic devices have been worked out for the lubrication of the wicket bearings, although some inexpensive simple system would seem warranted. Even the present grease-cup method is not entirely adequate because there is usually no method of insuring equal distribution of grease between the upper and lower wicket bearings. This is a problem the waterwheel manufacturers should take steps to solve.

Thermostat protection should always be provided for all main bearings. The guide bearings of vertical machines and the main bearings of horizontal machines should have the active element in actual contact with the babbit. In the horizontal type this contact should always be established at the center of the bottom of the bearing, as this is the point of greatest pressure and consequent heating. The thrust-bearings of vertical machines are customarily operated under oil. The temperature of the oil is therefore a good clue to that of the bearing. The active element of the thermostat is immersed in the oil near the thrust surfaces. Most of the thermal devices used for bearing protection are of the vapor-expansion type, which insures ample energy for operation of contacts. These devices are made suitable for the bearing to be protected and are not provided with adjustments for changing the temperature at which operation of the contacts is effected.

Generator Characteristics and Equipment

The generators used in modern unattended stations should be of the self-synchronizing type. To prevent disturbance to the system at time of connection to the line, these generators should have as high a reactance as is feasible, to limit the rush of current when the oil breaker is closed. Heavy damper windings are necessary to quickly pull the generator in step with the line. These generators are usually accelerated to approximate synchronous speed and then connected to the line before excitation is applied. Immediately after the closing of the breaker, the field switch is closed. The normal time element introduced by the high inductance of the field winding is sufficient to prevent excessive mechanical stresses in the windings.

Generators for unattended stations with automatic control should always be equipped with direct connected exciters. There are a few exceptions to this rule, such as excitation drawn from d-c. lighting net work or from an excitation bus in an adjoining station. Belted exciters should be avoided even though the reduction in price makes this type apparently desirable. Troubles may be expected with the belt and with the idler pulley.

Two forms of speed relays are used for indicating approximation to synchronous speed. A centrifugal

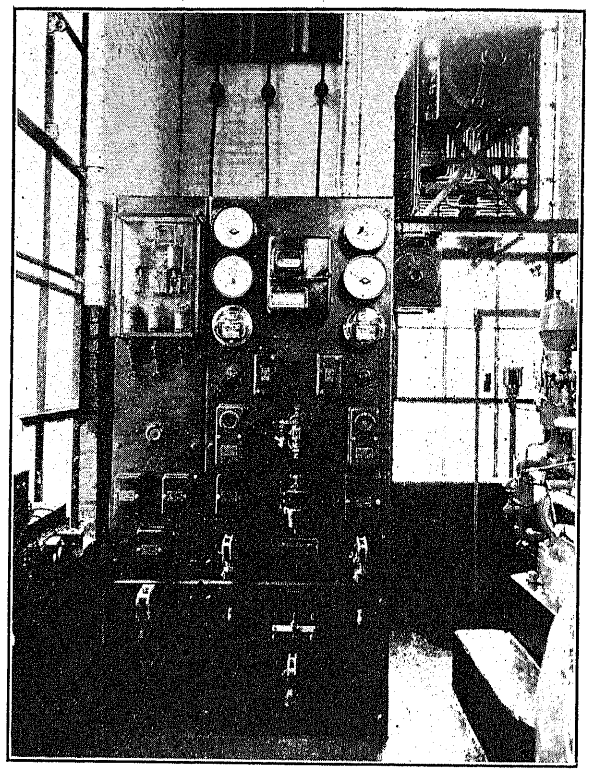

Fig. 1—Small Automatic Hydroelectric Generating Station with Vertical Self-Synchronizing Generator. This is a Typical Installation

switch may be attached to the end of the generator shaft or a specially designed magneto generator may be geared to the shaft, its voltage, as indicated by a relay, constituting the desired indication.

A second element in the centrifugal switch or a second voltage relay on the magneto is used to indicate excessive speed.

Functions of Control Equipment

The initial starting indication for the automatic control may be obtained in any one of several ways. The following list covers the majority of the methods which have been used or discussed.

(A) Water level.
(B) System frequency.
(C) Remote control by pilot wire.
(D) Supervisory control over the telephone circuit.

(E) Manual operation of control switch in station.
(F) Control by manipulation of the a-c. line.
(G) Control by time switch.

Combinations of one or more of the above have been used in several installations. Where the station is controlled entirely by (A) the indication is obtained from a float switch which makes contact when the water in the forebay rises above a predetermined point. Some small systems are using the method (B) to call additional capacity into service when the drop in system frequency indicates an overload on the generating equipment in service. This method has a very limited application to systems fed principally from small water plants. If any steam turbine stations are used, the overload capacity of the turbine will maintain the normal frequency and defeat the purpose of the automatic station. If several automatic stations are used on the same system with this form of control, there is no suitable method of selection, therefore several stations may be called into service when only one is wanted. If differential timing is attempted, the time required to start the last stations is prohibitive since it must exceed all the time required for the first stations to start and connect to the line.

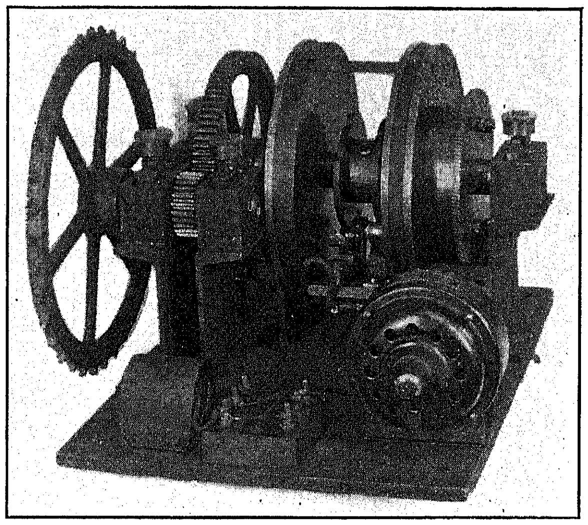

FIG. 2—CONTACT DEVICE WITH ELECTRICALLY OPERATED ANTIHUNTING MECHANISM FOR AUTOMATIC CONTROL OF WATER LEVEL IN FOREBAY. THIS DEVICE IS LOCATED ABOUT 2000 FT. FROM THE STATION IT CONTROLS WHICH CONTAINS A 1000-KV-A. GENERATOR AND IMPULSE WHEEL OPERATION ON 450-FT. HEAD

Method (C) is suitable where the distance to an adjoining station with manual operation is not excessive. Method (D) is being used to a large extent in the stations being installed at the present time. There are several types of equipment available at a wide range in price. By the use of some of these it is possible to control the starting and stopping of the unit, the load, the voltage, and the outgoing feeders. The same equipment enables the distant operator to ascertain the available head of water, the gate opening, the load in kilowatts, the condition of the feeders and any other indications that may be desired. All these functions may be obtained with the various forms of equipment over circuits of from two to four wires, which wires may be used for magneto or local battery telephones. None of these systems will work on the same circuit with common battery telephones.

Where natural conditions and the size of the plant warrant the expense, it is customary to have one resident maintenance man who starts and stops the station with a control-switch method (E) as instructed by the load dispatcher. This man is not expected to remain in the station but is subject to call by the dispatcher whenever required. A siren on the station roof is frequently used for this purpose.

Method (F) is occasionally employed where the automatic station is on an independent line which may be switched from another station. The station is started by closing the oil switch on the line in the manual station. An a-c. voltage relay then causes the unit to be started. Upon opening the oil switch the machine will be tripped by overspeed, due to the sudden reduction in load, or by a contact on the waterwheel gate which is closed in the no-load position, which position the governor will promptly cause the gates to assume, if the overspeed trip does not have a chance to operate.

Method (G) may be employed where hydroelectric units are used to supply energy to industrial plants having fixed working hours or to switch on additional capacity in advance of known periods of peak load.

In addition to the automatic means described above, there are two methods of partial automatic starting, one by means of a multi-wire control and actual synchronizing by hand, the other by actual hand starting with protective features so that the station may be permitted to operate without an attendant.

Current for the operation may be drawn from a transformer connected to the a-c. line or from a small storage battery maintained in a charged condition by automatic devices with current from the exciter. If the first method is used, the unit cannot be put into service unless the line voltage is above 80 per cent normal. If the second method is used, the unit may be put into service regardless of the line condition.

SEQUENCE OF OPERATIONS

The usual sequence of operations after the initial starting signal is given by any one of the automatic indications is mentioned below.

(1) The master relay is energized.

At this time the exciter-field rheostat is short-circuited to aid the exciter to build up to normal voltage as rapidly as possible. The generator-field contactor is in the de-energized position, its back contact shorting the field through a discharge resistance.

(2) The governor solenoid is energized.

The gates are thus caused to open and the unit accelerates. The exciter builds up rapidly.

(3) At an approximation of synchronous speed the speed-indicating device closes the control for the oil switch. The closing energy for this switch is obtained from the exciter. If the voltage has not built up to the minimum operating point for the breaker, there will be a slight delay in closing until the voltage does reach this point.

(4) The oil switch closes, connecting the unexcited generator to the a-c. line. The short circuit is also removed from the exciter field rheostat. The circuit of the field-switch operating coil is energized.

(5) The field switch closes, connecting full excitation to the generator field. The generator pulls into step with the line and as the gates continue to open, picks up its load.

The normal sequence of operations provides for the shutting down of the unit without disturbance by first de-energizing the governor solenoid to close the gates and then tripping the oil breaker with a contact on the

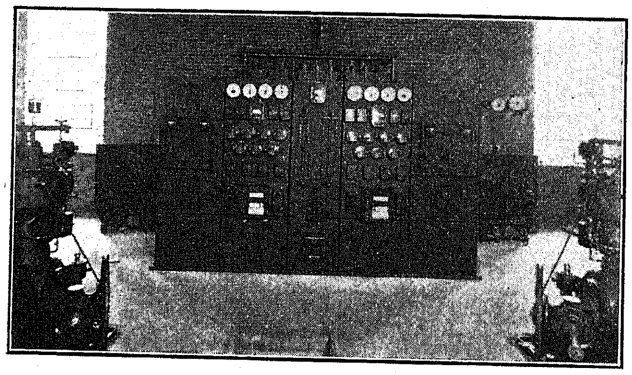

Fig. 3—Switchboard for the Automatic Operation of Two-2200-Kv-A. Waterwheel Generators. The Large Square Case in the Center of Either End Panel is the Speed Matching Device. Above is the Automatic Synchronizer and Below is the Control Element of the High Speed Rheostatic Regulator

gate mechanism at the position corresponding to no load. The field switch is then opened and the brakes, if any, are applied.

Regulation of Voltage

There are several methods of operation with regard to voltage control. Those in general use are as follows:

(1) Fixed excitation. This is only applicable where the automatic unit is electrically close to a regulated generator and where it carries a considerable proportion of its full load at all times.

(2) Regulation by the standard vibrating regulator.

(3) Regulation by a contact-making voltmeter and an ordinary motor-operated field rheostat in the generator circuit.

(4) Regulation by the high-speed rheostatic regulator.

With any one of the three types of regulation it is necessary that some form of wattless compensation be employed, so that the automatic unit will not carry an undue share of the wattless load of the system.

Protective Features

As the automatic stations must operate under all conditions without human attention, it is necessary that the generator be protected against almost every imaginable operating contingency. It is manifestly impossible to anticipate all forms of trouble and it is manifestly impracticable for financial reasons to furnish protective devices for the extremely remote contingencies; therefore, it is customary to disregard those troubles which require the coincidence of two or more improbable events to damage the machine.

All larger generators are equipped with balanced relay protection to open the breaker and field switch should there be an insulation failure. The cost of this protection is considerable and an arbitrary lower limit of 500 kv-a. has been set, below which it is not customary to furnish such protection.

Two thermal relays are connected in the secondary circuits of the current transformers to measure the heating effect of the output of the generator. Should the safe limit of heating be approached, these relays will shut down the unit until cooled down, after which restarting is permitted.

Field failure is caught by a relay in series with the generator field with a time element sufficient to bridge over any ordinary surge.

Short circuits external to the station are caught by two different means. The first employs the usual overload relays and shuts down the unit until the rise in a-c. line voltage, fed from other stations, indicates that the trouble has been remedied. The second method uses the line voltage as an indication of trouble and allows the machine to deliver as much current as it is able, until the reduction in voltage operates a line voltage relay or until a thermal relay operates. The machine is reconnected on rise in line voltage as in the first case.

It is advisable to provide protective devices against excessive rise in either exciter or generator voltage. Relays which form a crude vibrating regulator insert large amounts of resistance in the exciter field under either of such emergencies.

Any high-tension equipment should be located outside the building. The high-tension construction should be as simple as possible, without any high-tension circuit breaker if the unit be under 500 kv-a. The arrester should be of the non-fluid type which require no charging or attention. A separate set of disconnecting switches should be provided for the arresters.

Special Forms of Control

When a generator forms too great a percentage of the total generation to permit of self-synchronizing, or if the generator be difficult or expensive to equip with damper windings, an automatic speed matcher and synchronizer is available. The speed matcher consists of two small synchronous motors, one for the machine and one for the bus. These are connected to a me-

chanical differential, which in turn is connected to contacts which control the speed-adjusting motor on the waterwheel governor. Any difference in speed of the two motors results in a movement of the differential and consequent operation of the adjusting motor. The speed of the wheel is thus adjusted as though in an ordinary manual station. The automatic synchronizer awaits the first favorable point and closes the breaker. The governor is then opened wide to pick up the load.

It is also possible to ease the shock of self synchronizing by the use of current-limiting reactors which are connected between the machine and the bus until synchronous operation is attained. The reactors are then shorted by a second breaker. The same result may be obtained if step-up transformers are used for the output by synchronizing with a low voltage tap, after which the generator is transferred to full voltage just as a tap-started synchronous motor is controlled.

High head plants offer additional problems in control, as the velocity of the water is so great that it must be handled with great care. Load control is usually had by opening or closing the needle valve with a motor. The deflector which is used for speed control should be interconnected with the needle-valve control so that there will be no unnecessary waste of water off the deflector. Thus if the wheel is carrying 90 per cent load and system conditions cause the wheel to drop to 70 per cent load, the deflector will be wasting 20 per cent of the water. The automatic control should promptly close the needle valve sufficiently so that this 20 per cent of water may be saved. Hydraulic engineers will doubtless question the accuracy of these figures but the percentages are intended only for illustration.

In order that the small automatic generating stations may prove to be a financial success, it is obvious that construction costs must be minimized. Past manual practise in building design and equipment should be forgotten. It should be remembered that extreme simplicity of construction, small units located at frequent intervals and entire absence of emergency switching or reserve capacity in any one station, will deliver more kilowatt hours at less expense than a few large units with expensive hydraulic development, elaborate emergency equipment and fine buildings.

Discussion

PAPERS ON AUTOMATIC STATIONS

(Place, Wallau, Butcher, Bany, Wyatt, Wensley)
Chicago, Ill., June 25, 1924

R. H. Earle: In the development of the hydraulic division of automatic control systems for hydroelectric units, it has been the experience of the writer that the major problem is to obtain the desired action of the turbine gates during the periods of starting and stopping the machine. In response to electrical signals the turbine gates must be opened or closed and the gate opening must be controlled in such a manner as to prevent violent speed changes and to prevent unnecessary shocks to the machine itself, the water conduits, and the power system. As stated by Mr. Wensley this action is secured by modifying the usual governor system, by using motor-operated gates, or by using a special electrically controlled service motor to move the gates.

The operations of starting and stopping may be accomplished with varying degrees of refinement depending upon how much disturbance is allowable in the particular installation. In general the limiting feature is the amount of disturbance which the electrical power system or the penstocks can withstand, as the machine is sufficiently strong to withstand any shocks which are likely to occur. It follows, therefore, that when a small low-head machine is connected into a large power system, a comparatively crude type of control may be used satisfactorily, and as the machine becomes larger in comparison with the remainder of the power system, or where long penstocks are encountered, more precise methods of starting and stopping must be used.

Besides the main problem of starting and stopping, there is the question of holding the turbine gates closed when the machine is shut down and a number of protective features which fall in the hydraulic section of the control system.

If a governor is used means should be provided to close the gates in case of breakage of the governor belt or failure of power for the flyball motor.

In the governor oil-pressure system a pressure-operated switch is arranged to stop the turbine in case the pressure falls below a certain value. In some of the more elaborate systems the oil level is automatically maintained at the correct height in the pressure tank. Oil pressure is conserved in the pressure tank when the machine is shut down by an automatic valve in the pipe line between the pressure tank and governor. This valve closes automatically when the machine is stopped and thus prevents oil leakage. In addition, it is desirable that the oil pump be motor driven, the motor being controlled by a pressure regulator in such a manner as to maintain normal oil pressure in the pressure tank.

Except for bearing protection, explained by Mr. Wensley, the protective features just mentioned include all which are usually necessary.

It is interesting to observe the growing tendency to apply remote and automatic methods to large turbines in stations where there are operators in order to centralize the control at the switchboard and to obtain increased safety of the machinery.

One of the most common examples is an automatic stopping system which is being included as a safety feature on nearly all the large installations. By the opening of a single switch the switchboard operator is enabled to close the turbine gates quickly, disconnect the generator from the line and apply the brakes, all without the assistance of the second or third operator. Any number of such switches may be used, located as desired throughout the station.

These features will be recognized as the emergency stopping means found in the automatic station. in which case the opening of the control circuit is accomplished by the bearing-temperature relays or other protective devices.

This system is being adopted rapidly on the largest machines, not only because it affords means for stopping the unit in the minimum possible time, but because in case the operator becomes confused, he has to do but one thing to stop the machine. This system has prevented at least one disastrous accident to a large unit in the knowledge of the writer.

The most common remote-control features used in manually controlled stations are the switchboard control of the speed-setting and load-setting adjustments of the governor, together

with an indication at the switchboard of the gate opening at which the machine is running. This equipment is designed to be used with large units where it is especially desirable to have the machine under the direct control of the switchboard operator. With this equipment the switchboard operator can start and stop the machine with no assistance from the second operator instead of the usual custom of having the second operator start the machine and bring it up to speed by hand.

We have explained these applications to manually controlled stations to show how the developments in automatic control are not only influencing the smallest water power developments but are being adopted on the largest units just as fast as they prove to be as dependable as the human operator.

We would like to bring out the relation between the Types *C* and *D* control mentioned in Mr. Wensley's paper, Type *C* being the remote control of the distant station by pilot wire and Type *D* being supervisory control over the telephone circuit. The latter is, of course, only a special case of the Type *C* and is the method used by one manufacturer. The general form of the pilot wire control includes a few wires between the master and automatic stations together with suitable selectors by which these wires may be connected into various local circuits at the two stations. In this way various functions can be accomplished without having separate pilot wires for each. Different manufacturers accomplish these results by various forms of selectors.

As to general hydraulic practise, we received the impression from Mr. Wensley's statements regarding Francis and Nagler type runners that the efficiency of the runner alone should govern the choice between the two and that the Nagler type should be adopted with some caution.

We wish to point out that it is not the runner efficiency but the overall plant efficiency which determines the choice between the two types of runners. At the very lowest heads especially for very large units, the Francis wheel will not allow commercial speeds so that the Nagler type is practically the only solution. At a considerably higher range of heads and for smaller capacities the Nagler wheel is less suited because the gain from speed is insufficient to neutralize the lesser part gate efficiency and the Francis type should be used down to the limit of prohibitive clogging. Between these extremes is a region in which either type is practical. In making the choice here, the following points should be considered in addition to the first cost:

The efficiencies of the Nagler and Francis runners will usually be about the same at the normal load, but the Francis type may be better at fractional loads.

The speed of the Nagler wheel will be higher allowing a more efficient generator.

The Nagler runner will maintain its original efficiency and power whereas the passage of trash may clog the smaller passages of the Francis runner, reducing the efficiency and power if not necessitating a complete shut-down of the machine for cleaning.

The ability of the Nagler runner to pass large objects without clogging allows a wide spacing of the trash racks with a consequent smaller loss of head through the racks.

The resultant of all these conditions favors the Nagler type of wheel more and more as the head becomes less, particularly if the generator is connected into a large power system or in case there are several units in the station so that the turbine can run continuously at the most efficient load.

Considering motor-driven flyballs, we believe that this type is not superseding the older type to the extent that Mr. Wensley states: Belt-driven or direct-connected flyballs have certain inherent advantages over the motor-driven types as built at present in that they register the speed of the machine at all times independently of the electrical conditions of the generator. The older types are often preferred for this reason.

The advantage of the motor drive is, of course, that it is very flexible in its location, is neat and simple in appearance, and may be somewhat cheaper than the belt drive.

Mr. Wensley suggests a reduction in the WR^2 required in a hydroelectric unit, and states that the purpose of the flywheel effect is to stabilize the generator during changes of load while the governor is moving the gates. We wish to add that the purpose of the WR^2 is not only to smooth out load changes, but even more important to absorb changes in torque. Contrary to popular understanding a hydraulic turbine is not a constant-torque machine particularly under low heads which includes most of the automatic stations. In low-head machines the water velocities are high compared with the head and a large part of the total head is draft head. As a result the water flows at high velocities and low pressure and flow conditions are disturbed. The resulting torque on the wheel is not only variable but is likely to have sudden pulsations which must be ironed out by the flywheel.

A unit having too small a WR^2 is not only difficult to govern during synchronizing but does not deliver a constant amount of power. Even though the latter is not objectionable in itself, the varying output causes a continuuus re-adjusting of the gates by the governor with consequent wear on the regulating machinery. Although machines having too small a WR^2 are rare, they occur often enough to establish quite definitely what is the minimum flywheel effect required.

As for the necessity of brakes, the writer knows of some machines which have been in operation for a period of years which do not come to a dead stop but drift very slowly without damage to the thrust bearing. The real advantage of brakes appears when it is desired to stop quickly in emergency and we favor their use in automatic stations when the cost is not prohibitive.

H. A. S. Howarth (by letter): Abundant operating and test data show that Kingsbury thrust bearings do not require brakes for their protection. Enforced running at very low speed actually improves the bearing surfaces. (See *Transactions* A. S. M. E. 1919, Slow-Speed and Other Tests of Kingsbury Thrust Gearings). As a hydroelectric unit slows down complete separation of the bearing surfaces is maintained almost to the point of stopping. The better the fit of the surfaces the slower the bearing will rub before metallic contact is noticeable. From about one rev. per min. to rest the friction coefficient rises markedly and assists in bringing the unit to rest. When the unit is kept turning slowly by water leakage, no harm will result to the thrust bearings, but a brake will be required for stopping the wheel.

W. H. Millan: In connection with Mr. Bany's paper, it appears that the synchronous motor field is excited from the terminals of the generator. This is wrong because we would expect the set to stay on the line irrespective of the generator voltage. A situation may arise where it is necessary for this machine to operate possibly an hour at a voltage in the neighborhood of twenty-five or fifty and I do not believe that the motor would stay on the line as an induction motor (with the field open) without locking out on temperature. Also I do not quite understand how the set is held on the d-c. bus as a d-c. motor when a-c. power has disappeared (waiting for power return) when the d-c. reverse-power relay is set to take the machine off at a reverse value less than the running-light current of the set.

In connection with storage-battery trickle charge. we had quite a discussion in our subcommittee which brought out the fact that installing a storage battery in an automatic station and charging it continuously at 0.2 or 0.3 ampere did not satisfy conditions. Some of us have had experiences with pasted-plate batteries where 0.3 ampere applied continuously disintegrated the grids and at the end of a year and a half we suddenly found ourselves without a battery in an important automatic station.

Referring to the emergency lockout relay which Mr. Wallau mentions in connection with his a-c. reclosing feeder equipment

which prevents a feeder reclosing if the short circuit has been in excess of 900 amperes, I believe this an excellent idea but feel that on heavy or important circuits this limit should be increased. I have seen circuits burned clear only after three reclosures when the behavior of the switch gear indicated a short-circuit current many times this limit.

J. L. Woodbridge: I think the statement in this paper that "the 6-minute rating is the maximum current that can safely be taken from the batteries without serious injury to the plates" may be misleading. A battery may discharge at any rate that the cells can give for the length of time they can give that discharge, without injury to the battery. I call this point to attention because the paper as it now stands might be construed to mean that there is some high rate of discharge that is injurious to battery plates and this is not true.

There is, of course, a practical limit to the useful output of the battery both from the standpoint of voltage drop and from the standpoint of duration and the 6-minute rate of the battery is approaching this practical limit. In other words, at higher rates than the 6-minute rate, the voltage drop becomes excessive and the output of the battery is less useful on that account. Furthermore, the time limit is so short at higher rates that in many cases it would not cover the duration of the interruption. The 6-minute rate is, therefore, usually considered the practical limit in determining the size of the battery for a given service, although in special cases higher rates have been provided for.

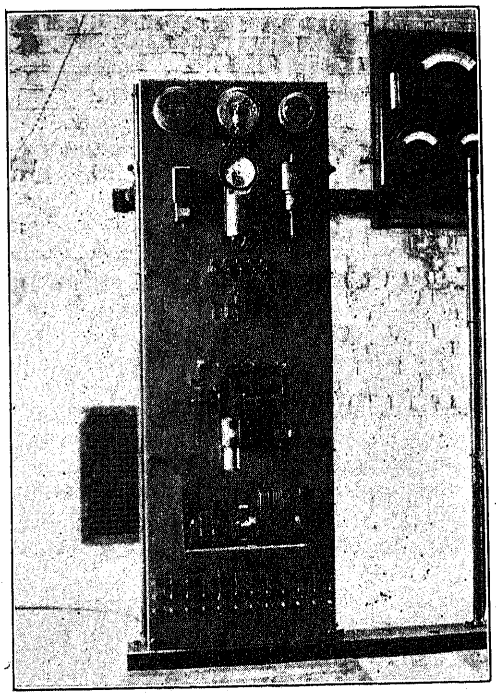

FIG. 1—AUTOMATIC FEEDER OR RAILWAY SWITCHBOARD

It should be carefully noted, however, that any limit thus fixed has nothing to do with any possible injury to the plates.

V. E. Thelin: We have developed a simplified type of substation in Chicago which is fully automatic, being operated in response to time. This station, which has been in operation for approximately five years, is just completing three years of operation without any maintenance or inspection being given and in that time we have had two interruptions. One was due to a finger on a relay being bent out of shape and the other due to the clock stopping on account of dirt which was cleaned out with gasoline and is running satisfactorily to date.

We are using Bullock compound-wound rotaries, which have the series field short-circuited and are, therefore, operating as shunt-wound rotaries. We have great confidence in the shunt-wound rotary due to the fact that on extreme overloads the voltage drops, thus transferring the load to surrounding substations.

We are using automatic reclosing circuit breakers on the feeders, without any resistance whatsoever in series with them, and if a feeder becomes short-circuited, it is cut off and the breaker closes again automatically when trouble is cleared.

The perfect operation of this equipment is due to its simplicity, the entire control panel being approximately 20 in. wide and 70 in. high. A brief description of the operation of this equipment is as follows:

Time clock No. 1 in the upper portion of the slide closes the master relay No. 2 which in turn closes the half-tap contactor No. 3 which connects the rotary to the half-voltage taps on

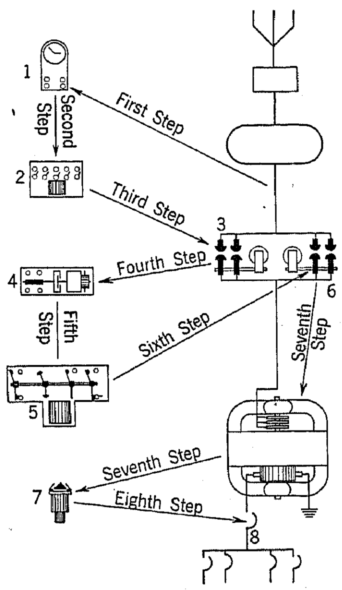

FIG. 2—DIAGRAM SHOWING SEQUENCE OF STARTING OPERATIONS

the transformer. The converter then starts up to synchronous speed with the field excited from the substation bus and the rotary, therefore, comes up with correct polarity. In case it should come up incorrect, the polarized relay will shut the station down, and after a definite time, it will start again, slip a pole and thus correct the polarity. Assuming that it comes up correctly, the polarized relay No. 4 then operates and closes the combination changeover switch No. 5 which opens the half-tap contactor No. 3, closes the full-tap contactor No. 6, changes the connection to the shunt-field windings from the bus to its own self excitation, after which relay No. 7 operates, closing the automatic reclosing circuit breaker No. 8 which picks up the station load.

Further details of the operation of this station can be found in the A. I. E. E. PROCEEDINGS for December 1922.

David K. Blake: The practise of applying small automatic substations to d-c. networks approaches a-c. distribution. As I see it, there are three factors which have hindered the use of alternating current in this territory. The first has been the battery, the second the elevator and the third the customer's equipment. The improved reliability of supply to substations has eliminated the necessity of the battery, at least for most companies. A-c. elevator equipment is now available to meet most requirements. The remaining factor is the customer's equipment which is by no means a small factor.

The practise of supplying small automatic a-c. substations in the surrounding territory approaches the higher voltage distribution with a consequent increase in distribution economy and improvement in voltage regulation. Other advantages of

this practise are that "all of the eggs are not in one basket" and the short-circuit currents on the distribution circuits are considerably reduced. This reduction in short-circuit currents has numerous advantages, such as the reduction in duty on oil circuit breakers and other substation equipment as well as the duty of the primary cutouts located on the distribution feeders.

G. I. Wright: While there has been a very rapid development in the automatic substation field, the methods of overload and short-circuit protection and arrangement of switching apparatus are far from standardized and substations made up of two 2000-kw. 1500-volt conversion sets, as described by Mr. Butcher, are about the largest so far and these are still under construction. When it is realized that a large suburban 1500-volt electrification will necessitate substations of 10,000 or 12,000 kw., which means either four, five, or six units, depending upon the size used, it is doubtful if full automatic operation is advisable. Partial automatic operation for such stations, such as the use of automatic feeder reclosing equipments, and push button control of starting the machines, is thought to be very advantageous.

The systems of supervisory control, which have recently been developed, give an excellent means of controlling circuit breakers at switching and tie stations from a remote point and thus isolate the affected portions of the distribution system in case of trouble.

The author, in general, states that with 60-cycle supply for 1500-volt service, the motor-generator is superior to the converter in reliability, maintenance cost, and the amount of installed capacity necessary to carry short time overloads. Where the machines are protected against injurious flashovers by modern high-speed circuit breaker, it is not thought that the maintenance of a two-unit synchronous converter should be any greater than that of a three-unit motor-generator set. There is considerable difference in opinion as to the amount of installed capacity necessary for a given load in this class of service. The author states that where the capacity of the substation is determined by the short-time or commutating capacity of the machines, it is necessary to install 50 per cent more converter capacity than if motor generators were used. The substations which fall in this classification are those in the outlying sections of a suburban system where the maximum loads are those caused by simultaneously starting of long trains during the rush-hour periods, and which do not occur more than a very few times each day. Due to the infrequency of these loads, the ability of the stations to shift overloads to adjoining stations and the fact that it is considered desirable to install a complete spare unit in each station, which could be operated for these short periods if necessary, it is not thought essential to install appreciably more capacity if converters rather than motor-generators are used.

Even if the maintenance of the converters is decreased by not loading them up to their rated capacity, the investments in extra capacity to reduce this maintenance would be out of all proportion to the savings which could be expected. This can be appreciated when it is realized that one 2000-kw. unit installed complete represents an investment of possibly $80,000.

In regard to the relative efficiency of conversion of the two types of apparatus, all-day efficiencies were carefully calculated for a large suburban steam-railroad electrification, using 2000-kw. 1500-volt conversion sets, and a difference of 3¾ per cent in efficiency was found in favor of the synchronous converter.

A. M. Garrett: Mr. Butcher's paper deals principally with future installations, because the first installation of such capacity in this country is yet on paper. In comparing the efficiencies of the converter and the motor generator, I agree with Mr. Wright in his deductions that there is a pronounced difference in the amount of efficiency when the study is made in economies in regard to 24-hour load. It is gratifying to the operating companies whenever a railway company decides to make its traction system 1500 volts direct-current as this is in line with the operating company's policy of one frequency in generation. It will give greater flexibility to the operating company and therefore better service to the customer.

The paper shows the manufacturers are apparently alive to the design and the problems that will come up with the 1500-volt direct-current service. They are designing machines of a size that will apply to steam-road electrification where the substations will have capacities of 8000, 12,000, possibly 16,000 kw. They are not only providing machines to take care of the higher current and voltage, but they are providing the necessary application for automatic operation.

In the case of automatic operation with either a converter or motor generator, the necessary protection should be taken to prevent certain lockout features from coming into action with every abnormal condition. A flashover on a commutator by no means indicates the unit is disabled or even requires inspection, and precautions should be taken to prevent, under such circumstances, the withdrawal of the machine from service until inspected.

A. C. Grayson: The Public Service Electric Company of New Jersey has recently placed in operation three noiseproof automatic substations, which are known as the Miller Street, Norfolk Street and Race Street Substations. The Miller and Norfolk Street Substations are located in Newark, N. J., within a mile radius of the center of the city, and the Race Street Substation is located in Bloomfield, N. J., about 4 miles from Newark.

The Miller Street Substation is probably one of the largest combined commercial and railway automatic substations in the country. The present capacity consists of two 13,200-volt supply feeders, one bank of three 1000-kv-a. one-phase, transformers: one bank of three 2000 kv-a. one-phase transformers, two 1500-kw., 600-volt d-c. synchronous motor-generator sets, and three 4150-volt, three-phase feeders. The ultimate capacity will consist of five 13,200-volt feeders, two banks of transformers having a capacity of 10,000 kv-a. each, two- 1500-kw. motor-generator sets and twelve 4150-volt, three-phase feeders. The entire equipment is fully automatic with the exception of the 13200-volt supply feeders, which are manually controlled and equipped with reverse-power relay protection.

The transformer banks have automatic control so arranged that they are connected or disconnected from the bus depending upon the amount of load carried. In addition to this they are equipped with the usual protective features such as overload, differential and temperature relays.

The commercial 4150-volt, three-phase feeders are automatic d-c. controlled, with three reclosures on overload before lock-out.

Either of the two motor-generator sets (depending upon which one is leading), starts up automatically on low voltage and the second machine cuts in when the load exceeds the capacity of the first. Shut-down is of course accomplished in the inverse order. Starting voltage is supplied from 30 per cent starting taps on the power transformers, thus eliminating the use of starting compensators.

A double railway bus is provided, one operating at 550 and the other at 600 volts, direct-current. By means of double-throw switches the railway feeders may be connected to either of the two buses. Usually the local heavy feeders operate at 550 volts and the long feeders at 600 volts. The two buses are connected by a bus tie breaker which is closed when only one machine is in operation, the bus voltage being 550 volts. When the first machine is overloaded the second machine cuts in at 550 volts; the bus tie breaker then opens and the second machine builds up its voltage to 600. Each railway feeder is protected by a high-speed circuit breaker which cuts in a load indicating resistance when the breaker opens on short circuit. There is a spare equipment connected to a transfer bus so that it can replace any equipment taken out of service for inspection or repairs.

The substation building is 60 ft. x 100 ft. x 30 ft. high of two story construction. It is divided into four separate rooms for the high-tension equipment, transformers, commercial equipment and motor generators.

On account of the location and the noisy operation of motor-generator sets, sound-proof construction was used throughout with special sound-proofing in the motor-generator room.

Forced ventilation is supplied to the motor generator by means of two 20,000 cu. ft. per min. blowers, one for each unit. Air is taken at the top of the rear of the building, and is drawn through a series of baffles to the blowers in the basement which discharge the air to the pits under each machine. Each blower is started and stopped automatically with its machine. After the air leaves the machines it escapes through another series of baffles to the outside. The baffles are so arranged as to give alternate contraction and expansion of the air without causing an appreciable drop in static pressure.

The walls and ceiling of the motor-generator room are covered with a one-half inch thickness of flaxilinum with a one inch air space between the flaxilinum and the brick wall. The flaxilinum is then covered with plaster to give a finished appearance. As a precaution against transmission of vibrations, the motor-generator foundations are completely isolated from the building. The foundation block is cast separately and rests on what is known as "anti-vibro" block. The vertical spaces between the foundation and the floor are filled with a plastic compound. There is only one door leading from the motor-generator room to the outside and this is a double refrigerator type.

With both machines running the noise cannot be detected when standing on the outside of the building, and for all practicable purposes it is a 100 per cent noise-proof installation.

No sound-proofing is used in the other rooms of the substation except that which is afforded by the solid brick walls.

The substation has been operating automatically about four months and has proved very satisfactory.

The Norfolk St. substation is of the same design as Miller St. except that the present installed capacity consists of two 13200-volt feeder equipments, three 2000-kv-a. transformers, two 4150-volt three-phase feeders and one 1500-kw. synchronous motor-generator set. On account of its location, the architecture is not quite as elaborate as Miller Street but the same methods of sound-proofing were used. This substation has been operating satisfactorily for about three months.

The Race Street Substation is a single unit, automatic railway substation with one 100-kw. rotary converter. The building is of sound-proof construction with solid brick walls, but no sound-proofing is used on the inside of the walls. This precaution was not thought necessary because of its location, and the fact that the converter is less noisy than a motor generator.

No forced ventilation is used, the converter drawing the air from the outside of the building and discharging it through the roof.

This substation has also been in satisfactory operation for about three months.

The Public Service Electric Company have now in the process of design or construction, fourteen new automatic substations. These are divided into three classes: (1) Commercial (4150 Volt, a-c.); (2) Railway; (3) Combined commercial and railway.

In addition to these, a number of the older substations are being changed over from 2400 volts, two-phase, to 4150 volts, three-phase and the new three-phase feeders will be made automatic reclosing even though an operator is required for the remaining apparatus in the substation. It is thought that the satisfactory operation resulting from automatic reclosing feeders justifies the slight increase in expense as compared to the manually operated.

A study is now being made on the use of supervisory control and it is very probable that it will be adopted for these substations in the near future.

H. T. Porter: An important advantage of automatic operation of hydroelectric plants is the increased amount of kilowatt hours obtainable as compared with manually operated plants. The average operator knows little and cares less about efficient utilization of water and in the latter type of station he is to a large extent in control of the manner in which water is used. In the automatic type proper consideration by the engineers of the best way to operate the plant first determines the type of control to be adopted and secondly the method of operation. Many variable factors are eliminated from operation and the plant may be so designed as to shut down under unfavorable conditions and await more favorable conditions of load, or water, provided of course, that some storage, or pondage, is available and the station is tied into a fairly large system. This point is brought out because it has proved an important factor in several recent cases in the decision to install automatic equipment.

Mr. Wensley's paper clearly explains the methods of operation, but does not state how the turbine gates are held closed. In practically all types of automatic control the governor is provided with a solenoid-operated oil-cylinder brake which holds the turbine gates closed when the unit is not in operation. Further, along the line of governor, a good practise is to provide for starting the oil-pressure pump when oil pressure is admitted to governor. Coincident with these occurrences the brake on the turbine-gate shaft is released and the turbine swing gates partially open allowing the unit to come up to synchronizing speed and under governor control. Proper design of the turbine gates prevents their swinging fully open, except under governor control and upon a heavy demand for load, since they are generally designed to balance at from ¼ to ¾ of full open position. This prevents the unit from ever obtaining full runaway speed, and also precludes possibility of the gates slamming shut or opening violently. The gates can, of course, be designed to balance at any predetermined opening.

The motor-driven governor flyball has thoroughly demonstrated its superiority over the mechanically belt-driven element. Its use eliminates belts, pulleys, belt tighteners and attendance, and replaces a heretofore source of weakness, especially in the automatic plant.

Where automatic stations are a part of, and subordinate to, a comparatively large system and main stations, their generator flywheel effect may be considerably reduced. In other words, if the system is previously provided with sufficient inertia to hold the system frequency to satisfactory limits the automatic plant need as a minimum require only enough inertia to allow of synchronizing and placing the unit on the line. As a rule, however, the generator flywheel effect should be such as to give a constant of at least 2,500,000 in the formula $C \frac{W^2 \times R.P.M.^2 R.}{B\,H\,P}$

In instances where a plant is required to do considerable regulating, this value should be in the neighborhood of 5,000,000 and in the case of a plant designed to take care of regulation of the major part of a system this value may be as high as 10,000,000.

Engineers usually specify $W\,R^2$ as computed from the formula

$W\,R^2 \frac{810{,}000 \times \text{h. p.} \times T}{(R\,P\,M)^2 \times d}$. Where h. p. is load applied, T is time of governor action, and d is percentage of speed rise. As a matter of convenience full-load conditions are generally assumed. This application should always be made with a view towards what will occur when load changes smaller than ½ load occur, since full and very large load changes are infrequent and of little consequence. Under approximately open-water conditions the governor should ordinarily be set to operate the gates through their full stroke in not less than 1½ seconds and through a stroke corresponding to about $^1/_{10}$ load change in ¾ to 1 second. Very large units require longer time of governor action to avoid racking the operating mechanism. For practi-

cal purposes proportional load changes may be assumed to require a directly proportional time of governor action. Further, a $^1/_{10}$-load change should not cause a speed variation of more than 2½ per cent from normal and a good value is 1½ per cent. This may be applied to the above formula to determine proper $W R^2$. This load change is commercial and the engineer must use his judgment and knowledge of the system to determine permissible speed or frequency variation. Also it should be kept in mind that the above formula is for a water-rheostat load and does not take into account the effect of the rest of the electrical system in steadying the frequency. If closed conduits supply water to the unit, the governor time element must be such as to limit pressure variations to safe values and the $W R^2$ must be increased. Pressure variations in themselves affect regulation approximately in direct proportion to the 3/2 power of the momentary increase or decrease in effective head. Regulation is dependent to a large extent upon local conditions and it is almost impossible to set forth any definite methods for determination of $W R^2$ required which will be applicable to all cases.

Automatically oil-operated brakes in the speaker's opinion should not usually be required. They introduce an extra item of control with attendant complications and cost. Oil is usually taken from the governor system for their operation and the piping is liable to develop leaks. When the turbine gates are closed conditions can be made and should be such that the unit will stop. Hand-operated mechanical brakes should be provided to stop the wheel if the gates should get clogged and to hold the unit when under inspection, etc. When the turbine-gate mechanism becomes so worn that the wheel continues to rotate, adjustments or repairs as found necessary should be made.

The lubrication of turbine bearings is more or less difficult because water under pressure containing foreign matter is always introduced and it is a question of lubricating each bearing individually. The grease cup is practically a thing of the past, since it is hard to put grease under sufficient pressure, to lubricate properly some bearings without having grease squeeze out through the threads. Pressure fittings of various types such as the "alemite" have been used with good success. The grease compressor may be of the portable type for small plants or the stationary type for large plants with a flexible hose connection. This lubrication need only be periodic and can be taken care of by the visiting attendant. If the grease compressor is portable it should have sufficient capacity to grease all of the turbine bearings with one filling. The main turbine bearing is always of the water-lubricating lignum-vitae type, or oil-lubricated babbitted type. The latter is gaining some favor for large vertical units. Its principal disadvantages are inaccessibility on vertical units and possibility of mixture of water and oil. A motor-driven oil pump and auxiliary belt-driven oil pump should be supplied so that one pump will always be available. Thermostat protection is usually provided for this type. With the lignum-vitae type an electrical alarm attachment should be provided to indicate failure of lubricating water supply to bearing. Water-supply piping should be suitably lagged to prevent danger of water freezing in winter in an unheated automatic plant.

There are some plants being installed from which governor has been omitted and a mechanical hand and electrically operated control supplied. The only reason is to effect a saving in first cost, and this saving is small if properly designed equipment is supplied. Usually a governor is justified since it allows greater flexibility of operation and makes the unit more independent of the rest of the system in case of trouble.

F. R. George: Mr. Wensley issued somewhat of a challenge to the operating man. The operating man in California deals with the steam plant as a standby, and, therefore, his hydro becomes the base load of his system and requires more attention than the steam plants. However, the efficiencies in the steam plant, as Mr. Wensley stated, are more carefully looked after. The hydro plants are not looked after in the same manner, I think perhaps because of a lack of satisfactory unit of efficiency comparable to so many kilowatts per barrel of oil.

We have a great deal of difficulty in keeping ahead of the demand, and, therefore, when it comes to a question of going to our boards of directors and asking them for appropriations to put in an automatic plant or to revamp an old plant to automatic operation, the first question asked us is: "About how many kilowatts shall we get out of the plant? Naturally the automatic plant lends itself only (I say so advisedly) to small capacities. When we have our plans all worked up and find that it is practical and perfectly possible to convert an old plant and we reach the point where we are asked the amount of kilowatt hours we are going to get from that plant, and it is a comparably insignificant amount, the Board of Directors say: "No, we must devote our time and money at present to the development of new power in order to keep abreast of the demand" and, therefore, the installation of the automatic control device is again delayed or postponed.

The California situation at the present time lends itself very well to the thought and to the entertainment of the application of automatic devices. We are now facing one of the driest seasons in our history, meaning that our operating costs are going to be quite excessive due to the necessity for reversing our operation and placing dependence upon our steam generating equipment to offset the shortage in the hydro-power plants due to the drought, and therefore any economies which we could effect in the operation of our hydro plants would help in a measure to offset the unusual high operating costs which will maintain due to the drought.

E. E. Woodward: There seems to be a great deal of misunderstanding in regard to the synchronous-motor governor drive. Our company was probably the pioneer in using it to any extent, and we have been using it for about three years, and we have no complaints so far.

While called a synchronous-motor drive, the motor is not synchronous at all but is squirrel-cage induction three-or two-phase motor. This motor will start at 25 per cent of full voltage, and while it is not synchronous at this voltage it is very nearly so at 50 per cent voltage, and at full voltage the lag is so small that it cannot easily be detected.

Mr. Porter brought out the matter of brakes being needed to hold the gates closed on an automatic plant. That was one of the first things we discovered, and we have a very simple brake on the governor which is operated by oil pressure. It is really operated by a spring. We have an automatic throttle valve which is closed so as to keep the pressure in the tank during the period of rest. By this means we are able to hold the pressure for two or three weeks, if necessary, and have enough to start with. When the oil pressure is shut off from the governor, the spring sets the brake and the gates are locked closed. As soon as the oil pressure is thrown into the governor, the brake is released.

In the matter of generator brakes, we don't undertake to say whether they should be used or not, but if they are and if they use oil from the governor, we want that oil pressure to be shut off after the wheel is stopped, otherwise we might lose much oil through the brake cylinders and leakage elsewhere. We are now developing a brake valve that will apply the brakes and release them after an interval of five, ten or fifteen minutes, as may be desired.

L. F. Harza: I am not fully in accord with Mr. Wensley's belief that automatic operation will result in dividing up an available head into several smaller heads for reduction in flowage damages and saving in the cost of dams. The saving in cost of dams is doubtful when we consider the resulting multiplication of cofferdams, control gates and machinery. The storage obtained usually justifies the higher dam. Likewise the higher dam is not crippled in time of flood while the several substitute low head projects might cease entirely to operate under flood condi-

tions. However, this is a question which can be settled only for each individual river.

It is our belief that many of the features developed for the automatic plant can well be applied to a manual station of any size, regardless of how well its size may justify the expense of operators. We are all familiar with mistakes made by operators in emergencies. Cool headed action by a human operator can be least expected when most needed. Protective relays may at times fail to function but should be more reliable under emergencies than human operators.

We are also of the opinion that self synchronizing either by damper windings or synchronous motors and mechanical differential will ultimately replace manual synchronizing even in manual stations. It would eliminate the human element in one more operation where a mistake might be disastrous. All the operator would then need to do would be to close a master switch which would start the cycle of operation necessary to put a unit into service.

We have developed several automatic stations, equipped with hand brakes only. I regret to advise that the units do not all stop rotating when tripped out of service, even though the heads are low, in two cases as low as 8.5 ft. No harm has resulted as yet from failure to stop but the slow speed of rotation suggests the danger of failure of the oil film and injury to the bearing. Moreover, if tripped out by the bearing thermostats failure, to stop rotating would defeat the purpose of these thermostats. I shall be inclined for future installations to favor automatic brakes. Automatic brakes can be operated from the governor tank by air as well if not better than by oil as far as interfering with the normal functions of the governor is concerned. Connection to the governor tank should be closed automatically as soon as the unit stops, to prevent continued loss of air or oil. Most units when once stopped will not start again after releasing the brakes.

I am not convinced that engineers usually waste money on flywheel effect. Where an installation is a small part of the generating capacity of a system operating in parallel with a system of steam turbo-generators, a small flywheel effect can be used and the mistake of over-weight of rotor may at times be made. More often however, the case is that the manufacturer has a standard line of patterns which he tries to adapt to vertical or horizontal machines, water wheel or engine-driven by the least possible adjustments. The manufacturer should have a vertical line of machines developed for water-wheel service.

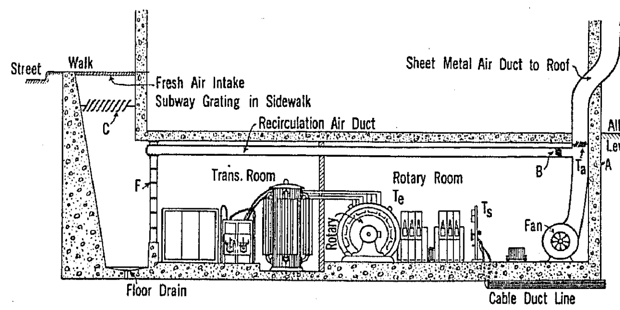
The writer is convinced by experience with the development of several automatic stations that they have a great future. Automatic means are now available for meeting almost any operating condition or emergency with a degree of success and reliability, dependent chiefly upon the relays. Different manufacturers, to avoid patent infringement, accomplish the same purpose with relays often operating upon widely different principles and sometimes with widely different degrees of success. It behooves the purchaser to examine carefully into the relays offered with any installation, as to the extent of their previous application and success.

F. C. Hanker: There are one or two points I would like to bring out in connection with the automatic generator station. Mr. Harza has mentioned the effect of the method of starting on the system operation. If you take the small, low-speed machines, the current they will draw when thrown on the line at full voltage will not exceed three times the rating of the unit. But when you consider the larger, high-speed machines, that current becomes more of a factor in the system operation and must be recognized in the method of operation or the method of control that is selected.

The experience in manual operation with the starting of large synchronous condensers shows conclusively that those machines can be started on a system of comparatively small size without disturbance by using proper precautions in the starting. But when you come to a high-speed large-capacity unit relative to the size of the system, then it is necessary to take the starting current into account. That is one place where the automatic synchronizer is quite important.

Another phase of the problem involves manually operated stations. In the Northwest, and I presume in other systems, there has been trouble experienced following an interruption to service in getting the stations back on the line and restoring service in a minimum of time. In some cases recent failures have shown that the time to restore units to service is about fifteen minutes. A good deal of that time is spent by the operators in getting the various water wheels and hydraulic elements stabilized, so that if they had automatic synchronizers, those automatic synchronizers could be applied to the main units and the operators could devote their entire time to the operation of the hydraulic parts, governors and water wheels, and get those stabilized.

The automatic control equipment of itself has been well developed in the synchronous-converter, motor-generator and the synchronous-generator application. No equipment is perfect, but the experience we have had makes us very hopeful that this equipment can be developed to a point where its efficiency and reliability will more than equal the hand-operated station.



T_a	(Thermostat)	Closes A and C Opens B	When Temperature falls below 85 deg. Fahr.

T_s	"	Turns steam into radiators when temperature is below 80 deg. Fahr.	
F	Dry type filter		

S. E. Bettes (by letter): Where automatic substations are located in building basements a special ventilation system is required to insure an adequate supply of clean air to keep the operating temperature below the danger point. This system must adopt itself to all the requirements of the automatic station operation and as in the case of the station itself change its own operation to suit the conditions existing.

The following outline of operation is used in our automatic rotary-converter substations and is proving very satisfactory. The accompanying sketch shows the ventilation schematically.

All air entering the station is drawn through the sidewalk grating and through the dampers C. After passing through the dry-type air filters which remove the dirt, the clean air goes through the transformer and high-tension switch room into the rotary-converter room. Self-closing fire doors are provided in this wall to prevent fire from passing from one room to the other.

The fans in the rear of the station draw the hot air out of the station and force it up the duct to the discharge which is above the roof of the building. There are two fans, each capable of supplying sufficient air to cool the station.

The automatic features provided are:

The fans are automatically started when the rotary is put on the line unless the temperature is lower than 70 deg. Fahr. When the air coming from the rotary is warmer than 70 deg. the

thermostat *T e* closes the automatic starter and the fan starts. If the air passing the thermostat *T a* is above 85 deg. fahr., all the air goes up the duct to the exhaust. If the air is just less than 85 deg. fahr., the dampers at *A* and *C* start to close and the damper *B* starts to open. This allows part of the air to return to the intake end of the station and tempers the cold air coming in. A further reduction in temperature of the air passing thermostat *T a* causes *A* and *C* to close entirely and all the air goes back through the station.

To provide a source of heat when no machines are operating, steam radiators are placed so as to warm parts likely to be damaged by cold. The thermostat *T s* turns on the steam if the temperature goes below 60 deg. fahr.

The failure of the damper control will cause the *A* and *C* damper to open and the *B* damper to close so that the machines will get the maximum amount of cooling air.

Any draft action caused by warm air up the exhaust duct after the machines are shut down will remove warm air from the station until the temperature reaches 85 deg. when the thermostats will close *C* and *A* and prevent further cooling. This is important during the winter months.

Rain coming through the sidewalk grating cannot enter the station and is disposed of through the drains.

H. Bany: In answer to Mr. Millan's question regarding whether the generator is disconnected from the d-c. bus upon reverse power, nothing further occurs than the three operations mentioned under operating features on the fifth page of the paper. The d-c. line breakers do not open and the set merely runs idle from the d-c. end. If any other operations do occur, they must be caused by some other abnormal condition, such as, a-c. undervoltage or a-c. power failure.

It does not seem that there is any sacrifice being made by having the motor field excited directly from the generator as Mr. Millan questions, instead of from the exciter. Since normal excitation on the motor gives about 0.8 leading power factor at full load, if the load and excitation are both reduced proportionally, the motor will not pull out of step at the lower d-c. bus voltages. If the a-c. voltage should be low so that the motor does pull out of step, the time delay of 40 seconds mentioned in the first paragraph of the second column, page 765, will shut down the set and a restart will not be allowed until the a-c. line voltage is again 80 per cent of normal or above.

C. A. Butcher: With reference to remarks by Messrs. Wright and Garrett, concerning comparative efficiencies of converters and motor-generators, the difference in all-day efficiency is less in favor of converters, if it is established that smaller motor generators may be used to supply the peak loads incident to infrequently scheduled heavy trains, or in other words, if the substation capacity is based on commutating capacity, rather than the continuous rating of the machines. Mr. Wright states that this may apply to the outlying substations; however, it would seem that during periods of light traffic, such as is the case during the off-peak load, the same applies to all stations.

The largest 1500-volt automatic railway substation soon to be placed in operation has a total capacity of 8000 kw., made up of four 2000-kw. converter sets.

R. J. Wensley: It is my feeling that the purpose of this paper has been accomplished. It was intentionally written in such a manner as to bring out in discussion some of the disputed points in the operation of Automatic Hydroelectric Generating Equipments. The discussions by Mr. R. H. Earle and Mr. H. T. Porter are both distinct contributions to the general subject. The discussion of the desirable amount of flywheel effect as given by Mr. Porter is of especial value.

C. W. Place: I wish to point out that the method of operation as outlined by the previous speaker, is not the one that will most nearly meet conditions in the middle western territory. The most economical operation will be that of using the steam plants as base-load plants and the hydroelectric stations for carrying peaks. The introduction of more and more interconnection of systems and the building of base-load steam plants, makes this use of hydroelectric stations particularly valuable.

Selective Circuits and Static Interference

BY JOHN R. CARSON

Associate, A. I. E. E.

Department of Development & Research, American Tel. & Tel. Company, New York, N. Y.

Review of the Subject.—*The present paper has its inception in the need of a correct understanding of the behavior of selective circuits when subjected to irregular and random inteference, and of devising a practically useful figure of merit for comparing circuits designed to reduce the effects of this type of interference. The problem is essentially a statistical one and the results must be expressed in terms of mean values. The mathematical theory is developed from the idea of the spectrum of the interference and the response of the selective circuit is expressed in terms of the mean square current and mean power absorbed. The application of the formulas deduced to the case of static interference is discussed and it is shown that deductions of practical value are possible in spite of meager information regarding the precise nature and origin of static interference.*

The outstanding deductions of practical value may be summarized as follows:

1. *Even with absolutely ideal selective circuits, an irreducible minimum of interference will be absorbed, and this minimum increases linearly with the frequency range necessary for signaling.*

2. *The wave-filter, when properly designed, approximates quite closely to the ideal selective circuit, and little, if any, improvement over its present form may be expected as regards static interference.*

3. *As regards static or random interference, it is quite useless to employ extremely high selectivity. The gain, as compared with circuits of only moderate selectivity, is very small, and is inevitably accompanied by disadvantages such as sluggishness of response with consequent slowing down of the possible speed of signaling.*

4. *A formula is developed, which, together with relatively simple experimental data, provides for the accurate determination of the spectrum of static interference.*

5. *An application of the theory and formulas of the paper to representative circuit arrangements and schemes designed to reduce static interference, shows that they are incapable of reducing, in any substantial degree, the mean interference, as compared with what can be done with simple filters and tuned circuits. The underlying reason lies in the nature of the interference itself.*

* * * * *

I

The selective circuit is an extremely important element of every radio receiving set, and on its efficient design and operation depends the economical use of the available frequency range. The theory and design of selective circuits, particularly of their most conspicuous and important type, the electric wave filter, have been highly developed, and it is now possible to communicate simultaneously without undue interference on neighboring channels with a quite small frequency separation. On the other hand too much has been expected of the selective circuit in the way of eliminating types of interference which inherently do not admit of elimination by any form of selective circuit. I refer to the large amount of inventive thought devoted to devising ingenious and complicated circuit arrangements designed to eliminate *static interference.* Work on this problem has been for the most part futile, on account of the lack of a clear analysis of the problem and a failure to perceive inherent limitations on its solutions by means of selective circuits.

The object of this paper is twofold: (1) To develop the mathematical theory of the behavior of selective circuits when subjected to random, irregular disturbances, hereinafter defined and designated as *random interference.* This will include a formula which is proposed as a measure of the *figure of merit of selective circuits with respect to random interference.* (2) On the basis of the theory to examine the problem of *static interference* with particular reference to the question of its elimination by means of selective circuits. The mathematical theory shows, as might be expected, that the complete solution of this problem requires experimental data regarding the frequency distribution of static interference which is now lacking. On the other hand, it throws a great deal of light on the whole problem and supplies a formula which furnishes the theoretical basis for an actual determination of the spectrum of static. Furthermore, on the basis of a certain mild and physically reasonable assumption, it makes possible general deductions of practical value which are certainly qualitatively correct and are believed to involve no quantitatively serious error. These conclusions, it may be stated, are in general agreement with the large, though unsystematized, body of information regarding the behavior of selective circuits to static interference, and with the meager data available regarding the wave form of elementary static disturbances.

The outstanding conclusions of practical value of the present study may be summarized as follows:

(1) Even with absolutely ideal selective circuits, an irreducible minimum of interference will be absorbed, and this minimum increases linearly with the frequency range necessary for signaling.

(2) The wave-filter, when properly designed, approximates quite closely to the ideal selective circuit, and little, if any, improvement over its present form may be expected as regards static interference.

(3) As regards static or random interference, it is quite useless to employ extremely high selectivity. The gain, as compared with circuits of only moderate selectivity, is very small, and is inevitably accompanied by disadvantages such as sluggishness of response with consequent slowing down of the possible speed of signaling.

(4) By aid of a simple, easily computed formula, it

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

should be possible to determine experimentally the frequency spectrum of static.

(5) Formulas given below for comparing the relative efficiencies of selective circuits on the basis of signal-to-interference energy ratio are believed to have considerable practical value in estimating the relative utility of selective circuits as regards static interference.

II

Discrimination between signal and interference by means of selective circuits depends on taking advantage of differences in their wave forms, and hence on differences in their *frequency spectra*. It is, therefore, the function of the selective circuit to respond effectively to the range of frequencies essential to the signal while discriminating against all other frequencies.

Interference in radio and wire communication may be broadly classified as *systematic* and *random*, although no absolutely hard and fast distinctions are possible. *Systematic interference* includes those disturbances which are predominantly steady-state or those whose energy is almost all contained in a relatively narrow band of the frequency range. For example, interference from individual radio-telephone and slow-speed radio telegraph stations is to be classified as systematic. *Random interference*, which is discussed in detail later, may be provisionally defined as the aggregate of a large number of elementary disturbances which originate in a large number of unrelated sources, vary in an irregular, arbitrary manner, and are characterized statistically by no sharply predominate frequency. An intermediate type of interference, which may be termed either *quasi-systematic* or *quasi-random*, depending on the point of view, is the aggregate of a large number of individual disturbances, all of the same wave form, but having an irregular or random time distribution.

In the present paper we shall be largely concerned with random interference, as defined above, because it is believed that it represents more or less closely the general character of *static* interference. This question may be left for the present, however, with the remark that the subsequent analysis shows that, as regards important practical applications and deductions, a knowledge of the exact nature and frequency distribution of static interference is not necessary.

Now when dealing with random disturbance, as defined above, no information whatsoever is furnished as regards instantaneous values. In its essence, therefore, the problem is a statistical one and the conclusions must be expressed in terms of mean values. In the present paper formulas will be derived for the *mean energy* and *mean square current* absorbed by selective circuits from random interference, and their applications to the static problem and the protection afforded by selective networks against static will be discussed.

The analysis takes its start with certain general formulas given by the writer in a recent paper[1], which may be stated as follows:

Suppose that a selective network is subjected to an impressed force $\phi(t)$. We shall suppose that this force exists only in the time interval, or epoch, $o \leqq t \leqq T$, during which it is everywhere finite and has only a finite number of discontinuities and a finite number of maxima and minima. It is then representable by the Fourier Integral

$$\phi(t) = 1/\pi \int_0^\infty |f(\omega)| \,.\, \cos[\omega t + \theta(\omega)]\, d\omega \tag{1}$$

where

$$|f(\omega)|^2 = \left[\int_0^\infty \phi(t) \cos \omega t \, dt\right]^2 + \left[\int_0^\infty \phi(t) \sin \omega t \, dt\right]^2 \tag{2}$$

Now let this force $\phi(t)$ be applied to the network in the *driving* branch and let the resulting current in the *receiving* branch be denoted by $I(t)$. Let $Z(i\omega)$ denote the steady-state *transfer* impedance of the network at frequency $\omega/2\pi$: that is the ratio of e. m. f. in *driving* branch to current in *receiving* branch. Further let $z(i\omega)$ and $\cos \alpha(\omega)$ denote the corresponding impedance and power factor of the receiving branch. It may then be shown that

$$\int_0^\infty [I(t)]^2 \, dt = 1/\pi \int_0^\infty \frac{|f(\omega)|^2}{|Z(i\omega)|^2} \, d\omega \tag{3}$$

and that the total energy W absorbed by the receiving branch is given by

$$W = 1/\pi \int_0^\infty \frac{|f(\omega)|^2}{|Z(i\omega)|^2} |z(i\omega)| \,.\cos \alpha(\omega) \,.\, d\omega \tag{4}$$

To apply the formulas given above to the problem of random interference, consider a time interval, or epoch, say from $t = o$ to $t = T$, during which the network is subjected to a disturbance made up of a large number of unrelated elementary disturbances or forces, $\phi_1(t), \phi_2(t) \ldots \phi_n(t)$.

If we write

$$\Phi(t) = \phi_1(t) + \phi_2(t) + \ldots + \phi_n(t)$$

then by (1), $\Phi(t)$ can be represented as

$$\Phi(t) = 1/\pi \int_0^\infty |F(\omega)| \,.\, \cos[\omega t + \theta(\omega)]\, d\omega$$

and

$$\int_0^\infty [I(t)]^2 \, dt = 1/\pi \int_0^\infty \frac{|F(\omega)|^2}{|Z(i\omega)|^2} \, d\omega \tag{3}$$

We now introduce the function $R(\omega)$, which will be termed the *energy spectrum* of the random interference, and which is analytically defined by the equation

$$R(\omega) = 1/T\, |F(\omega)|^2 \tag{5}$$

1. Transient Oscillations in Electric Wave Filters, Carson and Zobel, *Bell System Technical Journal*, July 1923.

Dividing both sides of (3) and (4) by T we get

$$\bar{I}^2 = 1/\pi \int_0^\infty \frac{R(\omega)}{|Z(i\omega)|^2} d\omega \qquad (6)$$

$$\bar{P} = 1/\pi \int_0^\infty \frac{R(\omega)}{|Z(i\omega)|^2} |z(i\omega)| . \cos\alpha(\omega) . d\omega \qquad (7)$$

$\bar{I}^2$, $\bar{P}$ and $R(\omega)$ become independent of the T provided the epoch is made sufficiently great. *$\bar{I}^2$ is the mean square current and $\bar{P}$ the mean power absorbed by the receiving branch from the random interference.*

In the applications of the foregoing formulas to the problem under discussion, the mean square current $\bar{I}^2$ of the formula (6) will be taken as the relative measure of interference instead of the mean power $\bar{P}$ of formula (7). The reason for this is the superior simplicity, both as regards interpretation and computation, of formula (6). The adoption of $\bar{I}^2$ as the criterion of interference may be justified as follows:

(1) In a great many important cases, including in particular experimental arrangements for the measurement of the static energy spectrum, the receiving device is substantially a pure resistance. In such cases multiplication of $\bar{I}^2$ by a constant gives the actual mean power $\bar{P}$.

(2) It is often convenient and desirable in comparing selective networks to have a standard termination and receiving device. A three-element vacuum tube with a pure resistance output impedance suggests itself, and for this arrangement formulas (6) and (7) are equal within a constant.

(3) We are usually concerned with relative amounts of energy absorbed from static as compared with that absorbed from signal. Variation of the receiver impedance from a pure constant resistance would only in the extreme cases affect this ratio to any great extent. In other words, the ratio calculated from formula (6) would not differ greatly from the ratio calculated from (7).

(4) While the interference actually apperceived either visually or by ear will certainly depend upon and increase with the energy absorbed from static, it is not at all certain that it increases linearly therewith. Consequently, it is believed that the additional refinement of formula (7) as compared with formula (6) is not justified by our present knowledge and that the representation of the receiving device as a pure constant resistance is sufficiently accurate for present purposes. It will be understood, however, that throughout the following argument and formulas, $\bar{P}$ of formula (7) may be substituted for $\bar{I}^2$ of (6), when the additional refinement seems justified. The theory is in no sense limited to the idea of a pure constant resistance receiver, although the simplicity of the formulas and their ease of computation is considerably enhanced thereby.

The problem of random interference, as formulated by equations (6) and (7) was briefly discussed by the writer in "Transient Oscillations in Electric Wave Filters"[2] and a number of general conclusions reached. That discussion will be briefly summarized, after which a more detailed analysis of the problem will be given.

Referring to formula (6), since both numerator and denominator of the integrand are everywhere $\geq o$, it follows from the mean value theorem that a value $\bar{\omega}$ of ω exists such that

$$\bar{I}^2 = \frac{R(\bar{\omega})}{\pi} \int_0^\infty \frac{d\omega}{|Z(i\omega)|^2} \qquad (8)$$

The approximate location of $\bar{\omega}$ on the frequency scale is based on the following considerations:

(a) In the case of efficient selective circuits designed to select a continuous finite range of frequencies in the interval $\omega_1 \leq \omega \leq \omega_2$, the important contributions to the integral (6) are confined to a finite continuous range of frequencies which includes, but is not greatly in excess of, the range which the circuit is designed to select. This fact is a consequence of the impedance characteristics of selective circuits, and the following properties of the spectrum $R(\omega)$ of random interference, which are discussed in detail subsequently.

(b) $R(\omega)$ is a continuous finite function of ω which converges to zero at infinity and is everywhere positive. It possesses no sharp maxima or minima, and its variation with respect to ω, where it exists, is relatively slow.

On the basis of these considerations it will be assumed that $\bar{\omega}$ lies within the band $\omega_1 \leq \omega \leq \omega_2$ and that without serious error it may be taken as the mid-frequency ω_m of the band which may be defined either as $(\omega_1 + \omega_2)/2$ or as $\sqrt{\omega_1 \omega_2}$. Consequently

$$\bar{I}^2 = \frac{R(\omega_m)}{\pi} \int_0^\infty \frac{d\omega}{|Z(i\omega)|^2} \qquad (9)$$

From (9) it follows that the mean square current $\bar{I}^2$, due to random interference, is made up of two factors: one $R(\omega_m)$ which is proportional to the energy level of the interference spectrum at mid-frequency $\omega_m/2\pi$: and, second, the integral

$$\rho = 1/\pi \int_0^\infty \frac{d\omega}{|Z(i\omega)|^2} \qquad (10)$$

which is independent of the character and intensity of the interference. Thus

$$\bar{I}^2 = \rho R(\omega_m) \qquad (11)$$

Formula (11) is of considerable practical importance, because by its aid the spectral energy level $R(\omega)$ can be determined, once $\bar{I}^2$ is experimentally measured and the frequency characteristics of the receiving network specified or measured. It is approximate, as discussed

2. L. c.

above, but can be made as accurate as desired by employing a sufficiently sharply selective network.

The formula for the *figure of merit of a selective circuit with respect to random interference* is constructed as follows:

Let the signaling energy be supposed to be spread continuously and uniformly over the frequency interval corresponding to $\omega_1 \leqq \omega \leqq \omega_2$. Then the mean square signal current is given by

$$\frac{E^2}{\pi} \int_{\omega_1}^{\omega_2} \frac{d\,\omega}{|Z\,(i\,\omega)|^2}$$

or, rather, on the basis of the same transmitted energy to

$$E^2 \frac{1}{\pi\,(\omega_2 - \omega_1)} \int_{\omega_1}^{\omega_2} \frac{d\,\omega}{|Z\,(i\,\omega)|^2} = E^2\,\sigma \qquad (12)$$

The ratio of the mean square currents, due to signal and to interference, is

$$\frac{E^2}{R\,(\omega_m)} \cdot \sigma/\rho \qquad (13)$$

The first factor $\frac{E^2}{R\,(\omega_m)}$ depends only on the signal and interference energy levels, and does not involve the properties of the network. The second factor σ/ρ depends only on the network and measures the efficiency with which it excludes energy outside the signaling range. It will, therefore, be termed *the figure of merit of the selective circuit* and denoted by S, thus

$$S = \sigma/\rho = \frac{1}{\omega_2 - \omega_1} \int_{\omega_1}^{\omega_2} \frac{d\,\omega}{Z\,(i\,\omega)^2} \div \int_0^\infty \frac{d\,\omega}{|Z\,(i\,\omega)|^2} \qquad (14)$$

Stated in words, *the figure of merit of a selective circuit with respect to random interference is equal to the ratio of the mean square signal and interference currents in the receiver, divided by the corresponding ratio in an ideal band filter which transmits without loss all currents in a "unit" band* ($\omega_2 - \omega_1 = 1$) *and absolutely extinguishes currents outside this band.*

III

Before taking up practical applications of the foregoing formulas, further consideration will be given to the hypothesis, fundamental to the argument, that over the frequency range which includes the important contributions to the integral $\int_0^\infty \frac{d\,\omega}{|Z\,(i\,\omega)|^2}$ the spectrum $R\,(\omega)$ has negligible fluctuations so that the integral

$$\int_0^\infty \frac{R\,(\omega)}{|Z\,(i\,\omega)|^2}\,d\,\omega$$

may, without appreciable error, be replaced by

$$R\,(\omega_m) \int_0^\infty \frac{d\,\omega}{|Z\,(i\,\omega)|^2}$$

where $\omega_m/2\,\pi$ is the "mid-frequency" of the selective circuit.

The original argument in support of this hypothesis was to the effect that, since the interference is made up of a large number of unrelated elementary disturbances distributed at random in time, any sharp maxima or minima in the spectrum of the individual disturbances would be smoothed out in the spectrum of the aggregate disturbance. This argument is still believed to be quite sound: the importance of the question, however, certainly calls for the more detailed analysis which follows:

Let
$$\Phi\,(t) = \sum_1^N \phi_r\,(t - t_r) \qquad (15)$$

where t_r denotes the time of incidence of the r^{th} disturbance $\phi_r\,(t)$. The elementary disturbances $\phi_1, \phi_2 \ldots \phi_N$ are all perfectly arbitrary, so that $\Phi\,(t)$ as defined by **(15)** is the most general type of disturbance possible. The only assumption made as yet is that the instants of incidence $t_1 \ldots t_N$ are distributed at random over the epoch $o \leqq t \leqq T$; an assumption which is clearly in accordance with the facts in the case of static interference. If we write

$$C_r\,(\omega) = \int_0^\infty \phi_r\,(t) \cos \omega\,t\,d\,t$$

$$S_r\,(\omega) = \int_0^\infty \phi_r\,(t) \sin \omega\,t\,d\,t \qquad (16)$$

it follows from **(2)** and **(15)**, after some easy rearrangements that

$$|F\,(\omega)|^2 = \sum_{r=1}^N \sum_{s=1}^N \cos \omega\,(t_r - t_s)\,[C_r\,(\omega)\,C_s\,(\omega) + S_r\,(\omega)\,S_s\,(\omega)] = \sum C_r^2\,(\omega) + S_r^2\,(\omega) \qquad (17)$$
$$+ \sum_{r \neq s} \sum \cos \omega\,(t_r - t_s)\,[C_r\,(\omega)\,C_s\,(\omega) + S_r\,(\omega)\,S_s\,(\omega)]$$

The first summation is simply $\sum |f_r(\omega)|^2$. The double summation involves the factor $\cos \omega\,(t_r - t_s)$. Now by virtue of the assumption of random time distribution of the elementary disturbances, it follows that t_r and t_s, which are independent, may each lie anywhere in the epoch $o \leqq t \leqq T$ with all values equally likely. The mean value of $|F\,(\omega)|^2$ is therefore gotten by

averaging[3] with respect to t_r and t_s over all possible values, whence

$$|F(\omega)|^2 = \sum |f_r(\omega)|^2 + 2/T^2 \frac{1-\cos\omega T}{\omega^2} \times$$
$$\sum\sum [C_r(\omega) C_s(\omega) + S_r(\omega) S_s(\omega)] \quad (18)$$

and

$$\bar{I}^2 = \frac{1}{\pi T} \sum \int_0^\infty \frac{|f_r(\omega)|^2}{|Z(i\omega)|^2} d\omega$$
$$+ \frac{2}{\pi T^2} \sum\sum \int_0^\infty \frac{1-\cos\omega T}{\omega^2 T} [C_r(\omega) C_s(\omega)$$
$$+ S_r(\omega) S_s(\omega)] \frac{d\omega}{|Z(i\omega)|^2}$$

Now in the double summation if the epoch T is made sufficiently great, the factor $\frac{(1-\cos\omega T)}{\omega^2 T}$ vanishes everywhere except in the neighborhood of $\omega = o$. Consequently, the double summation can be written as

$$\frac{2}{\pi T^2} \int_0^\infty \frac{1-\cos\omega T}{\omega^2 T^2} d\omega T \cdot \sum\sum \frac{C_r(o) C_s(o)}{|Z(o)|^2}$$
$$= \frac{1}{T^2} \sum\sum \frac{C_r(o) C_s(o)}{|Z(o)|^2}$$

Finally, if we write $N/T = n$ = average number of disturbances per unit time, and make use of formula (**2**), we get

$$\bar{I}^2 = \frac{n}{N} \sum 1/\pi \int_0^\infty \frac{|f_r(\omega)|^2}{|Z(i\omega)|^2} d\omega \quad (19)$$
$$+ \frac{n^2}{N^2} \cdot \frac{1}{|Z(o)|^2} \cdot \sum\sum \int_0^\infty \phi_r(t)\, dt \cdot \int_0^\infty \phi_s(t)\, dt$$

which can also be written as

$$\bar{I}^2 = \frac{n}{N} \sum \int_0^\infty i_r^2\, dt$$
$$+ \frac{n^2}{N^2} \sum\sum \int_0^\infty i_r\, dt \cdot \int_0^\infty i_s\, dt \quad (20)$$

when $i_r = i_r(t)$ is the current due to the r^{th} disturbance $\phi_r(t)$.

Now the double summation vanishes when, due to the presence of a condenser or transformer, the circuit does not transmit direct current to the receiving branch. Furthermore, if the disturbances are oscillatory or alternate in sign at random, it will be negligibly small compared with the single summation. Consequently, it is of negligible significance in the practical applications contemplated, and will, therefore, be omitted except in special cases. Therefore, disregarding the double summation, the foregoing analysis may be summarized as follows:

$$R(\omega) = \frac{n}{N} \sum |f_r(\omega)|^2 = n . r(\omega) \quad (21)$$

$$\bar{I}^2 = \frac{n}{N} \sum 1/\pi \int_0^\infty \frac{|f_r(\omega)|^2}{|Z(i\omega)|^2} d\omega \quad (22)$$

$$= \frac{n}{N} \sum \int_0^\infty i_r^2\, dt = n \int_0^\infty \bar{i}^2\, dt \quad (23)$$

$$\bar{P} = \frac{n}{N} \int_0^\infty \frac{r(\omega)}{|Z(i\omega)|^2} |z(i\omega)| \cdot \cos\alpha(\omega) \cdot d\omega \quad (24)$$

$$= \frac{n}{N} \sum w_r = n . \bar{w} \quad (25)$$

In these formulas n denotes the average number of elementary disturbances per unit time, w_r the energy absorbed from the r^{th} disturbance $\phi_r(t)$, and $\bar{P}$ the mean power absorbed from the aggregate disturbance. $r(\omega)$ is defined by formula (**20**) and is the mean spectrum of the aggregate disturbance, thus

$$r(\omega) = 1/N \sum |f_r(\omega)|^2 = R(\omega)/N \quad (26)$$

We are now in a position to discuss more precisely the approximations, fundamental to formulas (**9**)-(**14**),

$$\int_0^\infty \frac{R(\omega)}{|Z(i\omega)|^2} d\omega = R(\omega_m) \int_0^\infty \frac{d\omega}{|Z(i\omega)|^2} \quad (27)$$

The approximation involved in this formula consists in identifying $\omega_m/2\pi$ with the "mid-frequency" of the selective circuit, and is based on the hypothesis that over the range of frequencies, which includes the important contribution to the integral (**22**), the fluctuation of $R(\omega)$ may be ignored.

Now it is evident from formulas (**21**)-(**25**) that the theoretically complete solution of the problem requires that $R(\omega)$ be specified over the entire frequency range from $\omega = o$ to $\omega = \infty$. Obviously, the required information cannot be deduced without making some additional hypothesis regarding the character of the interference or the mechanism in which it originates. On the other hand, the mere assumption that the individual elementary disturbances $\phi_1 \ldots \phi_N$ differ among themselves substantially in wave form and duration, or that the maxima of the corresponding spectra $|f_r(\omega)|$ are distributed over a considerable frequency range, is sufficient to establish the conclusion that the individual fluctuations are smoothed out in the aggregate and that consequently $r(\omega)$ and hence

3. The averaging process with respect to the parameters t_r and t_s employed above logically applies to the average result in a very large number of epochs during which the system is exposed to the same set of disturbances with different but random time distributions. Otherwise stated, the averaging process gives the mean value corresponding to all possible equally likely times of incidence of the elementary disturbances. The assumption is, therefore, that if the epoch is made sufficiently large, the actual effect of the unrelated elementary disturbances will in the long run be the same as the average effect of all possible and equally likely distributions of the elementary disturbances.

$R(\omega)$ would have negligible fluctuations, or curvature with respect to ω, over any limited range of frequencies comparable to a signaling range.

It is admitted, of course, that the foregoing statements are purely qualitative, as they must be in the absence of any precise information regarding the wave forms of the elementary disturbances constituting random interference. On the other hand, the fact that static is encountered at all frequencies without any sharp changes in its intensity as the frequency is varied, and that the assumption of a systematic wave form for the elementary disturbances would be physically unreasonable, constitute strong inferential support of the hypothesis underlying equation (**27**). Watt and Appleton (*Proc. Roy. Soc.* April 3, 1923) supply the only experimental data regarding the wave forms of the elementary disturbances which they found to be classifiable under general types with rather widely variable amplitudes and durations. Rough calculations of $r(\omega)$, based on their results, are in support of the hypothesis made in this paper, at least in the radio frequency range. In addition, the writer has made calculations based on a number of reasonable assumptions regarding variations of wave form among the individual disturbances, all of which resulted in a spectrum $R(\omega)$ of negligible fluctuations over a frequency range necessary to justify equation (**27**) for efficient selective circuits. However, the problem is not theoretically solvable by pure mathematical analysis, so that the rigorous verification of the theory of selectivity developed in this paper must be based on experimental evidence. On the other hand, it is submitted that the hypothesis introduced regarding static interference is not such as to vitiate the conclusions, qualitatively considered, or in general to introduce serious quantitative errors. Furthermore, even if it were admitted for the sake of argument that the figure of merit S was not an accurate measure of the ratio of mean square signal to interference current, nevertheless, it is a true measure of the excellence of the circuit in excluding interference energy outside the necessary frequency range.

IV

The practical applications of the foregoing analysis depend upon the formulas

$$\bar{I}^2 = \frac{R(\omega_m)}{\pi} \int_0^\infty \frac{d\,\omega}{|Z(i\,\omega)|^2} = \rho \cdot R(\omega_m) \qquad (11)$$

and

$$S = \frac{1}{\omega_2 - \omega_1} \int_{\omega_1}^{\omega_2} \frac{d\,\omega}{|Z(i\,\omega)|^2} \div \int_0^\infty \frac{d\,\omega}{|Z(i\,\omega)|^2}$$

$$= \frac{1}{\omega_2 - \omega_1}\,\sigma/\rho \qquad (14)$$

which contain all the information which it is possible to deduce in the case of purely random interference. They are based on the principle that the effect of the interference on the signaling system is measured by the mean square interference current in the receiving branch, and that the efficiency of the selective circuit is measured by the ratio of the mean square signal and interference currents. As stated above, in the case of random interference results must be expressed in terms of mean values, and it is clear that either the mean square current or the mean energy is a fundamental and logical criterion.

Referring to formula (**11**), the following important proposition is deducible.

If the signaling system requires the transmissions of a band of frequencies corresponding to the interval $\omega_2 - \omega_1$, and if the selective circuit is efficiently designed to this end, then the mean square interference current is proportional to the frequency band width $\dfrac{(\omega_2 - \omega_1)}{2\,\pi}$.

This follows from the fact that, in the case of efficiently designed band-filters, designed to select the frequency range $\dfrac{(\omega_2 - \omega_1)}{2\,\pi}$ and exclude other frequencies, the integral $\int_0^\infty \dfrac{d\,\omega}{|Z(i\,\omega)|^2}$ is proportional to $\omega_2 - \omega_1$ to a high degree of approximation.

The practical consequences of these propositions are important and immediate. It follows that as the signaling speed is increased, the amount of interference inevitably increases practically linearly and that this increase is inherent. Again, it shows the advantage of single vs. double side-band transmission in carrier telephony, as pointed out by the writer in a recent paper.[4] It should be noted that the increased interference with increased signaling band width is not due to any failure of the selective circuit to exclude energy outside the signaling range, but to the inherent necessity of absorbing the interference energy lying inside this range. The only way in which the interference can be reduced, assuming an efficiently designed band-filter and a prescribed frequency range $\dfrac{(\omega_2 - \omega_1)}{2\,\pi}$, is to select a carrier frequency, at which the energy spectrum $R(\omega)$ of the interference is low.

Formula (**11**) *provides the theoretical basis for an actual determination of the static spectrum.* Measurement of $\bar{I}^2$ over a sufficiently long interval, together with the measured or calculated data for evaluating the integral $\int_0^\infty \dfrac{d\,\omega}{|Z(i\,\omega)|^2}$, determines $R(\omega_m)$ and this determination can be made as accurate as desired by employing a sufficiently sharply tuned circuit or a sufficiently narrow band filter. It is suggested that

4. Signal-to-Static-Interference Ratio in Radio Telephony, *Proc. I. R. E. E.*, June 1923.

the experimental data could be gotten without great difficulty, and that the resulting information regarding the statistical frequency distribution of static would be of large practical value.

The selective figure of merit S as defined by (**14**) is made up of two factors, $\dfrac{1}{(\omega_2 - \omega_1)}$ which is inversely proportional to the required signaling frequency range; and the ratio of the integrals σ/ρ. This ratio is unity for an ideally designed selective circuit, and can actually be made to approximate closely to unity with correctly designed band-filters. Formula (**14**) is believed to have very considerable value in comparing various circuits designed to eliminate interference, and is easily computed graphically when the frequency characteristics of the selective circuit are specified.

The general propositions deducible from it may be briefly listed and discussed as follows:

With a signaling frequency range $\dfrac{(\omega_2 - \omega_1)}{2\pi}$ *specified, the upper limiting value of* S *with a theoretically ideal selective circuit is* $\dfrac{1}{(\omega_2 - \omega_1)}$, *and the excellence of the actual circuit is measured by the closeness with which its figure of merit approaches this limiting value.*

Formula (**14**) for the figure of merit S has been applied to the study of the optimum design of selective circuits and to an analysis of a large number of arrangements designed to eliminate or reduce static interference. The outstanding conclusions from this study may be briefly reviewed and summarized as follows:

The form of the integrals σ and ρ, taking into account the signaling requirements, shows that the optimum selective circuit, as measured by S, is one which has a constant transfer impedance over the signaling frequency range $\dfrac{(\omega_2 - \omega_1)}{2\pi}$, and attenuates as sharply as possible currents of all frequencies outside this range. Now this is precisely the ideal to which the band filter, when properly designed and terminated, closely approximates, and leads to the inference that *the wave filter is the best possible form of selective circuit, as regards random interference.* Its superiority from the steady-state point of view has, of course, long been known.

An investigation of the effect of securing extremely high selectivity by means of filters of a large number of sections was made, and led to the following conclusion:

In the case of an efficiently designed band-filter, terminated in the proper resistance to substantially eliminate reflection losses, the figure of merit is given to a good approximation by the equation

$$S = \frac{1}{\omega_2 - \omega_1} \, \frac{1}{1 + 1/16\, n^2}$$

where n is the number of filter sections and $\dfrac{(\omega_2 - \omega_1)}{2\pi}$ the transmission band. It follows that *the selective figure of merit increases inappreciably with an increase in the number of filter sections beyond 2, and that the band filter of a few sections can be designed to have a figure of merit closely approximating the ideal limiting value,* $\dfrac{1}{(\omega_2 - \omega_1)}$.

This proposition is merely a special case of the general principle that, as regards static interference, it is useless to employ extremely high selectivity. The gain obtainable, as compared with only a moderate amount of selectivity is slight and is inherently accompanied by an increased sluggishness of the circuit. That is to say, as the selectivity is increased, the time required for the signals to build up is increased, with a reduction in quality and possible signaling speed.

Another circuit of practical interest, which has been proposed as a solution of the "static" problem in radio-communication consists of a series of sharply tuned oscillation circuits, unilaterally coupled through amplifiers.[5] This circuit is designed to receive only a single frequency to which all the individual oscillation circuits are tuned. The figure of merit of this circuit is approximately

$$S = L/R \, \frac{2^{2n-2}\,(n-1)!^2}{(2n-2)!}$$

where n denotes the number of sections or stages, and L and R are the inductance and resistance of the individual oscillation circuits. The outstanding fact in this formula is the slow rate of increase of S with the number of stages. For example, if the number of stages is increased from 1 to 5, the figure of merit increases only by the factor 3.66, while for a further increase in n the gain is very slow. This gain, furthermore, is accompanied by a serious increase in the "sluggishness" of the circuit: That is, in the particular example cited, by an increase of 5 to 1 in the time required for signals to build up to their steady state.

The analysis of a number of representative schemes, such as the introduction of resistance to damp out disturbances, balancing schemes designed to neutralize static without affecting the signal, detuning to change the natural oscillation frequency of the circuit, demodulation through several frequency stages, etc. has shown that they are one and all without value in increasing the ratio of mean square signal to interference current. In the light of the general theory, the reason for this is clear and the limitation imposed

5. See U. S. Patent No. 1173079 to Alexanderson.

6. When the number of stages n is fairly large, the selective figure of merit becomes proportional to $\sqrt{n}$ and the building-up time to n.

on the solution of the static problem by means of selective circuits is seen to be inherent in the nature of the interference itself.

Discussion

L. W. W. Morrow: I would just like to ask the question, if we are faced with the proposition of always suffering from static interference and is there no remedy?

J. R. Carson: The question of static interference is the same problem we come across in telephone transmission, that is, when the signal comes so weak that the interference energy level becomes comparable with the signal, we have got to either face interference or we have got to raise our power.

To my mind, the attempt to actually eliminate static by any form of selective circuit would be comparable with the attempt to find a perpetual motion machine. It is there and we have certainly got to receive a frequency range for signaling and from the very nature of the thing, must receive the interference in that range. We have all recognized that principle more or less in telephone engineering: in engineering long lines we must put in repeaters at intervals, depending upon the amount of interference or the interference energy level.

J. D. Robinson: Mr. Carson modifies his statement in a manner which possibly might be a little bit indeterminate for most of us. He says that he has no hopes for the selective circuit. Now that bears out an unknown number of things. Just why that modification?

J. R. Carson: There are, of course, possibilities other than frequency selection. For example, we all know that the wave antenna has been successful to a certain extent in eliminating interference, and I don't wish to imply that that form will not be successful in reducing it by a substantial amount, but that is a different basis, that is not frequency discrimination, that is discrimination with respect to direction in which the signal interference comes. That is, the interference comes in from all directions, the signal from one direction. We have here, therefore, a means of excluding part of the interference, and in some cases a very large part without any frequency discrimination whatsoever. Here again, however, we encounter an irreducible minimum of interference, namely the interference arriving from substantially the same direction as the signal.

L. J. Peters: About a year ago I carried on some studies, some of those carried on by Mr. Carson, using about the same methods, although not quite so elaborate.

On the second basis, that is the basis of average power over a period of time or the average grouping square current, I arrived at about the same conclusions, but my own dissatisfaction with the method of average power was the uncertainty as to whether you could compute the actual interference by using average power, that is, over a period of time. I would like to know Mr. Carson's idea on that subject. You might have a condition that would produce considerable noise in your receiver, and yet the average power that you got from that might figure out to be fairly low. I was hoping that I could arrive at some means by which you could actually estimate the maximum amount of noise you might get in your receivers.

Mr. Carson: The question, as I understand it, really comes down to how close a measure of interference the mean square current furnishes, I mentioned in the paper that that is a question that can't be answered, exactly, except by experiment.

On the other hand, suppose we have two circuits and they absorb the same amount of power. In the first place since we don't know what the individual form of disturbance is, the only basis which we can define our circuit to is as shown in the paper, on the other hand it is reasonably certain that they will be substantially the same in the long run though at any particular instant and for some particular type of interference, one circuit might be superior to the other and vice-versa. In the case of random disturbances, however, it is impossible to attempt to deal with the particular wave form of the instantaneous interference.

I have also examined the question as to whether, for example, a wave-filter of a large number of sections as compared with the wave-filter of a small number of sections, having practically the same mean current, might reduce the peak, and found that it would depend upon the relative frequency and form of the individual disturbances. In one case you might find that in a long wave-filter the peak would actually be larger than in the short wave-filter, but owing to the absolute random character of the interference, nothing in the way of design can be done on that basis, and as regards the actual effect in reducing intelligibility, that would have to be subject to experiment. That is, if we have two filters which absorb the same mean interference, it is purely a question for experiment as to whether we can distinguish in the two circuits any difference in the effects of the interference on the intelligibility of the signal, with which we are primarily concerned.

J. Slepian (by letter): Every observer of radio progress must be bewildered by the great variety of circuits, most plausibly and ingeniously contrived for eliminating the great bugbear of radio, static interference. Now, Mr. Carson sheds a great light on this subject by showing that practically all those various schemes are inherently alike; that when properly designed they are capable of reducing the static signal ratio just so far, and no farther. This is a very great achievement, and if it could be popularized, and made widely known, it would save a tremendous amount of useless work on the part of not only amateurs, but many professional men. Also, much of this effort might be diverted into paths which are beyond the assumptions of Mr. Carson's analysis, and may therefore have a chance of success. It is with this last in mind, that I would like to ask some questions, with the hope of specifying more precisely the types of circuit or apparatus to which Mr. Carson's analysis applies.

Apparently, the selective circuits of Mr. Carson's paper exercise only a frequency discrimination. That is, they have impedances which depend only on the frequency, when steady state is reached with a sinusoidal input. Circuits made up only of elements with linear characteristics will always have this property.

Now, frequency is not an instantaneous property of a voltage or current. A voltage or current must be watched for a finite length of time before periodicity can be noted, and a frequency assigned to it. Thus determining a frequency or a component frequency, must involve a remembering or integrating process, by which the past is tied up with the present. It is only natural therefore to find that Mr. Carson's analysis is based on the properties of certain integrals. Mr. Carson finds that the integrating processes, which determine the response of the selective circuits, when applied to random disturbances such as static, give residues, which can not be reduced below a certain figure.

Now the question I wish to raise, is whether the introduction of elements with non-linear characteristics does not get outside the limitations which Mr. Carson shows inherently exist for linear elements. The response of such elements cannot be described only in terms of frequency, but such instantaneous quantities as amplitude must be considered. For example, I am told, that considerable improvement in static ratio may be obtained by limiting devices, which prevent response to inputs exceeding a certain amplitude. Such a device has no selectivity whatsoever, being independent of frequency, and the formulas of Mr. Carson, if blindly applied, would indicate that it would be entirely ineffective; yet the device does actually reduce static.

I had an opportunity to mention these points to Mr. Carson, and he told me he thought it possible to take into account non-

linear elements by considering relations between combination frequencies. I would be very pleased if he would outline how this might be done. When dealing with elements which depend on instantaneous quantities such as amplitude, will it not be necessary to consider the whole infinite series of combination frequencies?

J. R. Carson: Dr. Slepian, in his interesting discussion has very properly called attention to the fact that the selective circuits dealt with in my paper are linear networks and function solely by *frequency* discrimination. He has also raised the important question as to what can be done in the way of eliminating static interference by *non-linear* devices which function on the base of *amplitude* discrimination. This is a very complicated question, quite outside the scope of the paper itself.—I am rather afraid that in our conversation referred to by Dr. Slepian, I gave him a too optimistic impression. At any rate, while I have given the problem considerable study, I am not prepared as yet, to make any extensive discussion of it, certainly not an analytical one. There are, however, a few features of the problem which are of interest, and which indicate that a great deal more experimental data regarding the physical and psychological phenomena of audition must be accumulated before anything like a satisfactory handling of the problem is possible.

If the receiving circuit includes a non-linear circuit element, then when interference and signal are simultaneously present, *the signal is modulated by the interference.* If the non-linear characteristic is given analytically, it is possible to calculate the form of the modulated or distorted signal, but it is not, as yet, possible to predict the effect of such modulation in the intelligibility of the signal received. That, however, this effect and the possible benefits to be expected from the non-linear device must be dependent on the intensity and frequency of the interfering disturbances can be inferred from the following ideal limiting case of the non-linear device.

Suppose that we have an ideal device which automatically destroys both signal and interference during the intervals of time when the interference exceeds a specified tolerable limit, but does not affect the signal except during these intervals. It will be clear, I think, that such a device may prove either beneficial or injurious, depending on the duration and frequency of these intervals and the relative intensity of the interference. For occasional bursts of intense interference of short duration its effect ought to be beneficial. For frequent bursts of interference of duration, it would probably completely kill the intelligibility. Consideration of this ideal case does not permit us to make any general inferences; it does, however, I think, show how the whole problem is bound up with the phenomena of audition, and that it depends strictly on the character of the interference. In other words no such general statements can be made regarding non-linear devices for reducing static interference, as can be made in the case of frequency selection.

The Transmission Unit
and Telephone Transmission Reference Systems

BY W. H. MARTIN
Member, A. I. E. E
Department of Development & Research, American Tel. & Tel. Co., New York, N. Y.

Review of the Subject.—*Consideration is given to the method of determining and expressing the transmission efficiencies of telephone circuits and apparatus, and of the desirable qualifications for a unit in which to express these efficiencies. The "transmission unit" described in this paper has been selected as being much more suitable for this purpose under present conditions than the "mile of standard cable" which has been generally used in the past.*

* * * * *

THE "mile of standard cable" has been used in telephone engineering in this country for over twenty years, and during that time has been adopted in other countries, as the unit for expressing the transmission efficiency of telephone circuits and apparatus. In the present state of the telephone art, this unit has been found, however, to be not entirely suitable and it has recently been replaced in the Bell System by another unit which for the present, at least, has been called simply the "transmission unit." Before considering the reasons for such a fundamental change and the relative merits of the two units, it may be well to review briefly the general method of determining the efficiency of such circuits and the apparatus associated with them.

The function of a telephone circuit is to reproduce at one terminal the speech sounds which are impressed upon it at the other terminal. The input and output of the circuit are in the form of sound and its efficiency as a transmission system may be expressed as the ratio of the sound power output to the sound power input. For commercial circuits, this ratio may be of the order of 0.01 to 0.001.

In the operation of the system, the sound power input is converted by the transmitter into electrical power, which is transmitted over the line to the receiver and there reconverted into sound power. The effect of inserting a section of line or piece of apparatus or of making any change in the circuit can be determined in terms of the variation which it produces in the ratio of the sound power output to the sound power input, or, if this latter is kept constant, in terms of the ratio of sound power output after the change to that obtained before the change was made. It should be noted particularly that the change in the output power of the system is the real measure of the effect of any part of the circuit on the efficiency of the system and that the ratio of the power leaving any part to that entering it is not necessarily the measure of this effect. For example, a pure reactance placed in series between the transmitter and the line, may change the power delivered to the line by the transmitter and hence the output of the receiver—the magnitude and direction of the change being determined by the impedance

Presented at the Annual Convention of the A. I. E. E., Edgewater Beach, Chicago, Ill., June 23-27, 1924.

relations at the point of insertion. The ratio of the power leaving the reactance to that entering it is, of course, unity, as no power is dissipated in a pure reactance. In other words, the transmission efficiency of any part of a circuit cannot be considered solely from the standpoint of the ratio of output to input power for that part, or the power dissipated in that part, but must be defined in terms of its effect on the ratio of output to input power for the whole system.

By determining the effect of separately inserting the many pieces of apparatus that may form parts of typical telephone circuits, an index can be established for each of these parts of its effect on the efficiency of the circuit for the conditions of which the circuit tested is typical. Similarly, the power dissipated in unit lengths of the various types of line can be determined by noting the change in power output of the receiver caused by increasing any line by a unit length. Such indices of the transmission efficiencies of the various parts of a circuit obviously have many applications in designing and engineering telephone circuits. These indices could be taken as the ratios expressing the change in the output power of the system. This, however, has certain disadvantages. For example, the

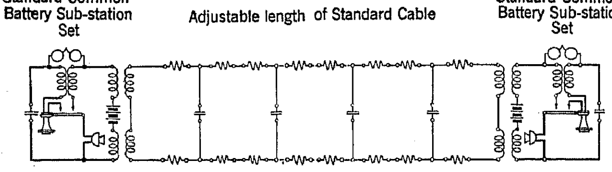

FIG. 1

combined effect of a number of parts would then be expressed as a product of a number of ratios. Likewise, for the case of a number of parts n of the same type in series, such as a line n miles in length, the effect would be expressed as the ratio for one part or one mile of the line, raised to the nth power. In many cases, these ratios and the powers to which they would need to be raised would be such as to make their handling cumbersome. If, however, these indices are expressed in terms of a logarithmic function of a ratio selected as a unit, the sum of any number of such indices for the parts of a circuit is the corresponding index for the power ratio giving the effect of the combination of these parts.

The "mile of standard cable" is such a logarithmic function of a power ratio. The new unit also meets this important requirement.

DEFINITION OF THE TRANSMISSION UNIT

The "transmission unit" (abbreviated $T\,U$) has been chosen so that two amounts of power differ by one transmission unit when they are in the ratio of $10^{0.1}$ and any two amounts of power differ by N units when they are in the ratio of $10^{N(0.1)}$. The number of transmission units corresponding to the ratio of any two powers P_1 and P_2, is then the common logarithm (logarithm to the base 10) of the ratio P_1/P_2, divided by 0.1. This may be written $N = 10 \log_{10} P_1/P_2$. Since N is a logarithmic function of the power ratio, any two numbers of units, N_1 and N_2, corresponding respectively to two ratios, P_a/P_b and P_c/P_d, may be added and the result $N_1 + N_2$, will correspond to the product of the ratios, $P_a/P_b \times P_c/P_d$.

From the above it is seen that the measure in transmission units of the ratio of two amounts of power P_1 and P_2 is N, where

$$N = \frac{\log \frac{P_1}{P_2}}{\log 10^{0.1}}$$

In other words, the transmission unit is a logarithmic measure of power ratio and is numerically equal to $\log 10^{0.1}$.

The reasons for the selection of this unit and the method of applying it, can probably be best brought out by a consideration of the practise which has been followed in determining and expressing the efficiencies of telephone circuits and apparatus in terms of "miles of standard cable."

STANDARD REFERENCE CIRCUIT

Fig. 1 shows what has been designated the "standard reference circuit." It consists of two common battery telephone sets of the type standard in the Bell System at the time this circuit was adopted, connected through repeating coils or transformers to a variable length of "standard cable." This cable is an artificial line having a resistance of 88 ohms and a capacity of 0.054 microfarad per loop mile which is representative of the type of telephone cable then generally used in this country.

For a given loudness of speech sounds entering the transmitter at one end of the circuit, the loudness of the reproduced sounds given out by the receiver at the other end can be varied by changing the amount of standard cable in the circuit. Also, the amount of cable in the circuit can be used to express the ratio of the power of the reproduced sounds to that of the impressed sounds. Due to the dissipation of electrical power in the cable, this ratio and consequently the loudness of the reproduced sounds become less as the amount of cable is increased and greater as the length of cable is decreased.

This circuit then became the measuring or reference system for engineering the telephone plant and the "mile of standard cable" became the unit in which the measurements were expressed. This circuit was used to set the service standards in designing and laying out the telephone plant. Thus, the reproduction obtained over this circuit with a length of cable of about twenty miles was found suitable and practicable for local exchange, that is, intracity service, and that corresponding to about thirty miles for toll or intercity service.

Any telephone circuit was rated by its comparison with the standard circuit. This comparison was on the basis of a speaker talking alternately over the circuit to be measured and the standard circuit and a listener switching similarly at the receiving ends, the amount of cable in the standard circuit being adjusted until the listener judged the volume of the sounds reproduced by the two systems to be equal. The number of miles of cable in the standard circuit was then used as the "transmission equivalent" of the circuit under test. The effect of any change in the circuit under test on the efficiency of that circuit could then be measured by determining the variation in the amount of standard cable required to make the sounds reproduced by the two systems again equal and the number of miles of standard cable required to compensate for this change was used as the index of this effect. In this way the relative efficiencies of two transmitters or receivers could be determined. Likewise, the power dissipation per unit length or the attenuation, of the trunk in the circuit under test could be equated to miles of standard cable. Since in each case, the standard cable is used to adjust the volume of the reproduced sound, "the mile of standard cable" corresponds to the ratio of two amounts of sound power, or as this change in sound power is produced by changing the power delivered to the telephone receiver, to a ratio of two amounts of electrical power.

If the addition of a mile of standard cable to a long trunk of the standard circuit causes the power reaching the end of the trunk to decrease by a ratio r, then the insertion of two miles will decrease the received power by a ratio of r^2 of that obtained before the two miles were inserted. A number of miles of cable, n, inserted will reduce the received power to a ratio r^n. Thus the power ratio corresponding to any given number of miles of cable is an exponential function of the ratio corresponding to one mile, the exponent being the length in miles. The length in miles is, therefore, a logarithmic function of the power ratio.

In an infinite length of uniform line having resistance, inductance, capacity and conductance of R, L, C and G per unit length, the attenuation a per unit length, of a current of frequency f flowing along the line can be shown to be equal to the real part of the expression

$$a + j\,b = \sqrt{(R + j\,2\,\pi\,f\,L)\;(G + j\,2\,\pi\,f\,C)}$$

For the standard cable line, since L and G are zero

$$a = \sqrt{\pi\,f\,R\,C}$$

and since $R = 88$ ohms and $C = 0.054$ microfarad per mile the current attenuation per mile of standard cable is

$$a = 0.00386\,\sqrt{f}$$

If I_1' and I_2' are the currents, respectively, at the beginning and end of a mile of line, then

$$I_1'/I_2' = e^a \text{ or } a = \log_e I_1'/I_2'$$

Similarly if I_1 and I_2 are the currents, at points 1 and 2, respectively, at the beginning and end of a section of l miles

$$I_1/I_2 = e^{La} \text{ and } l\,a = \log_e I_1/I_2$$

For this case, the effect of inserting the section of l miles into the line on the current at point 2, or at any point beyond 2, is that the currents at the point before and after the insertion are in the same ratio as I_1/I_2. Furthermore, since the impedance of the line looking toward the receiving end is the same at points 1 and 2 (and at any other points), then the ratio of the powers at the two points is equal to the square of the current ratio.

Thus the power attenuation is represented by

$$P_1/P_2 = (I_1/I_2)^2 = e^{2la}$$

Similarly for a line, terminated in a fixed impedance which may be different from the characteristic impedance of the line, the ratio of the powers received before and after a change in the length of the line is equal to the square of the ratio of the corresponding currents. On the basis of this relation, and because it is in general more convenient to measure or compute currents than powers, the current ratio has often been used in determining the equivalent of any piece of apparatus or line in terms of standard cable. It should be noted, however, that such a current ratio can be properly used as an index of the transmission efficiency of a part of a circuit only when it is equal to the square root of the ratio of the corresponding powers. Also, of course, the voltage ratio can be similarly used when it meets the same requirement.

Limitations in Use of Standard Cable Unit

As shown above, the attenuation, either of current or power, corresponding to the mile of standard cable is directly proportional to the square root of the frequency of the current under consideration. This means that the standard cable mile corresponds not only to a certain volume change in the reproduced speech sounds, but also to a distortion change. For comparisons between the standard cable circuit and commercial circuits with talking tests and as long as most of the commercial circuits had distortion comparable to that of standard cable, this two-fold effect of standard cable was desirable. At present, however, many types of circuits are being used which have much less distortion than standard cable. Also, the use of voice testing has been largely given up in the plant and it is now the general practise to determine the efficiency of circuits and apparatus on the basis of measurements and computations for single-frequency currents, a correlation having been established between these latter results and those of voice tests. These factors have made it desirable to have a unit for expressing transmission efficiencies which is distortionless, that is, not a function of frequency.

Qualifications of a New Unit

The consideration of a new unit for measuring transmission efficiency brought out the following desirable qualifications:

1. *Logarithmic in Character*. Some of the reasons for this have already been discussed. In addition, the

application of such a unit in measurements of sound make a logarithmic unit desirable, since the sensation of loudness in the ear is a logarithmic function of the energy of the sound.

2. *Distortionless.* The advantages of a unit which is independent of frequency have been referred to above. In expressing the efficiency of the transmission of the high frequencies involved in carrier and radio circuits, such a unit is particularly desirable.

3. *Based on Power Ratio.* This is desirable because the power ratio is the real measure of transmission efficiency. As pointed out above, the current ratio can be used only when it is equal to the square root of the power ratio. Having the unit based on a power ratio does not, of course, require that measurements or computations be made on a power basis.

In considering the conversions between sound and electrical energy, it is obviously advantageous to have a unit based directly on a power ratio.

4. *Based on Some Simple Relation.* This is desirable in connection with the matter of getting a unit which may be widely used and may find applications in several fields.

5. *Approximately Equal in Effect on Volume to a "Mile of Standard Cable."* One reason for this is the practical one of avoiding material changes in the conceptions which have been built up regarding the magnitude of such things as transmission service standards. Also, the sound power changes which can be detected by the ear are of the order of that corresponding to a mile of standard cable. In measuring telephone lines and apparatus with single-frequency currents, it has been found that an accuracy of about one-tenth of a mile can be obtained readily and is sufficient practically.

6. *Convenient for Computations.* This refers to the matter of changing from computed or measured current or power ratios to transmission units or vice versa.

Properties of the Transmission Unit

A consideration of the above qualifications and of the various units suggested, led to the adoption of the power ratio of $10^{0.1}$ as the most suitable ratio on which to base the unit of transmission efficiency. The transmission unit is logarithmic, distortionless, is based on a power ratio and its relation to that ratio is a simple one. Its effect on the transmission of telephonic power corresponding to speech sounds is about 6 per cent less than that of one mile of standard cable. Regarding its use in computations, it has the advantage that the number of units corresponding to any power ratio, or current ratio, can be determined from a table of common logarithms.

For a power ratio of 2, the logarithm is 0.301 and the corresponding number of units is, therefore, this logarithm multiplied by 10, which is 3.01 *T U.* For a power ratio of 0.5, the logarithm is $9.699-10 = -0.301$ and the number of units is -3.01 *T U.* A power ratio of 2 represents a gain of 3.01 units, and a power ratio of 0.5 corresponds to a loss of 3.01 units. If the above ratios were for current, the logarithms would be multiplied by 20. Thus a current ratio of 2 corresponds to a gain of 6.02 units and a current ratio of 0.5 corresponds to a loss of 6.02 units.

It will be noted that the *T U* is based on the same ratio $10^{0.1}$ as the series of preferred numbers which has been used in some European countries and has been proposed here as the basis for size standardization in manufactured articles.[1] In common with this series, the *T U* has the advantage that many of the whole numbers of units correspond approximately to easily remembered ratios as shown in the following table.

APPROXIMATE POWER RATIO

Transmission Units	For Losses Fractional	For Losses Decimal	For Gains Decimal
1	4/5	0.8	1.25
2	2/3	0.63	1.6
3	1/2	0.5	2.
4	2/5	0.4	2.5
5	1/3	0.32	3.2
6	1/4	0.25	4.
7	1/5	0.2	5.
8	1/6	0.16	6.
9	1/8	0.125	8.
10	1/10	0.1	10.
20	1/100	0.01	100.
30	1/1000	0.001	1000.
